Remark 4.3. Let us turn to Hsiang's laws. Brehm's angular invariants $\Lambda(A)$, $\Phi(A)$, $\Psi(A)$ correspond to the angular invariants $\Lambda(A)$, $\frac{\pi}{2} - \mu(A)$, $\frac{\pi}{2} - \theta(A)$, respectively, which have been defined by Hsiang in [10]. Of course Hsiang derived the same laws of sines but instead of (10) or (13) he obtained a more complicated equivalent equation which we do not give here.

Shirokov took two angular invariants at each vertex: the Riemannian angle $\Lambda(A)$ between the two sides and the holomorphy inclination $\gamma(A)$. By comparing his three laws, we easily see that the holomorphy inclination is linked to Brehm's angles as follows:

$$\sin(\Lambda(A))\cos(\gamma(A)) = \sin(\Psi(A)).$$

The trigonometric laws found by Rozenfeld and Shirokov are the same as (8), (9), (10), or (13) where we replace $\sin(\Psi(A))$ by $\sin(\Lambda(A))\cos(\gamma(A))$ and $\sin(\Phi(A))$ by $\sin(\Lambda(A))\sin(\gamma(A))$ and by a cyclic permutation of the letters A, B, C. This can be found in [14], [16], and [13].

5 Concluding remarks

1. A slight modification of the definitions and computation yields similar results for triangles in complex hyperbolic spaces. The results can be found in [4].

2. It follows from the normal form that each triangle in $\mathbb{K}P^n$ ($n \geq 2$, $\mathbb{K} = \mathbb{C}, \mathbb{H}$) is contained in some totally geodesic $\mathbb{C}P^2$.

3. It is known from Wolf [19] that each isometry of a totally geodesic $\mathbb{C}P^2$ in $\mathrm{Cay}(P^2)$ can be extended to the Cayley plane. Thus, it is sufficient to regard triangles of the Cayley plane only in $\mathbb{C}P^2$. The results are also valid for triangles in $\mathrm{Cay}(H^2)$.

4. According to Wang [18], $\mathbb{K}P^n$, $\mathbb{K}H^n$, $\mathbb{K} = \mathbb{R}, \mathbb{C}, \mathbb{H}$, $\mathrm{Cay}(P^2)$, $\mathrm{Cay}(H^2)$ are besides the classical spaces all the two-point homogeneous spaces.

5. Let $([x], [y], [z])$ be a triangle in $\mathbb{C}P^2$ and let S be the surface generated by the geodesic arcs issued from $[x]$ with endpoints on the geodesic arc between $[y]$ and $[z]$. Let I be the integral of the Kähler form on the surface S. Hangan and Masala showed that $\omega = -2I + 2k\pi$, for some integer k, see [8].

6. The result of [8] made more clear a result obtained in [6]. the author constructed regular tetraedra of $\mathbb{C}P^3$ which have symmetry groups isomorphic to the symmetric group S_4. It turns out that a regular tetrahedron with edge $a < \arccos \frac{\sqrt{3}}{3}$ is necessarily contained in a real projective sub-space. Indeed, by regularity and Stokes' theorem, the integral I performed on its faces vanishes and we get from (3) and (6) that $\sin \Psi(A) = 0$. However, in [6], he proved that for any a such that $a \geq \arccos \frac{\sqrt{3}}{3}$ there exists a regular tetrahedron with edge a and with zero shape invariant. In this case, $2I = \frac{\pi}{2} + k\pi$. This means that the quadruple with the geodesic arcs between the vertices and the faces generated by the geodesic arcs issued from a vertex with endpoints on the opposite edge, constitute a simplicial complex of dimension 2 whose homology class of dimension 2 generates the homology group $H_2(\mathbb{C}P^n, \mathbb{Z})$ which is isomorphic to $\mathbb{Z}$ [9].

Trigonometry in general symmetric spaces is still at its infancy.

1. The trigonometry of symmetric spaces of rank 1 was studied by Hsiang in 1989 using integration of the geodesic flow [10]. A different approach using models in projective spaces has been given by Brehm in 1990 [4]. The trigonometry of a complex projective plane was first studied by Blaschke and Terheggen in 1939 [2], Terheggen in 1940 [15] and later pursued in 1957 by Rozenfeld [14] and independently by Sirokov in 1957 [16].

2. Aslaksen in 1989 [1] developed trigonometry for triangles in the Lie group SU(3) using algebraic invariants. Leuzinger in his Ph.D. thesis in 1990 [11] developed trigonometry for arbitrary Riemannian symmetric spaces of non-compact type using the general theory of symmetric spaces.

3. Hangan [9] wrote some trigonometric formulae for Grassmann manifolds.

4. The congruence criteria for triangles in Grassmann manifolds was stated by Masala in his Ph.D. thesis in 1996 using matrices of projections [12].

Pág. 241 (256) – Gauss Curvature

Fermat's principle of least time saying that the path take between two points by a light ray is the path which can be traversed in the least time. (60).

↳ Letter (January 1, 1662) to M. C. de la Chambre

Employing it, he deduced the law of refraction.

Hence shortest curves on a surface are regarded as something similar to paths traced by light rays (see Sect 6.12),

and it is reasonable to say that a quantity (or a concept) attached to a surface is "intrinsic" if it is derived from distance and angle measured by using shortest curves.

Pág. 337 (352) →

Olinde Rodrigues (1795-1851)

Rodrigues is known for a formula

also dissatisfied with the state of affairs surrounding metaphysics, in contrast to the scientific model cultivated in his days, Kant strove to lay his philosophical foundation of reason and judgement on secure grounds.

He was an enthusiast of Newtonian physics framed on Euclidean geometry, and asked himself, "Are space and time real existences? Are they only determinations or relations of things as Leibniz insists?" His inquiry brought him to the conclusion that Euclidean geometry is the inevitable necessity of thought and *inherent in nature* because our space (as an "absolute" entity) is a "sacrosanct" framework for all and any experience. He also held that space (as a "relative" entity) is the "subjective constitution of the mind" (see Sect. 6.22), He stressed further that mathematical propositions are formal descriptions of the a priori structures of space and time.[56]

In the work *Allgemeine Naturgeschichte und Theorie des Himmels* (1755), Kant discussed infiniteness of the universe. He believed that the universe is infinite, because God is the "infinite being," and creates the universe in proportion to his power (recall Bruno's view). In turn, he argues that it is not philosophically possible to decide whether the universe is infinite or finite; that is, we are incapable of perceiving so large distance, because the mind is finite.[57]

As Kant emphasized in the *Kritik der reinen Vernunft* (1781), abstract speculation must be pursued without losing touch with reality grasped by intuition; otherwise the outcome could be empty. This is not least the case for scientific knowledge. Yet intuition about our space turned out to be a clinging constraint on us; it was not easy to free ourselves from it.

6.7 Gauss: Intrinsic Description of the Universe

In Christianity, God is portrayed to be omnipresent, yet His whereabouts are unknown. Nonetheless, the laity usually personify God (if not a person literally), and believe that He "dwells" outside the universe (or *empyrean*). Imagining such a deity is not altogether extravagant from the view that we will take up in investigating a model of the universe though we do not posit the existence of God. What is available in place of God is, of course, *mathematics*.[58] Thus, we pose the question, "Is it mathematically possible to tell how the universe is curved without mentioning any outside of the universe?"

---

[56] Affected by the science in his time, Kant developed further the *nebular hypothesis* proposed by E. Swedenborg in 1734 (this hypothesis that the solar system condensed from a cloud of rotating gas was discussed later by Laplace in 1796).

[57] Hegel dismissed the claim that the universe extends infinitely.

[58] Robert Grosseteste (ca. 1175–1253) in medieval Oxford says, "mathematics is the most supreme of all sciences since every natural science ultimately depends on it" (*De Luce*, 1225). He maintained, by the way, that stars and planets in a set of nested spheres around the earth were formed by crystallization of matter after the birth of the universe in an explosion.

The answer is "Yes." To explain why, let us take a look at smooth *surfaces* as 2D toy models of the universe.[59] That is, we human beings are supposed to be confined in a surface. Here space in which the surface is located is thought of as the "outside," and is called the *ambient space*. A person in the outside plays the role of God incarnate. In our story, we allow him to exist for the time being; that is, we investigate surfaces in an *extrinsic* manner. At the final stage, we are disposed to remove him (and even the outside) from the scene, and to let the inhabitants in the surface find a way to understand his universe. In other words, what we shall do is, starting from an extrinsic study of surfaces, to look for some geometric concepts with which one can talk about how surfaces are curved without the assistance of the outside. Such concepts will be called *intrinsic*, one of the most vital key terms in this essay.

A few words about intrinsicness. Imagine that an inhabitant confined in a surface wants to examine the structure of his universe. The only method he holds is, like us, measuring the distance between two points and the angle between two directions. In our universe, we use the *light ray* to this end, which in a uniform medium propagates along shortest curves (straight lines) in space; a very special case of *Fermat's principle of least time* saying that the path taken between two points by a light ray is the path which can be traversed in the least time.[60] Hence shortest curves on a surface are regarded as something similar to paths traced by light rays (see Sect. 6.12), and it is reasonable to say that a quantity (or a concept) attached to a surface is "intrinsic" if it is derived from distance and angle measured by using shortest curves.

The progenitor of the intrinsic theory of surfaces is Johann Carl Friedrich Gauss (1777–1855). In 1828, he brought out the memoir *Disquisitiones generales circa superficies curvas*, where he formulated *bona fide* intrinsic curvature, which came to be called *Gaussian curvature* later.

Just for the comparison purpose, let us primarily look at the curvature of plane curves. Subsequent to the pioneering studies by Kepler (*Opera*, vol. 2, p. 175) and Huygens (1653–4), Newton used his calculus to compute curvature.[61] His approach is to compare a curve with *uniformly curved figures*; i.e., circles or straight lines. To be exact, given a point p on a smooth curve C, he singles out the circle (or the straight line) C_0 that has the highest possible order of contact with C at p, and then defines the curvature of C at p to be the reciprocal of the radius of C_0 (when C_0 is a straight line, the curvature is defined to be 0); thus the smaller the circle C_0 is, the more curved C is. To simplify his computation, take a coordinate system (x, y) such that the x-axis is the tangent line of C at p, and express C around p as the graph associated with a smooth function $y = f(x)$ with $f(0) = f'(0) = 0$ and $f''(0) \geq 0$. Compare $f(x) = \frac{1}{2}f''(0)x^2 + \frac{1}{3!}f'''(\theta x)x^3$ $(0 < \theta < 1)$ (Taylor's theorem) with the function $f_0(x) = R - \sqrt{R^2 - x^2} = \frac{1}{2}R^{-1}x^2 + \cdots$ corresponding to the circle C_0 of radius R, tangent to the x-axis at $x = 0$. Thus C_0 has the second order of contact with C at $(0, 0)$ if and only if $R = 1/f''(0)$. Therefore the curvature is equal to $f''(0)$.

---

[59] Throughout, "smooth" means "infinite differentiable."

[60] This principle was stated in a letter (January 1, 1662) to M. C. de la Chambre. Employing it, he deduced the *law of refraction*. The first discoverer of the law is Harriot (July 1601), but he died before publishing. W. Snellius rediscovered the law (1621). Descartes derived the law in *La Dioptrique* under a wrong setup; actually he believed that light's propagation was instantaneous. The finite speed of light was demonstrated by O. Rømer in 1676.

[61] *Tractus de methodis serierum et fluxionum* (1670–1671).

Remark 7.1 For an *oriented curve* C (a curve with a consistent direction defined along the curve), we select a coordinate system (x, y) such that the direction of x-axis coincides with that of C at p. Then $f''(0)$ is possibly negative. We call $\kappa(p) := f''(0)$ the *signed curvature* of C at p. If $c : [a, b] \longrightarrow \mathbb{R}^2$ is a parameterization of C with $\|\dot{c}\| \equiv 1$, then $\ddot{c}$ is perpendicular to $\dot{c}$, and $\ddot{c}(s) = \kappa(c(s))\boldsymbol{n}(s)$, where $\boldsymbol{n}(s)$ is the unit vector obtained by the 90° counterclockwise rotation of $\dot{c}(s)$. Writing $c(s) = (x(s), y(s))$, we have $\boldsymbol{n}(s) = (-\dot{y}(s), \dot{x}(s))$, and $\kappa(c(s)) = \langle \ddot{c}(s), \boldsymbol{n}(s)\rangle = \dot{x}(s)\ddot{y}(s) - \dot{y}(s)\ddot{x}(s)$. □

In the eighteenth century, Continental mathematicians polished calculus as an effectual instrument to handle diverse problems in sciences. Leonhard Euler (1707–1783) was among those who helped to brings calculus to completion and employed it as a tool for the extrinsic geometry of surfaces. His particular interest was the curvature of the curve obtained by cutting a surface with the plane spanned by a tangent line and the normal line. This study brought him to the notion of *principal curvature*.[62] Then in 1795, Gaspard Monge (1746–1818) published the book *Application de l'analyse à la géométrie*, an early influential work on differential geometry containing a refinement of Euler's work. However neither Euler nor Monge arrived at arrived at intrinsic curvature. Here came Gauss, who found how to formulate it with absolute confidence in its significance.

What comes to mind when defining the curvature of a surface S at p is the use of a coordinate system (x, y, z) with origin p such that the xy-plane is tangent to S at p,[63] with which S is locally expressed as a graph of a smooth function $f(x, y)$ defined around $(x, y) = (0, 0)$ with $f(0, 0) = f_x(0, 0) = f_y(0, 0) = 0$, where $f_x = \partial f/\partial x$ and $f_y = \partial f/\partial y$. Then we obtain $f(x, y) = \frac{1}{2}(ax^2 + 2bxy + cy^2) + r(x, y)$, where $a = f_{xx}(0, 0)$, $b = f_{xy}(0, 0)$, $c = f_{yy}(0, 0)$, and $r(x, y)$ is of higher degree than the second. The shape of the graph (and hence the shape of S around p) is roughly determined by the quantity $ac - b^2$; it is paraboloid-like (resp. hyperboloid-like) if $ac - b^2 > 0$ (resp. $ac - b^2 < 0$) (Fig. 6.7). Given all this, we define the curvature $K_S(p)$ to be $ac - b^2$, which is independent of the choice of a coordinate system. For example, $K_S \equiv R^{-2}$ for the sphere of radius R.

To account the exact meaning of intrinsicness of the Gaussian curvature, we consider another surface S', and let Φ be a one-to-one correspondence from S to S' preserving the distance of two points and the angle between two directions (such

---

[62] *Recherches sur la courbure des surfaces*, Mém. Acad. R. Sci. Berlin, **16** (1767), 119–143.

[63] Gauss's original definition uses the map (*Gauss map*) from S to the unit sphere which associates to each point on S its oriented unit normal vector (*Disquisitiones generales*, Art. 6).

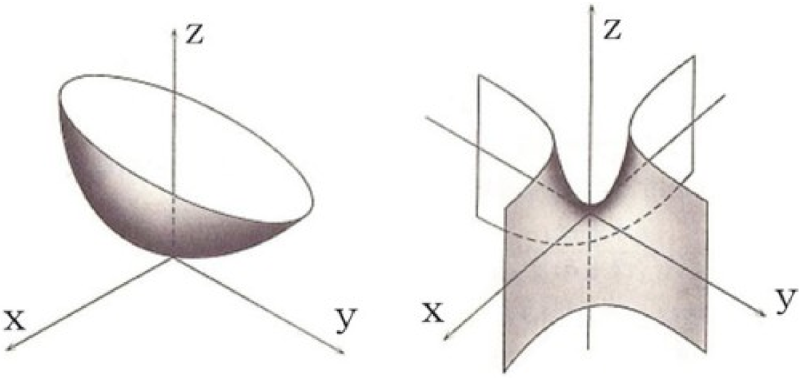

Fig. 6.7 Paraboloid and Hyperboloid

Φ is called an *isometry* in the present-day terms; see Sect. 6.20). If we would adopt the approach mentioned above on intrinsicness, Gauss's outcome could be rephrased as "$K_{S'}(\Phi(p)) = K_S(p)$." In particular, $K_S \equiv 0$ for a cylindrical surface S, since S, which is ostensibly curved, is deformed without distortion to a strip in the plane. This example articulately signifies that the Gaussian curvature could be possibly defined without the aid of the outside.

Executing lengthy computations, Gauss confirmed the intrinsicness of K_S (see Sect. 6.17).[64] Since the goal is more than a pleasing astonishment, Gauss named his outcome "Theorema Egregium (remarkable theorem)" (*Disquisitiones generales*, Art. 12). Actually, it is no exaggeration to say that this theorem is a breakthrough not only in geometry, but also in cosmology. The following is his own words (1825) unfolded in a letter to the P. A. Hansen:

This research is deeply entwined with much else, I would like to say, with metaphysics of space and I find it difficult to shake off the consequences of this, such as for instance the true metaphysics of negative or imaginary quantities (*Werke*, XII, p. 8. See [3]).[65]

Although the Theorema Egregium has a deep metaphysical nature as Gauss put it, his incipient motivation came from the practical activity pertaining to the *geodetic survey* of Hanover to link up with the existing Danish grid that started in 1818 and continued for 8 years. He traveled criss-cross in order to cover the whole country. Fueled by this arduous activity, he brought out many papers on the geometry of curves and surfaces from about 1820 onwards. The Theorema Egregium was a culmination of his intensive study in this field.

---

[64] Crucial in his argument is the commutativity of partial differentiation. Euler and A. C. Clairaut knew it, but the first correct proof was given by K. H. A. Schwarz in 1873.

[65] Even in the eighteenth century, there were a few who did not accept negative number. For example, F. Maseres said, "[negative numbers] darken the very whole doctrines of the equations and make dark of the things which are in their nature excessively obvious and simple" (1758). Although limited to the practical use, negative numbers already appeared in the *Jiuzhang Suanshu* (The Nine Chapters on the Mathematical Art) written in the period of the Han Dynasty (202 BCE–8 CE). The reason why the Chinese accepted negative numbers is, in all likelihood, that they had the concept of *yin* (negative or dark) and *yang* (positive or bright). Negative numbers were in use India at least from about the 7th century.

Remark 7.2 In her study of elasticity (1831), Sophie Germain introduced the *mean curvature* $H_S(p) := \frac{1}{2}(a + c)$, which appears in a characterization of *minimal surfaces*; that is, the surface area of S is locally minimized if and only if $H_S \equiv 0$. Putting $A = \begin{pmatrix} a & b \\ b & c \end{pmatrix}$, we have $K_S(p) = \det A$ and $H_S(p) = \frac{1}{2}\mathrm{tr}\, A$. The eigenvalues $\kappa_1(p)$, $\kappa_2(p)$ of A are called the *principal curvatures* of S. Obviously $K_S(p) = \kappa_1(p)\kappa_2(p)$ (*Disquisitiones generales*, Art. 8) and $H_S(p) = \frac{1}{2}(\kappa_1(p) + \kappa_2(p))$. □

6.8 Number Systems

It is off the subject, but while looking at the background behind Gauss's opinion about complex numbers quoted above, we shall prepare some material related to what we shall describe later (Sect. 6.21).

Gerolamo Cardano (1501–1576), who stood out above the rest at that time as an algebraist, acknowledged the existence of complex numbers in his *Ars Magna* (1545) that contains the first printed solutions to cubic and quartic equations. He observed that his formula may possibly involve complex numbers even when applied to a cubic equation possessing only real solutions.[66] Yet, he did not understand the nature of complex numbers and even thought that they are useless. Subsequently, Rafael Bombelli (1526–1572) took down the rules for multiplication of complex numbers (*binomio*) in his Book I of *L'Algebra*, while Descartes used the term "imaginary number" (*nombre imaginaire*) with the meaning of contempt. Wallis insisted that imaginary numbers are not unuseful and absurd when properly understood by using a geometric model just like negative numbers (*Algebra*, Vol. II, Chap. LXVI, 1673). Meanwhile, Euler persuaded himself that there is an advantage for the use of imaginary numbers (1751), and introduced the symbol i for the imaginary unit (1755). It was around 1740 that he found the earth-shaking formula $e^{\sqrt{-1}\theta} = \cos\theta + \sqrt{-1}\sin\theta$.

In 1799, Gauss gained his doctorate in absentia from the University of Helmstedt. The subject of his thesis is *the fundamental theorem of algebra*,[67] which, with a long history of inspiring many mathematicians, says that every polynomial equation of sand have led, by extension, to general theorems on mathematical optics [39, p. 131].

---

[66] For example, his formula applied to the cubic equation $x^3 - 15x - 4 (= (x-4)(x+2+\sqrt{3})(x+2-\sqrt{3})) = 0$ yields a solution $x = \sqrt[3]{2+\sqrt{-124}} + \sqrt[3]{2-\sqrt{-124}}$.

[67] *Demonstratio nova theorematis omnem functionem algebraicam rationalem integram unius variabilis in factores reales primi vel secundi gradus resolvi posse*. However, his proof had a gap. He gave three other proofs (1816, 1849) (see Sect. 6.21 for a "topological" proof).

Dupin later became a naval engineer, and a friend and a confident of Napoleon. He was a lover of modern Greece. He spent several years in the island of Corfu and he founded there, in 1808, together with Antoine-Marie Augoyat, a fellow student at the École polytechnique, an academy which became known as the Ionian Academy. He became a senator under Napoleon III.

To conclude with the work on Dupin, let us note that Poincaré, in 1847, published a paper titled *Démonstration nouvelle des propriétés de l'indicatrice d'une surface* (A new proof of properties, of the indicatrix of a surface) [98] in which he gives new proofs and complements to results of Dupin. Poincaré starts by giving a proof of the following result: If at each normal section at a given point on a surface we take, at the intersection with the tangent plane, a segment whose length is the square root of the radius of curvature of that section, then the result obtained is a conic. He then gives a new proof of Meusnier's theorem as well as a generalization, and a series of properties of the Dupin indicatrix, including results on conjugate tangents. Poincaré's proofs do not involve any calculation or equation, but only the synthetic theory of conics.

Olinde Rodrigues (1795–1851), who belonged to the circle of Monge,[53] wrote in 1815 and 1816 two memoirs on lines of curvature, *Sur quelques propriétés des intégrales doubles et des rayons de courbure des surfaces* (On some problems of double integrals and radii of curvature of surfaces) [104], and *Recherches sur la théorie des lignes et des rayons de courbure des surfaces, et sur la transformation d'une classe d'intégrales doubles qui ont un rapport direct avec les formules de cette théorie* (Researches on the theory of lines and of radii of curvature of surfaces, and on the transformation of a class of double integrals which have a direct relation with the formulas of this theory) [105]. Rodrigues is known for a formula on this subject carrying his name, and for developing the idea of a representation of a differentiable surface on a sphere of radius one which amounts to the Gauss map. He used such a representation to study the ratio of the area of (a piece of) the original surface to the area of its image on the sphere, arriving at a measure of curvature which in fact is the Gaussian curvature at a point of a surface.

7.7 Twentieth Century: Return to Euclid

The work of Busemann and Feller on which we shall comment below is strongly influenced by Hilbert's vision on mathematics. Both Busemann and Feller obtained their PhD in Göttingen, and although their thesis advisor was Courant, they were shaped by Hilbert's view on the foundations of geometry. Feller obtained his PhD in 1927, and Busemann in 1931. Before talking about their work, let us say a few words on some work of Hilbert related to our topic.

---

[53] Strictly speaking, Rodrigues was not a student of Monge, but according to Taton [112], Monge considered him as his student. Rodrigues became a follower of Saint-Simon (1760–1825), the famous utopian socialist whom he met in 1823, 2 years before Saint-Simon's death, and he became the main promoter of his ideas.

In 1932, together with Stephan Cohn-Vossen,[54] Hilbert published his remarkable book *Geometry and the Imagination*[55] [69] which is based on Hilbert's lectures held in 1920/21. Let us quote Hilbert from the preface, about the aim of this book:

> Here we want to look at geometry in its present condition from the point of view of the imagination. With imagination, we can approach the manifold geometric facts and questions, and moreover in many cases we can give an idea in imaginative form of the methods of investigation and proof leading to the discovery of the facts, without having to give all the details of the conceptual theories and the calculations.[56]

The point of view is indeed purely geometric, unlike the one of Euler or Monge and his students, which is based on analytic geometry. In a sense, it is a return to the methods of the Greeks. Let us quote from the chapter on differential geometry [69, p. 155] their description of the osculating circle at a point P_1 on a plane curve, a notion which we encountered several times in this essay. It says the following:

> We draw a circle through P_1 and two neighbouring points on the curve. If we let the two neighbouring points approach P_1, the corresponding circle converges to a limit position [...] This limit circle is called the osculating circle at P_1. Because of the construction described, it is usual to say that the curvature circle has three points running together in common with the curve. Similarly, one says that the tangent and the curve have two points running together in common.[57]

The osculating circle of a curve at a point P typically changes sides of the curve at the touching point P. If we consider all circles through P touching the curve at P, then in general those circles of radius greater than the radius of curvature r lie on one side of the curve whereas those of radius less than r lie on the other side of the curve. This is represented in Fig. 7.10, which is extracted from Cohn-Vossen's book (see [69, Figure 186]).

These ideas directly translate to space curves. To construct the osculating plane of a space curve at a point P, we can consider the limiting position of the

---

[54] For a comprehensive review on Cohn-Vossen's work, we refer the reader to the article [1] by Alexandrov.

[55] The original German title is: Anschauliche Geometrie.

[56] Wir wollen hier die Geometrie in ihrem gegenwärtigen Zustand von der Seite des Anschaulichen aus betrachten. An Hand der Anschauung können wir uns die mannigfachen geometrischen Tatsachen und Fragestellungen nahebringen, und darüber hinaus lassen sich in vielen Fällen auch die Untersuchungs- und Beweismethoden, die zur Erkenntnis der Tatsachen führen, in anschaulicher Form andeuten, ohne daß wir auf die Einzelheiten der begrifflichen Theorien und der Rechnung einzugehen brauchen.

[57] Wir legen einen Kreis durch P_1 und zwei benachbarte Punkte auf der Kurve. Wenn wir dann die beiden Nachbarpunkte auf der Kurve gegen P_1 rücken lassen, nähert sich der Kreis einer Grenzlage. [...] Man nennt diesen Kreis den Krümmungskreis der Kurve in P_1. [...] Der angegebenen Konstruktion wegen pflegt man zu sagen, daß der Krümmungskreis drei zusammenfallende Punkte mit der Kurve gemein hat. Ebenso sagt man, die Tangente hat mit der Kurve zwei zusammenfallende Punkte gemein.

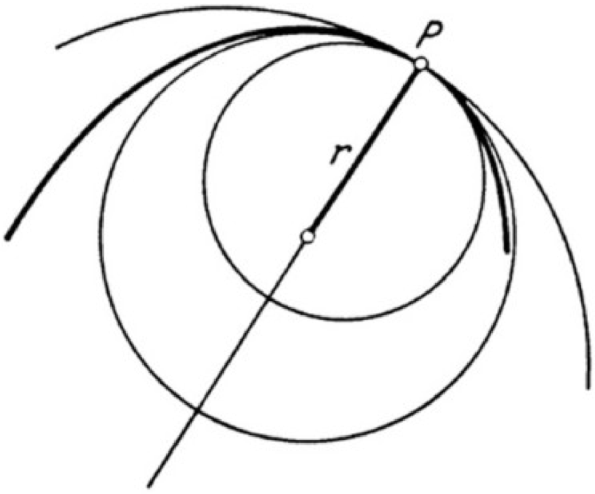

Fig. 7.10 The osculating circle at P separates two kinds of circles tangent to the curve at P: those that lie on one side of the curve and those that lie on the other side of the curve (in the neighbourhood of the point P). Figure from [69]

plane through the tangent at P and a neighbouring point that approaches P [69, p. 158]: "In the same sense as above, the osculating plane has three points that are running together in common with the curve."[58] Let us note incidentally that the term "osculating plane" can be traced back to Johann Bernoulli, specifically to his memoir *Problema: in superficie curva ducere lineam inter duo puncta brevissimam* (Problem: to draw on a curved surface a shortest line between two points) [13].[59] Bernoulli used this notion in the context of his study of geodesics on surfaces. In fact, he characterized geodesics as the curves on the surface whose osculating plane is always perpendicular to the tangent plane of the surface.

In [69], §32, Hilbert and Cohn-Vossen discuss eleven properties of the sphere, some of which characterize it and others do not. For example the third property says that the sphere is a surface of constant breadth and all the projections have constant circumference. The property of having constant breadth means that the distance between any two parallel tangent planes is constant. It is a generalization for surfaces of the property with the same name that we encountered in Euler's memoir on triangular curves [57]. As Hilbert and Cohn-Vossen explain, there are many other convex surfaces sharing this property. Figure 7.11 is extracted from Hilbert and Cohn-Vossen's book and reproduces pictures of such surfaces. In the

[58] Die Schmiegungsebene hat im früher erläuterten Sinn drei zusammenfallende Punkte mit der Kurve gemein.

[59] Bernoulli writes: Voco autem *planum osculans* quod transit per tria curvae quaesitae puncta infinite sibi invicem propinqua. (I also call an *osculating plane* one that passes through three points on the given curve that are infinitely close to each other).

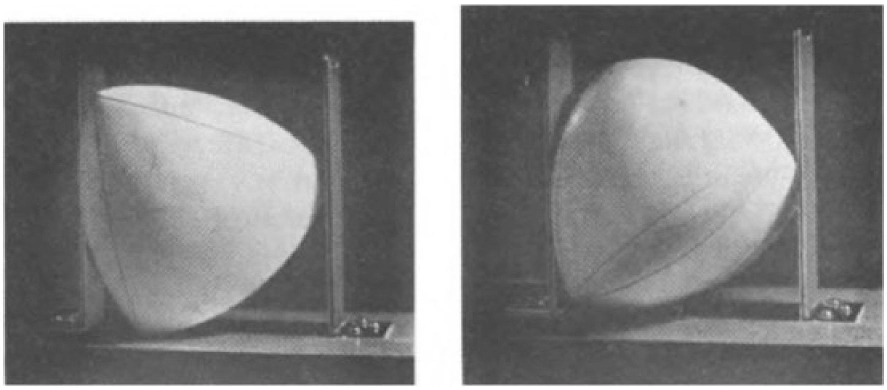

Fig. 7.11 Surfaces of constant breadth, from [69]

picture on the left hand side, one can see a surface having as a section a curve with three cusps (a triangular curve in the sense of Euler). The fourth property in §32 says that all points on a sphere are umbilical, which in fact characterizes the sphere. The fifth property concerns the focal points of a surface. Let us explain this notion. The set of centers of curvature of normal sections at a point of a surface is in general a segment contained in the normal section at that point, whose extremities are the centers of curvature of the principal directions. These extremities are called *focal points*, and we already saw that these two points coincide if and only if the given point is umbilical. The fifth property then states that the focal points of the sphere do not form a surface. Indeed the sphere is the only closed surface that has a unique focal point. But there are other surfaces where the set of focal points degenerates to a curve. These are the surfaces we mentioned, discovered by Dupin, called Dupin cyclides.

After Hilbert and Cohn-Vossen, and before going over to the work of Busemann and Feller, we briefly review the work of Bonnesen and Fenchel on convexity.

It is interesting to note that there was a strong interaction between the whole group of four mathematicians: Fenchel, Feller, Bonnesen and Busemann. Werner Fenchel obtained his PhD in 1928 in Berlin under Bieberbach. The title of his dissertation was *Über Krümmung und Windung geschlossener Raumkurven* (On curvature and torsion of closed space curves) [62]. The topic was differentiable curves in 3-space. The main results concern the image of the curve obtained by taking the tangent vectors of a given curve parametrized by arc length. This curve of tangents is considered as a curve lying on the unit sphere. Fenchel proves that (1) the total curvature of a space curve is bounded below by 2π, with equality if and only if the curve is planar and convex; (2) if the curve of tangents has a double point, then the torsion changes sign unless it is constant. The first of these two results is known as "Fenchel's theorem", and it was generalized in several ways by various people. The proofs of the results in Fenchel's thesis are very geometric in spirit. After his PhD, Fenchel moved to Göttingen, where he became Landau's assistant.

Busemann and Feller were also working in Göttingen, as young mathematicians. Fenchel remained there until 1933, when Hitler was appointed chancellor, with two interruptions between 1930 and 1932 during which he spent some time in Copenhagen, where Tommy Bonnesen was working. In 1933, Busemann, Feller and Fenchel fled to Denmark. Fenchel spent essentially the rest of his career there, whereas Busemann and Feller eventually moved to the US. The reader interested in this turbulent period of the history of Europe may refer to Feller and Busemann's biographies contained in their Selected Works editions, [61, Vol. 1] and [25, Vol. 1]. We also refer to Busemann's biography in [93].

The book [17] by Bonnesen and Fenchel, published in 1934, a year after Fenchel's move to Denmark, belongs to the Göttingen tradition of Hilbert's foundations of geometry. It is one of the founding books of modern convexity theory and, at the same time, of the synthetic point of view on curvature. §17 of the book starts with the following statement: "Far-reaching assertions can be made about the curvature relations of convex curves without making any assumption of differentiability" [17, p. 153]. Indeed, in that section and the next one, the authors attempt to develop a geometric theory of curvature of convex curves and surfaces without differentiability conditions.

Convex curves in the plane (respectively convex surfaces in 3-space) have support lines (respectively support planes) which sometimes can play the role of tangent lines (respectively planes). We recall that for any point on a convex hypersurface (that is, the boundary of a proper open convex set of maximal dimension in some Euclidean space), a support hyperplane is a hyperplane that contains that point but no point from the open convex subset it bounds. Any point on a convex surface is contained in a (not necessarily unique) support hyperplane. If the surface is differentiable at the given point, then the support hyperplane is unique and coincides with the tangent plane at that point.

Bonnesen and Fenchel call an *element* of a convex curve C in the plane a pair (P, s) consisting of a point P and a support line s at P. A *normal line* to this element is a line passing through P and perpendicular to s. An *osculating circle* at (P, s) is defined as a geometric limit of circles each of which touches s at P and which passes through a sequence of points on the curve that converges to P. The radius of such a circle is then a *radius of curvature* of the curve C at P. The values 0 and ∞ are allowed; in such cases the osculating circle is a point or a line respectively. To each element (P, s) is associated a set of osculating radii and of radii of curvature, each being an interval, the former contained in the latter. A *circle of curvature* at (P, s) is a limit of circles through P whose centers are the intersections of the normal of s at P with the normals of a sequence of elements that converge to (P, s). One also defines the *center of curvature* of C at P as the limit (if this limit exists) of the intersection of the normal line at p with the normal lines of a sequence of points on C that converge to P. The center of curvature, when it exists, may or may not coincide with the center of the osculating circle of C at P. For a given element (P, s), there may be several osculating circles and several circles of curvature. An osculating circle is a circle of curvature but the converse is not necessarily true. In the case where the osculating circle is unique, there exists also a unique circle of curvature, and both circles coincide. This occurs for almost all points of the convex curve, with respect to the Lebesgue measure of arc length on the curve; cf. Jessen [73]. In the cases where the limits do not exist (at a set of points of measure zero), one may define, by taking the smallest upper bound and the greatest lower bound, the upper and lower centers of curvature on the normal line n and then define the *upper* and *lower* curvature of the curve at the point P.

Bonnesen and Fenchel refer to the papers by Hjelmslev [71] and by Jessen [73] for these notions and their basic properties. They relate this notion of greatest lower bound of curvature radii to the question of the largest circle that can roll unhindered on a convex curve. This kind of questions remind us of questions that Aristotle addressed, and which we recalled in Sect. 7.2 of this paper. Bonnesen and Fenchel refer to papers by Bohr and Jessen [16], Mukhopadhyaya [90] and Brunn [20]. Then they discuss osculating conics to convex curves, referring to papers by Hayashi [65], Mukhopadhyaya [89] and others. In his paper *Circles incident on an oval of undefined curvature* [91] published in 1931, Mukhopadhyaya studied contact and osculation of circles relative to a convex continuous curve in the plane under the assumption that a definite tangent exists at each point but with no assumption on the existence of an osculating circle.

All this concerns curves. Regarding surfaces, Bonnesen and Fenchel state that "systematic investigations of the curvature properties of convex surfaces without differentiability assumptions are not available" [26, p. 154]. They mention preliminary tools and methods of attack due to Bouligand [19], Hadamard [64], Cohn-Vossen [29] and a few others.

In their article [26], Busemann and Feller investigate curvature properties of convex surfaces in Euclidean space. They describe their goal in the introduction thus:

> The aim of this paper is to develop the elements of differential geometry of convex surfaces without making the usual regularity assumptions. Hereby necessarily, purely geometric considerations often replace the usual analytic arguments.[60]

Consequently, they start from purely geometric definitions of tangent, tangent plane, osculating circle, radius of curvature etc. in the spirit of the book of Hilbert and Cohn-Vossen [69]. Their approach allows them to consider topological surfaces in 3-space with mild extra assumptions, and in particular convex surfaces, without further regularity conditions. Their starting point is a definition of tangent line, approximating circle, curvature and osculating plane, generalized from the setting of curves in space to that of sequences of points in space converging to a given point (Section 1 of [26]). At this point, the reader may stop and think about the meaning of these words, in the simplest situation, and without any differentiability assumption. Here is how Busemann and Feller proceed.

We start with a sequence of points $\{P_n\}$ in 3-space converging to a point P. If the lines joining P_n to P converge to a line t, this limit is called the *tangent line* of

---

[60] Cf. the English translation of the whole article in [25, Vol. 1, p. 235].

$\{P_n\}$. As in the treatise by Bonnesen and Fenchel, the pair (P, t) is said to be a *line element*. If the sequence $\{P_n\}$ has a tangent line t, then the circle in the plane (t, P_n) through P_n that is tangent to t is called the *approximating circle* of P_n with respect to the line element (P, t). If ρ_n denotes the radius of this circle and if the limit ρ of ρ_n exists, then this limit is called the *radius of curvature*, and its inverse $\frac{1}{\rho}$ the *curvature* of the sequence of points $\{P_n\}$. If the planes through P_n and t converge to a plane E, then this plane E is called the *osculating plane* of $\{P_n\}$.

Other metric notions associated with a sequence of points $\{P_n\}$ are introduced in the same paper, such as the *foot of the perpendicular*, *normal segment* and *tangent segment* from P_n to P. Formulae for curvature radii, etc. are given in terms of limits of normal segments, tangent segments, etc. generalizing the classical formulae given in terms of derivatives.

From this, Busemann and Feller introduce as follows the notions of tangent, curvature and osculating plane for a space curve:

Let κ be a continuous space curve and P a point on κ. If for any sequence P_n of points on κ converging to P the tangent and curvature exist and are independent of the choice of P_n, then these tangent and curvature are defined to be the *tangent* and *curvature of* κ at P. The osculating plane of κ at P is defined similarly.

Several other metric definitions in the same spirit are given. In particular, if the tangent and the osculating plane exist but the curvature depends on the chosen sequence, then the upper limit of all the possible curvatures is called the *upper curvature of* κ. Choosing the sequence P_n to be on the same side of P on the curve, one obtains notions of right-sided and left-sided tangent and curvature.

Busemann and Feller compare these definitions with the classical ones by taking derivatives in the special case of plane curves and they show that their concept is broader. Namely, if a curve κ is given as the graph of a continuous function f of one variable x and if at some point x_0 of the interval of definition the right second derivative of f exists, then the usual notion of right curvature of κ at x_0 coincides with the one they introduce. They show that the converse is not true: there exists a C^1-function f with right curvature at x_0 (in the sense of the authors) admitting no right second derivative at x_0.

The case of convex plane curves is of particular interest. Here, at each point of such a curve, a left and a right tangent exists. Because the slope of these one-sided tangents is monotone with respect to the point, the curve has a two-sided tangent almost everywhere (up to countably many exceptions). This monotonicity property also implies that up to a set of measure zero, f has also almost everywhere a second derivative.

In the same trend, the authors give a geometric definition of a strict tangent plane at a point of a surface [26, § 2]: given a point P on a surface Φ in the Euclidean space, a plane Π is called *strict tangent plane* of Φ at P if for every sequence of secants Q_nP_n of Φ converging to P, all the limits of the lines joining Q_n and P_n are contained in Π. Again, the case of a convex surface is a typical example: any tangent plane is automatically strict. Busemann and Feller indicate that this notion of strict tangent plane coincides with that of *paratangent* introduced by Bouligand [19].

Using these definitions, Busemann and Feller present generalizations of classical results on the differential geometry of surfaces. In particular, Euler's theorem on normal curvatures which we surveyed in Sect. 7.4 and Meusnier's formula which we mentioned in Sect. 7.6 serve as testing ground to demonstrate that the general setting is reasonable enough, that is, non-trivial results may be proven in it. More precisely, the general form of Meusnier's theorem, which holds also for non-convex surfaces, is the following: If at a point with a strict tangent plane some oblique plane section through a tangent t has curvature, then all plane sections through t have curvature as well, and the corresponding osculating circles lie on a common sphere. In particular, for a convex surface, Meusnier's formula holds almost everywhere.

For convex surfaces in 3-space, Busemann and Feller show that Euler's theorem on normal curvatures holds almost everywhere. They formulate their result in terms of Dupin's indicatrix. We already recalled in Sect. 7.6 that Dupin observed that Euler's equation relating to the normal curvatures at a point of an analytic surface define a conic (called Dupin indicatrix) in the tangent plane at the given point. In the case of a convex surface, the indicatrix can either be an ellipse or a pair of parallel lines unless all normal curvatures at the point vanish.

Busemann and Feller use the following construction as a definition of the indicatrix: Consider the tangent plane T at a point P of a convex surface where such a plane exists, and choose coordinates such that this tangent plane is not vertical and P is its origin. Take the plane parallel to T and lying above T, at distance ϵ. It intersects the surface in a curve, call it c_ϵ. Then, for almost every P, the curve c_ϵ rescaled by the factor $\frac{1}{\epsilon}$ converges, as $\epsilon \to 0$, to a curve, which the authors call the indicatrix at that point. Moreover, they show that it is either an ellipse or a pair of parallel lines. This means that for a convex surface, at almost all points normal curvatures exist and satisfy Euler's theorem. They then show that Rodrigues' formula for principal curvature directions holds in this general setting. They also obtain an umbilical theorem. We recall that in its classical form, the theorem says that an analytic surface in 3-space in which all points are umbilics (i.e. the maximal and minimal normal curvatures coincide) is either a piece of a sphere or a piece of a plane. In particular, this property characterizes the sphere among all convex closed analytic surfaces in 3-space (see also [69], §32, Property 4). Busemann and Feller generalize this result by proving that a differentiable convex surface where almost all points are umbilics and the upper normal curvatures are bounded is either a piece of a sphere or a plane. They also show, through a counterexample, that the extra condition of boundedness of the upper normal curvatures is essential. More precisely, they construct an example of a closed differentiable convex surface where almost all points are umbilics with the same curvature c and that is neither a piece of a sphere nor a plane. This example is obtained by a subtle algorithm starting with the unit ball and stepwise replacing parts by caps of curvature c and smoothing out the edges with canal surfaces of curvature greater than c.

In the last section of their paper, Busemann and Feller study geodesics on convex surfaces. They prove that a geodesic passing through (or emanating from) any point at which a tangent plane exists is in fact differentiable. Moreover, such a geodesic has a tangent line (or tangent ray) at that point, and an osculating plane which is perpendicular to the tangent plane. This generalizes a result of Johann Bernoulli which we already mentioned, from his article published in his 1728, *Problema: in superficie curva ducere lineam inter duo puncta brevissimam* [13] in which he used the term "osculating plane" for the first time.

For the proofs of all these theorems, Busemann and Feller acknowledge the strong influence of Bonnesen and Fenchel's *Theorie der konvexen Körper* [17] (1934), and this influence is also stressed in Busemann's monograph *Convex surfaces* [24] published in 1958. In the first chapter of that monograph, Busemann gives more detailed proofs of all these theorems. In the introduction, he writes that the first two chapters form a complement to Bonnesen and Fenchel's book, dealing in particular with subjects conjectured or suggested there. Zalgaller, in his paper [114], writes that Busemann took part in the preparation of the book by Bonnesen and Fenchel.

In the introduction of his monograph *Convex surfaces*, Busemann declares that his purpose is to present a subject, convex surfaces, which "during the past 25 years has experienced a striking and beautiful development, principally in Russia, but has remained largely unknown, at least in the USA." Indeed, the book is a tribute to the work of A. D. Alexandrov. As a matter of fact, this is the way Busemann presented his book project to the publisher.[61] We are not going to attempt any description of the results from Alexandrov or the school he founded, because this would lead us too far, but since our main subject matter in this article is curvature, we shall review his notion of nonpositive curvature.

We start with the definition of the length of a curve γ in a metric space (X, d), that is, of a continuous path $\gamma : [0, 1] \to X$. This is defined as

$$L(\gamma) = \sup \sum_i d(\gamma(t_i), \gamma(t_{i-1}))$$

where the supremum is taken over the set of subdivisions $0 = t_0 \leq t_1 \leq \ldots \leq t_n = 1$ of the interval $[0, 1]$. The definition is reminiscent of the notion of length of a curve as defined by Archimedes in his *On the sphere and the cylinder* [66]. If $\gamma(0) = A$ and $\gamma(1) = B$, we say that the curve joins A and B. We also say that the curve starts at A.

A metric on a surface (2-dimensional manifold) M is said to be intrinsic if the distance between two points is equal to the infimum of the lengths of curves in that surface that joins them.

A geodesic in M joining two points is a curve joining them which is the isometric image of a Euclidean interval.

---

[61] A letter written on July 23, 1956, from the editor-in-chief of Interscience Publishers Inc. (with copies to Courant, Stocker and Bers) starts with: "It is with very special pleasure indeed that we learn from Dr. Stocker of your willingness to preset in our Tracts series an account of important recent development of the work of certain Russian geometers." (A copy of the letter is kept with Courant's correspondence at the Elmer Holmes Bobst Library in New York University).

A triangle Δ in M is the union of three points in M (called the vertices of Δ) together with three minimizing geodesics (called the sides of Δ) joining them.

To each triangle Δ in M, one can associate a triangle Δ_E in the Euclidean plane E, together with a natural marking between the sides of Δ and the sides of Δ_E. The triangle Δ_E is called a comparison triangle of Δ. Now consider two curves γ_1 and γ_2 in S starting at a common point p. We wish to define the angle these curves make at p. We take a sequence of points x_n and y_n on the images of γ_1 and γ_2 respectively, both converging to p.

We then define the upper angle between γ_1 and γ_2 at p as the upper limit of the sequence of angles of the comparison triangles of p, x_n, y_n, all the angles being taken at the image of the point p in the Euclidean plane.

With this definition, each triangle in the metric surface M has a well-defined upper angle at each vertex. Let S be the sum of these three upper angles. The *angle excess* of such a triangle is then equal to $S - \pi$.

The surface M with an intrinsic metric is said to have (local) non-positive curvature in the sense of Alexandrov if (locally) each triangle has non-positive angle excess.

There are straightforward variations on this definition that lead to that of surfaces of bounded curvature (from below and from above), where, instead of taking comparison triangles in the Euclidean plane, one takes comparison triangles in one of the constant curvature geometries. Alexandrov thoroughly investigated this notion in several books and articles, see e.g. [2] and [3].

In his monograph [23] (and in other books and papers), Busemann introduced other (close but different) metric notions of curvature, and we recall the definition. He starts with the notion of a metric space *midpoint convex*, that is, for any two points x and y in that space, there exists a point z whose distances from x and from y are both equal to half the distance between x and y. Such a point z is called a *midpoint* of x and y (it is not unique). In a midpoint convex geodesic metric space which is complete, any two points may be joined by a geodesic.

Busemann defines a midpoint convex metric space (M, d) to be *non-positively curved* if for any three points a, b, c in M, if a' is a midpoint of a and c and b' a midpoint of b and c, then

$$d(a', b') \leq \frac{1}{2} d(a, b).$$

There are variations of this definition, namely, the space is called *negatively curved, non-negatively curved, or positively curved* depending on whether the above inequality is replaced by a strict inequality, or the reverse inequality or strict reverse inequality respectively. If the inequality is replaced by an equality, the space is said to be *zero curved*. These notions are used today under the name *Busemann non-positive (resp. non-negative, positive, negative, zero) curvature*.

In the same monograph, Busemann studied other notions of metric curvature, and we would like to mention three of them. The first one uses the notion of a *peakless function*. This is a continuous function f defined on an interval I of the real line such that for all $t_1 < t_2 < t_3$ in I we have

$$f(t_2) \leq \max(f(t_1), f(t_3))$$

with equality if and only if $f(t_1) = f(t_2)$. Using this, Busemann introduced the notion of *space whose distance function is peakless*, another generalization of nonpositive curvature.

Another notion of curvature, introduced by Busemann, uses the notion of *capsules* in metric spaces: If T is a segment in a metric space (M, d) and ρ a nonnegative number, a subset of the form

$$\{x \in M \mid d(x, T) \leq \rho\}$$

is said to be a *capsule* of axis T and radius ρ.

Busemann proves a local-implies-global result for convexity of capsules [23, Theorem 36.20], and he proves that a space which has Busemann non-positive (respectively negative) curvature has convex (respectively strictly convex) capsules. [23, Theorem 36.20]

In the same book, Busemann introduced a notion of curvature in terms of angle excess of triangles in spaces he calls G-spaces (G-stands for "geodesic"). These are metric spaces that are finitely compact (every bounded infinite sequence contains a convergent subsequence) and that satisfy a property of local uniqueness of extension of geodesics.

The notion of G-space, like many of the other metrical notions introduced by Busemann, is already contained in his early book *Metric Methods in Finsler Spaces and in the Foundations of Geometry* [21] (1942) and in his paper *On spaces in which points determine a geodesic* [22] (1943).

The metric notions of curvature introduced by Alexandrov and by Busemann turned out to be the bases of whole new fields in geometry, called after their names[62] and there is a multitude of theorems and research problems that rely on these definitions.

Like Busemann, Fenchel and some other twentieth-century geometers we mentioned, Alexandrov's interest abides in the most basic notions of geometry, putting isoperimetry, isoepiphany and other problems of classical mathematics at the forefront of research, with a dislike for a certain Riemannian geometry based on linear algebra and tensor calculus. We refer the reader to Alexandrov's book *Intrinsic geometry of convex surfaces* [2], in which he provided proofs of the theorems of Euler, Meusnier and Rodrigues in the general setting of convex surfaces, attributing these generalizations to Busemann and Feller. He proved in the same book [2] that any convex two-dimensional manifold is non-negatively curved in the sense he introduced it and which we recalled above, and that every non-negatively curved two-dimensional manifold homeomorphic to the sphere is isometric to some convex surface.

---

[62] There are AMS Mathematics Subject Classification codes that carry the names of Alexandrov and Busemann geometries.

As another link between the group of geometers we mentioned, let us note that in his treatise *Convex surfaces*, Busemann gives a proof of a theorem in convexity theory that was independently obtained by himself and Fenchel and Jessen [63] stating that if two convex bodies in Euclidean n-space have equal p-th order area measure (we shall not go into the definition here) for some p satisfying $1 \leq p \leq n-1$, then the two bodies are the same up to a translation.

In a tribute in memory of Alexandrov, S.S. Kutateladze, who belongs to Alexandrov's school, writes that Alexandrov's slogan in mathematics was "Retreat to Euclid" and that he used to declare that "the pathos of contemporary mathematics is the return to Ancient Greece" [76].

A geometry freed from the dominion of differential calculus kept growing since the last quarter of the twentieth century, reinvigorated in the works of Thurston whose methods constitute a return to the synthetic methods of non-Euclidean geometry, and of Gromov, closer in spirit to the Busemann and Alexandrov approaches.

Pág. 241(256) – Gauss Curvature

Fermat's principle of least time saying that the path take between two points by a light ray is the path which can be traversed in the least time. (60).

↳Letter (January 1, 1662) to M. C. de la Chambre

Employing it, he deduced the law of refraction.

Hence shortest curves on a surface are regarded as something similar to paths traced by light rays (see Sect 6.12),

and it is reasonable to say that a quantity (or a concept) attached to a surface is "intrinsic" if it is derived from distance and angle measured by using shortest curves.

Pág. 337(352) →

Olinde Rodrigues (1795-1851)

Rodrigues is known for a formula

on this subject carrying his
name, and for
developing the idea of a
representation of a differentiable
surface on a sphere of radius
one which amounts to the
Gauss map.

He used such a (fal) ✡
representation to study the ratio of
the area of (a piece of)
the original surface to the
area of its image on the
sphere.)

⟸

arriving
at a measure of curvature
which in fact is the
Gaussian Curvature
at a point of a surface

Pag. 448(461) →

Husserl was confusing
intrinsic and extrinsic
natures of space.
He did not see to pay attention
to the fact that spheres and Euclidean
planes can be realised even in hyperbolic
space.

* "" "' ?

in particular think of Frege, Husserl and Russell as those who studied seriously epistemological problem of space and time. All of them had an academic training in mathematics. Frege, who is often regarded as a precursor of logical positivism, studied the foundation of mathematics, as in [8], which inspired both Wittgenstein and the famous work of Russell-Whitehead, *Principia Mathematica*. Frege also had good knowledge on the work of Riemann. Still, his attitude toward the non-Euclidean geometries and epistemological problem of space can be regarded as staying within a Kantian framework: Frege seemed to believe that our space of intuition should be the Euclidean three-dimensional space, as can be seen in his correspondence with Hilbert and his review on Hilbert's book, both of which can be found in [9] (see also Shipley [45] for a more detailed account on Frege's epistemological view on geometry and space).

Husserl, who is now regarded as a precursor of phenomenology, also worked for philosophical aspects of mathematics. He gave a course on Riemann's theory of geometry at University of Halle in 1889 [16], where he dealt with Riemann's notion of metric critically. In particular, after criticising Riemann's definition of curvature, Husserl claimed that since Euclidean space is necessary to define Gaussian curvature, Euclidean space is a special entity which is given to us by pure intuition in Kantian sense. If we scrutinise his argument from the viewpoint of modern geometry, we notice that Husserl was confusing intrinsic and extrinsic natures of space. He did not seem to pay attention to the fact that spheres and Euclidean planes can be realised even in hyperbolic space. (Recall that this is why Lobachevsky coined the term "Pangeometry" as we noted in §4.)

Russell, who belongs to a younger generation than the other two, published in his twenties a book entitled *An essay on foundation of geometry* [42]. In this book, he criticised Kantian apriorism in geometry, and observed that there are two elements in geometry, what is a priori and what is empirical. Russell rejected the a-priority of Euclidean geometry, and claimed that experience can decide which of Euclidean or non-Euclidean geometry is valid. He further insisted that their common ground, which is projective geometry, should be a priori. This means that Russell embraced some part of conventionalism, but retained a weak version of Kantian apriorism. This position of Russell was harshly criticised by Poincaré in his review of this book.

Thus we have seen that even these three famous philosophers who were familiar with Riemann's work could not be as radical as Poincaré in abandoning Kantianism, and this seems to be caused by the fact that without experience of research on geometry and topology, they could not reach the level of Poincaré's understanding of space. In the latter half of the twentieth century, there appeared philosophers such as Merleau-Ponty, who analysed how our perception leads to our recognition of space, but in Poincaré's day no professional philosopher could approach the epistemology of space as deeply as Poincaré. According to Althusser, as we have explained above, the role of philosophers would be to draw a line of demarcation between science and ideology in spontaneous philosophy by scientists. However for this to be possible, philosophers need to have a deep understanding on what constitutes the core of spontaneous philosophy. In Poincaré's case, the core is nothing but his geometric conventionalism, which in turn depends on his research in geometry and topology. In his time, it was very difficult for other philosophers to reach this level for playing the role to draw such a line of demarcation in Poincaré's epistemology.

4.4 Post-Thurston Era

In this century, there were two miracles that independently resolved these extremely wild conjectures of 1982. We will briefly describe them in this section.

4.4.1 Geometrization Conjecture

There had been many attempts to partially answer or approach the geometrization conjecture for the case of infinite π_1 since it was formulated. However the case of finite π_1 had stayed completely outside of the development in the last century except for the orbifold theorem and Hamilton–Perelman's attempts.

Perelman put three papers [30–32] on arXiv in 2002 and 2003 and declared the resolution of the geometrization conjecture in the affirmative. The proof was based on Hamilton's Ricci flow, which is a flow on the space of Riemannian metrics on a manifold satisfying an evolutional PDE,

$$\frac{d}{dt} g = -2\,\mathrm{Ric}_g$$

where Ric represents the Ricci curvature tensor. This equation can be regarded as a variational equation that averages metrics in the long term. After Hamilton proved a sort of geometrization for 3-manifolds with positive Ricci curvature in [11], Yau suggested to Hamilton that the solution of the Ricci flow might converge to the metric that the geometrization conjecture expects. Hamilton had been seriously involved in Yau's suggestion and has been establishing a program to resolve the geometrization conjecture through several deep studies on the Ricci flow in a series of papers [12–14]. A survey by Chow [7] discusses Hamilton's work along these lines.

Perelman essentially followed Hamilton's program. However, he had to fill in conceptual and technical details and needed to modify Hamilton's set up. His breakthrough would be to establish a locally non-collapsing theorem which guarantees that the rescaling limit of the solution of the Ricci flow is controllable. This is presented in the first preprint [30]. Then following [13], Perelman introduced Ricci flow with surgery in [31] and claimed the resolution of the geometrization conjecture.

Theorem 6 (Perelman) *The geometrization conjecture is true.*

This theorem was officially recognized at the ICM 2006 in Madrid. Excellent expositions of this innovation were presented by Milnor [25] in its very early stage and by McMullen [23] in its mature stage. The third preprint [32] presents a bypath argument independent from a half of the argument in [31] to prove for instance the Poincaré conjecture, when we start with a connected sum of manifolds with finite π_1.

Perelman's proof of the geometrization conjecture has a similarity with the proof of the orbifold theorem. Both arguments are based on the deformation of metrics. The difference is that Thurston used hyperbolic metrics with cone singularities, while Perelman used nonsingular Riemaniann metrics. Thus Thurston's argument is geometric, while Perelman's involves more analysis. Perelman's arguments brought a big surprise not only to geometers but also to analysts world-wide. His arguments certainly led to a new direction for the study of singular solutions for some PDE. In fact, Perelman's work has promoted the popularity of the term "blow up" in contemporary PDE theory.

4.4.2 *Virtual Fiber Conjecture*

Once again, the virtual Haken conjecture by Waldhausen states that every irreducible 3-manifold with infinite π_1 is virtually Haken, namely, finitely covered by a Haken manifold. After Perelman's resolution of the geometrization conjecture, this conjecture remained unsolved only for hyperbolic manifolds. Thus, the virtual fiber conjecture came to include the virtual Haken conjecture, and this motivated a significant number of people. There were actually several serious studies by experts including Thurston, but most of them were rather illustrative or experimental before Agol [1]. In this paper, Agol presented a fairly generic criterion for virtual fibering that he called residually finite rational solvability. It is an effective refinement of separability of a subgroup in a group. Agol showed, in particular, that any subgroup of a right-angled Artin group has this useful property.

There was a strong reason for Agol to reach to this definition. Early this century, Wise and his many collaborators developed the theory of special groups. They started with groups acting effectively on non-positively curved (NPC for short) cube complexes. One of their most notable contributions was the discovery of the specialness of a group or an action defined in [15]. Specialness can be defined by a somewhat technical combinatorial structure of an NPC cube complex. Surprisingly, Haglund–Wise [15] showed that specialness can be characterized in a purely group theoretic fashion: that a special group is a subgroup of a right angled Artin group.

An epoch making result was provided by Kahn–Markovic [18] who showed that there are many almost geodesic quasi-Fuchsian surfaces in any closed hyperbolic 3-manifold. Their result, which was presented at the 21st Nevanlinna Colloquium held at Kyoto University in 2009, gave a completely new tool to discuss the virtual fiber conjecture. In fact, Bergeron–Wise [3] immediately noticed that the result could be used to build a wall system of Sageev, as in [36], in the 3-dimensional hyperbolic space invariant under the action of a cocompact Kleinian group. Then the recipe by Sageev [35, 36] leads to a construction of a proper group action on an NPC cube complex by the same group.

Agol then succeeded in showing that the action constructed in this way is special, and concluded that

Theorem 7 (Agol) *The virtual fiber conjecture is true, and so is the virtual Haken conjecture.*

What Agol actually proved in [2] was much stronger. He showed that every compact cube complex with a hyperbolic fundamental group is virtually special. In other words, a hyperbolic group that acts on an NPC cube complex cocompactly is virtually special. The resolution of the virtual fiber conjecture is one of its many consequences when combined with previous results by Sageev, Wise and his collaborators, Kahn–Markovic and Bergeron–Wise. Thus the theorem by Agol pertains not only to the theory of 3-manifolds. However, we would like to note that the idea of the proof was connected to the techniques developed in the theory of 3-manifold, in the Thurston Era, especially hyperbolic Dehn surgery theory in the context of group theory.

We would like to refer for more details of this innovative result to the articles by Klarreich [20] for general audiences, and Bestvina [4] and Friedle [9] for experts.

4.5 Epilogue

Thurston's vision of 3-manifold theory, as presented for instance in the problem set in [40], has been completed by Perelman and Agol. However, it is more important to mention that Thurston presented us simultaneously with many new directions in mathematics even within the theory of 3-manifolds. In fact, we found fine geometric nature of 3-manifolds and many interesting questions. The connection between quantum topology and hyperbolic geometry in 3-manifolds could be one such fascinating topics. For example, there is the volume conjecture, which expects to precisely identify the hyperbolic volume of a knot complement with a certain asymptote of special values of quantum invariants of the knot. This conjecture has motivated and involved many researchers including people in mathematical physics. There are many other germs to create new links from 3-manifold theory within topology, with the other mathematical fields including geometry and science in general. For instance, geometric group theory is now expanding in many new directions, Teichmüller theory is finding interest in a higher dimensional analogue, and so on.

What Thurston did and left to us was extremely incredible and more than dramatic indeed.

Chapter 5
Combinatorics Encoding Geometry: The Legacy of Bill Thurston in the Story of One Theorem

Philip L. Bowers

Abstract This chapter presents a whirlwind tour of some results surrounding the *Koebe–Andre'ev–Thurston Theorem*, Bill Thurston's seminal circle packing theorem that appears in Chapter 13 of *The Geometry and Topology of Three-Manifolds*.

Keywords Circle packing · Uniformization · Circle domain · Discrete conformal geometry · Conformal type · Inversive distance · Polyhedron

AMS Codes 52C26, 57M20

5.1 Introduction

Bill Thurston was the most original and influential topologist of the last half-century. His impact on the discipline of geometric topology during that time is unsurpassed, and his insights in the topology and geometry of three-manifolds led finally to the resolution of the most celebrated problem of topology over the last century—The Poincaré Conjecture. He made fundamental contributions to many sub-disciplines within geometric topology, from the theory of foliations on manifolds to the combinatorial structure of rational maps on the two-sphere, and from geometric and automatic group theory to classical polyhedral geometry. Of course his foundational work on three-manifolds, first laid out in his courses at Princeton in the late 1970s, compiled initially as a Princeton paper-back monograph inscribed by Bill Floyd and available upon request as *The Geometry and Topology of Three-Manifolds* (GTTM) [73], and maturing as the famous *Thurston Geometrization Conjecture* of the early 1980s, was the driving force behind the development of geometric topology for the next thirty years. The final confirmation of the Geometrization Conjecture

by Giorgi Perelman using the flow of Ricci curvature, following a program that had been introduced by Richard Hamilton, is one of the crown jewels of twentieth century mathematics.

Thurston marks a watershed in the short history of topology,[1] a signpost, demarcating topology before Thurston, and topology after Thurston. This is evidenced not only in the fabulous results he proved, explained, and inspired, but even more so in how he taught us to do mathematics. Topology before Thurston was dominated by the general and the abstract, entrapped in the rarified heights that captured the mathematical world in general, and topology in particular, in the period from the 1930s until the 1970s. Topology after Thurston is dominated by the particular and the geometric, a throwback to the nineteenth-century, having much in common with the highly geometric landscape that inspired Felix Klein and Max Dehn, who walked around and within Riemann surfaces, knew them intimately, and understood them in their particularity. Thurston's vision gave a generation of topologists permission to get their collective hands dirty by examining in great depth specific structures on specific examples.

One of the organizing principles that lies behind Thurston's vision is that geometry informs topology, and that the non-Euclidean geometry of Lobachevski, Bolyai, and Beltrami in particular is systemic to the study of topology. Hyperbolic geometry permeates topology after Thurston, and it is hyperbolic geometry that becomes the common thread of the present chapter. This will be seen in the interrelated studies presented here. All to varying degrees are due to the direct influence of Bill Thurston and his generalization of the earlier results of Koebe and Andre'ev. All involve hyperbolic geometry in some form or influence, and even further all illustrate how combinatorics encodes geometry, another of the principles that underlies Thurston's vision. To my mind, the proposition that *combinatorics encodes geometry, which in turn informs topology* has become a fundamental guiding motif for topology after Thurston. I offer this chapter as a celebration of Bill Thurston's vision and his immense influence over our discipline.

5.1.1 An Introductory Overview

The Koebe–Andre'ev–Thurston Theorem represents a rediscovery and broad generalization of a curiosity of Paul Koebe's from 1936, and has an interpretation that recovers a characterization of certain three-dimensional hyperbolic polyhedra due to E.M. Andre'ev in two papers from 1970. This theorem is the foundation stone of the discipline that has been dubbed as *discrete conformal geometry*, which itself has been developed extensively by many mathematicians in many different directions over the last thirty years. Discrete conformal geometry in its purest form is geometry born of combinatorics, but it has theoretical and practical applications.

---

[1] I will use the term *topology* henceforth to mean *geometric topology*. By dropping the adjective *geometric* I certainly mean no slight of general, set-theoretic, or algebraic topology.

In the theoretical realm, it produces a discrete analytic function theory that is faithful to its continuous cousin, a quantum theory of complex analysis from which the classical theory emerges in the limit of large scales. In the realm of applications, it has been developed in a variety of directions, for practical applications in areas as diverse as biomedical imaging and 3D print head guidance. This rather large body of work flows from simple insights that Thurston presented in his lecture at Purdue University in 1985 on how to use the most elementary case of his circle packing theorem to provide a practical algorithm for approximating the Riemann mapping from a proper, simply-connected planar domain to the unit disk. A personal accounting of this development can be found in the author's own review [14] of the bible of circle packing theory, Ken Stephenson's *Introduction to Circle Packing: The Theory of Discrete Analytic Functions* [71].

A perusal of the section and subsection headings of this chapter will give the reader a clue as to where I am going in this survey. I primarily stick with the theoretical results for which there are fairly direct lines from the Koebe–Andre'ev–Thurston Theorem to those results. This means in particular that I almost totally ignore the really vast array of practical applications that circle packing has found, especially in the last two decades as discrete differential geometry has become of primary importance in so many applications among computer scientists and computational geometers. A survey of applications will have to wait as space constraints preclude a discussion that does justice to the topic.

5.1.2 Dedication and Appreciation

This chapter is dedicated to the memory of Bill Thurston and his student Oded Schramm, and to an appreciation of Jim Cannon and Ken Stephenson. I have spoken already of Bill Thurston's legacy. Oded Schramm was one of the first to press Thurston's ideas on circle packings to a high level of development and application, and his great originality in approaching these problems has bequeathed to us a treasure trove of beautiful gems of mathematics. Most of Oded's work on circle packing and discrete geometry was accomplished in the decade of the 1990s. As Bill is a demarcation point in the history of topology, Oded is one in the history of probability theory. In the late nineties, Oded became interested in some classical open problems in probability theory generated by physicists, in percolation theory and in random planar triangulations in particular. Physicists had much theoretical and computational evidence for the veracity of their conjectures, but little mathematical proof, or even mathematical tools to approach their verifications. In Oded's hands these venerable conjectures and problems began to yield to mathematical proof, using ingenious tools developed or refined by Oded and his collaborators, chief among which are SLE_κ, originally Stochastic-Loewner Evolution, now renamed as Schramm–Loewner Evolution, and UIPT's, or Uniform Infinite Planar Triangulations. For a wonderful biographical commentary on Oded's contributions to mathematics, see Steffen Rohde's article *Oded Schramm: From Circle Packing to SLE* in [58].

The two individuals who have had the greatest impact on my mathematical work are Jim Cannon and Ken Stephenson, the one a mathematical hero of mine, the other my stalwart collaborator for three decades. Jim's work has influenced mine significantly, and I greatly admire his mathematical tastes and contributions. Pre-Thurston, Jim had made a name for himself in geometric topology in the flavor of Bing and Milnor, having solved the famous double suspension problem and having made seminal contributions to cell-like decomposition theory and the characterization of manifolds. In the beginning of the Thurston era, his influential paper *The combinatorial structure of cocompact discrete hyperbolic groups* [24] anticipated many of the later developments of geometric group theory, presaging Gromov's thin triangle condition and, à la Dehn, the importance of negative curvature in solving the classical word and conjugacy problems of combinatorial group theory. He with Thurston invented automatic group theory and then Jim settled upon the conjecture that bears his name as the work that for three decades has consumed his attention. Ken has been a joy with whom to collaborate over the past three decades. He was inspired upon attending Thurston's Purdue lecture in 1985 to change his mathematical attentions from a successful career as a complex function theorist, to a geometer exploring this new idea of circle packing using both traditional mathematical proof and the power of computations for mathematical experimentation. I began my foray into Thurston-style geometry and topology by answering in [17] a question of Ken and Alan Beardon from one of the first research papers [7] to appear on circle packings after Rodin and Sullivan's 1987 paper [62] confirming the conjecture of Thurston from the Purdue lecture. Ken and I are co-authors on a number of research articles and his down-to-earth approach to the understanding of mathematics has been a constant check on my tendency toward flights of fancy. I have learned from him how to tell a good story of a mathematical topic. For Ken's warm friendship and collaboration I am grateful.

5.2 The Koebe–Andre'ev–Thurston Theorem, Part I

5.2.1 Koebe Uniformization and Circle Packing

In the early years of the twentieth century, rigorous proofs of the Riemann Mapping Theorem and the more general Uniformization Theorem were given by such eminent mathematicians as Osgood, Carathéodory, Poincaré, and Koebe, and refinements and re-workings would continue to be made by others, even up to the present.[2] The generalization of the Riemann Mapping Theorem to multiply-

---

[2] The author recommends rather highly the article *On the history of the Riemann mapping theorem* [38] by Jeremy Gray and the monograph *Uniformization of Riemann Surfaces: Revisiting a Hundred-Year-Old Theorem* [32]. These two works give insightful historical accountings of the discovery, articulation, understanding, and finally rigorous proofs of the Riemann Mapping

CIRCULAR GEOMETRIES

If projective geometry is about incidences of points, lines, and planes, inversive geometry deals with point pairs, circles, and spheres. In a manner that closely parallels how a linear metric space can be extracted from projective or affine geometry, a circular metric space can be derived from inversive geometry by fixing a certain *central inversion* (Johnson 1981; cf. Alekseevsky, Vinberg & Solodovnikov 1988, chap. 2, § 2). Depending on the nature of the fixed inversion, the resulting geometry may be either *spherical* or *pseudospherical*.

When represented in Euclidean space, inversive geometry also provides a way to construct conformal (angle-preserving) models of elliptic and hyperbolic spaces. The two non-Euclidean metrics will be seen to have a kind of "pseudo-symmetry" that is evident in formulas relating the angles and sides of a triangle and in measurements of circular arcs and sectors.

3.1 INVERSIVE AND SPHERICAL GEOMETRY

We begin with a hyperbolic polarity in real projective $(n+1)$-space. Let the points X and hyperplanes $\check{U}$ of P^{n+1} have homogeneous coordinates

$$((x)) = (x_0, x_1, \dots, x_{n+1}) \quad \text{and} \quad [[u]] = [u_0, u_1, \dots, u_{n+1}],$$

and let an oval n-quadric Φ have the locus or envelope equation

$$x_1{}^2 + \cdots + x_{n+1}{}^2 = x_0{}^2 \quad \text{or} \quad u_1{}^2 + \cdots + u_{n+1}{}^2 = u_0{}^2,$$

corresponding to the matrix $\backslash -1,\ 1, \ldots,\ 1\backslash$. We may regard Φ as the real inversive, or *Möbius*, n-sphere I^n (Veblen & Young 1918, pp. 262–264). The case $n = 2$ is of particular interest; a fuller description of the properties of the real inversive sphere I^2 will be given in Chapter 9.

A. *Inversive geometry.* A projective hyperplane $\check{U}$, with coordinates $[[u]]$, meets Φ in an inversive $(n-1)$-sphere $\mathring{u}$, a *hypersphere* of I^n, which is

$$\begin{array}{lll} \textit{real} & \text{if} & [[u\,u]] > 0, \\ \textit{degenerate} & \text{if} & [[u\,u]] = 0, \\ \textit{imaginary} & \text{if} & [[u\,u]] < 0, \end{array}$$

where $[[u\,u]]$ is the quadratic form associated with the bilinear form

$$[[u\,v]] = -u_0v_0 + u_1v_1 + \cdots + u_{n+1}v_{n+1}.$$

A point X lies on I^n if its coordinates $((x))$ satisfy the locus equation for Φ and on the hypersphere $\mathring{u}$ with hyperplanar coordinates $[[u]]$ if $((x))[[u]] = 0$. The equation $((x))[[u]] = 0$ has at least two, just one, or no real solutions for $((x))$ (on I^n) according as $\mathring{u}$ is real, degenerate, or imaginary; in the last case, the equation has two or more imaginary solutions.

If the discriminant of two real or degenerate inversive hyperspheres $\mathring{u}$ and $\mathring{v}$ is defined by

$$||u\,v|| = [[u\,u]]\,[[v\,v]] - [[u\,v]]^2,$$

then the hyperspheres are

$$\begin{array}{lll} \textit{separating} & \text{if} & ||u\,v|| > 0, \\ \textit{tangent} & \text{if} & ||u\,v|| = 0, \\ \textit{separated} & \text{if} & ||u\,v|| < 0. \end{array}$$

Applied to two point-pairs $\ddot{u} = \{U_1,\ U_2\}$ and $\ddot{v} = \{V_1,\ V_2\}$ on a circle I^1, separation has the usual meaning associated with cyclic order (Coxeter 1966a, p. 218). That is, $\ddot{u}$ and $\ddot{v}$ are separating if $U_1U_2 \,/\!/\, V_1V_2$, tangent if $\ddot{u}$ and $\ddot{v}$ have a point in common, and separated otherwise. For $n \geq 2$, two hyperspheres of I^n are separating, tangent, or separated according as they intersect in a real, degenerate, or imaginary $(n-2)$-sphere.

The angle between two separating inversive hyperspheres $\mathring{u}$ and $\mathring{v}$ is given by

$$(\mathring{u}\ \mathring{v}) = \cos^{-1}\frac{|[\![u\ v]\!]|}{\sqrt{[\![u\ u]\!]}\sqrt{[\![v\ v]\!]}}. \tag{3.1.1}$$

Two separated inversive hyperspheres $\mathring{u}$ and $\mathring{v}$ have an analogous *inversive distance* (Coxeter 1966b), given by

$$)\mathring{u}\ \mathring{v}(= \cosh^{-1}\frac{|[\![u\ v]\!]|}{\sqrt{[\![u\ u]\!]}\sqrt{[\![v\ v]\!]}}. \tag{3.1.2}$$

Another inversive invariant of note is the cross ratio of four points (Wilker 1981, pp. 384–386; Beardon 1983, pp. 32–33). The distance between two points is not defined, and an inversive hypersphere has no center or radius.

B. *Spherical geometry.* A projective collineation of P^{n+1} that commutes with the polarity that defines the n-quadric Φ induces a circle-preserving transformation, or *circularity*, on Φ as the Möbius n-sphere I^n. In particular, a harmonic homology whose center O and median hyperplane $\check{O}$ are pole and polar with respect to Φ induces an *inversion* on I^n. When O and $\check{O}$ have the respective coordinates

$$(1,\ 0, \ldots,\ 0,\ 0) \quad \text{and} \quad [1,\ 0, \ldots,\ 0,\ 0],$$

this is an *elliptic* inversion $Z : \mathrm{I}^n \to \mathrm{I}^n$, i.e., the inversion in the imaginary hypersphere in which $\check{O}$ meets Φ, leaving no real points fixed. If we restrict ourselves to those circularities that commute with Z, we convert the Möbius n-sphere I^n into the *elliptic* n-sphere S^n ("spherical n-space"), with Z becoming the familiar *central inversion* that interchanges antipodal points. (It is a happy accident that two different, seemingly unrelated, meanings of "inversion"—in a hypersphere and in a point—are united in the same transformation.)

For every point X on S^n, $x_0 \neq 0$, and normalized coordinates for X are the last $n+1$ projective coordinates divided by x_0, i.e.,

$$\mathbf{(}x\mathbf{)} = (x_1, x_2, \ldots, x_{n+1}),$$

where ${x_1}^2+{x_2}^2+\cdots+{x_{n+1}}^2 = 1$. The points $\mathbf{(}x\mathbf{)}$ and $-\mathbf{(}x\mathbf{)}$ are antipodal. A hyperplane $\check{U}$ passing through the point O, so that $u_0 = 0$, intersects S^n in a *great hypersphere* $\check{U}$, with homogeneous coordinates

$$\mathbf{[}u\mathbf{]} = [u_1, u_2, \ldots, u_{n+1}].$$

We have $X \Diamond \check{U}$ if and only if $\mathbf{(}x\mathbf{)[}u\mathbf{]} = 0$. Other hyperplanes intersect S^n in real, degenerate, or imaginary "small" hyperspheres.

Two great hyperspheres of S^n are always separating, with any two great circles on an elliptic sphere S^2 meeting in a pair of antipodal points.

Whereas the geometry of I^n is only conformal, the elliptic n-sphere S^n is a full-fledged metric space. In terms of the bilinear forms

$$\mathbf{(}x\ y\mathbf{)} = x_1y_1 + \cdots + x_{n+1}y_{n+1} \quad \text{and} \quad \mathbf{[}u\ v\mathbf{]} = u_1v_1 + \cdots + u_{n+1}v_{n+1},$$

with $\mathbf{(}x\ x\mathbf{)} = \mathbf{(}y\ y\mathbf{)} = 1$, the distance (from 0 to π) between two points X and Y on S^n is given by

$$[\![X\ Y]\!] = \cos^{-1} \mathbf{(}x\ y\mathbf{)}, \tag{3.1.3}$$

and the angle (from 0 to $\pi/2$) between two great hyperspheres $\check{U}$ and $\check{V}$ by

$$((\check{U}\check{V})) = \cos^{-1} \frac{|\mathbf{[}u\ v\mathbf{]}|}{\sqrt{\mathbf{[}u\ u\mathbf{]}}\sqrt{\mathbf{[}v\ v\mathbf{]}}}. \tag{3.1.4}$$

The distance from a point X to a great hypersphere $\check{U}$ is given by

$$[\![X\check{U})\!) = \sin^{-1}\frac{|(x)[u]|}{\sqrt{[u\,u]}}. \tag{3.1.5}$$

An n-sphere S^n can be embedded in other metric spaces. For instance, the point O and the hyperplane $\check{O}$ may be taken as the origin and the hyperplane at infinity of Euclidean $(n+1)$-space E^{n+1}, and S^n is then the unit hypersphere $(x\,x) = 1$. If antipodal points are identified, as happens under projection from O to $\check{O}$, the elliptic n-sphere S^n is transformed into elliptic n-space $\mathrm{eP}^n = \mathrm{PS}^n = \mathrm{S}^n/\langle Z\rangle$. Great hyperspheres of S^n project into hyperplanes of eP^n.

EXERCISES 3.1

1. Show that the circles $[1, 1, 0, 1]$ and $[1, 0, -1, 2]$ on the inversive sphere I^2 are separating and find the angle between them.

2. Show that the circles $[1, 0, -1, 1]$ and $[1, 1, 2, 0]$ on the inversive sphere I^2 are separated and find the distance between them.

3. Find the distance from the point $(\tfrac{1}{3}, -\tfrac{2}{3}, \tfrac{2}{3})$ to the great circle $[4, 0, 3]$ on the elliptic sphere S^2.

3.2 PSEUDOSPHERICAL GEOMETRY

Returning to the Möbius n-sphere as an oval n-quadric Φ in P^{n+1} defined by

$$x_1{}^2 + \cdots + x_{n+1}{}^2 = x_0{}^2 \quad \text{or} \quad u_1{}^2 + \cdots + u_{n+1}{}^2 = u_0{}^2,$$

a harmonic homology whose center O and median hyperplane $\check{O}$ have the respective coordinates

$$(0, 0, \ldots, 0, 1) \quad \text{and} \quad [0, 0, \ldots, 0, 1]$$

induces a *hyperbolic* inversion $W : \mathrm{I}^n \to \mathrm{I}^n$—i.e., the inversion in the real inversive hypersphere $\mathring{\omega}$ in which $\check{O}$ meets Φ, leaving every point of $\mathring{\omega}$ fixed. If W is taken as the central inversion, interchanging antipodal points, then the Möbius n-sphere I^n is converted into the *hyperbolic* n-sphere $\ddot{\mathrm{S}}^n$, separated by $\mathring{\omega}$ into two n-hemispheres. We call $\mathring{\omega}$ the *equatorial hypersphere* of $\ddot{\mathrm{S}}^n$; all other hyperspheres and all points not on $\mathring{\omega}$ are *ordinary*. Up to a scalar factor, the hyperbolic n-sphere has the same metric as an n-pseudosphere (equidistant hypersurface) in H^{n+1}, and $\ddot{\mathrm{S}}^n$ may be called "pseudospherical n-space."

For an ordinary point X on $\ddot{\mathrm{S}}^n$, $x_{n+1} \neq 0$, and normalized coordinates for X are the first $n+1$ projective coordinates (rearranged) divided by x_{n+1}, i.e.,

$$\mathbf{(}x\mathbf{)} = (x_1, \ldots, x_n \,|\, x_0),$$

with ${x_1}^2 + \cdots + {x_n}^2 - {x_0}^2 = -1$. Two ordinary points X and Y with coordinates $\mathbf{(}x\mathbf{)}$ and $\mathbf{(}y\mathbf{)}$ lie in the same n-hemisphere if $x_0 y_0 > 0$. The points $\mathbf{(}x\mathbf{)}$ and $-\mathbf{(}x\mathbf{)}$ are antipodal, and points on the equatorial hypersphere are self-antipodal. A hyperplane $\breve{U}$ passing through O, so that $u_{n+1} = 0$, and having a real intersection with $\ddot{\mathrm{S}}^n$, so that $[\![u\ u]\!] > 0$, meets $\ddot{\mathrm{S}}^n$ in a *great hypersphere* $\breve{U}$, having homogeneous coordinates

$$\mathbf{[}u\mathbf{]} = [u_1, \ldots, u_n \,|\, u_0],$$

with ${u_1}^2 + \cdots + {u_n}^2 - {u_0}^2 > 0$. As before, $X \Diamond \breve{U}$ if and only if $\mathbf{(}x\mathbf{)}\mathbf{[}u\mathbf{]} = 0$. Other hyperplanes meet $\ddot{\mathrm{S}}^n$ in various real, degenerate, or imaginary "small" hyperspheres.

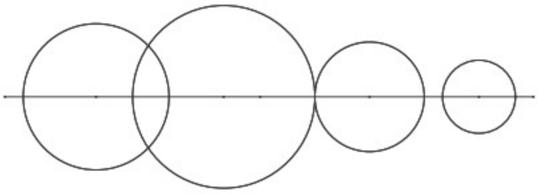

Figure 3.2a Separating, tangent, and separated great circles

Two great hyperspheres of $\ddot{\mathrm{S}}^n$ may be separating, tangent, or separated. (To distinguish the cases, apply the discriminant for inversive hyperspheres, assuming a final hyperplanar coordinate of zero.) Any two separating great circles on a hyperbolic sphere $\ddot{\mathrm{S}}^2$ meet in a pair of antipodal points; tangent great circles have one common equatorial point; separated great circles have no real points in common (see Figure 3.2a). An ordinary small circle on $\ddot{\mathrm{S}}^2$ is a *pseudocycle*, a *horocycle*, or a *pericycle* according as it and the equatorial circle are separating, tangent, or separated (see Figure 3.2b).

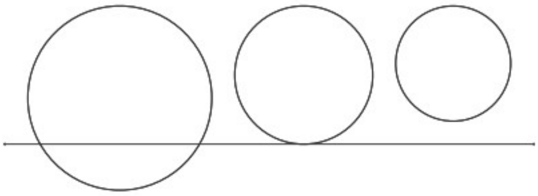

Figure 3.2b Pseudocycle, horocycle, and pericycle

In terms of the bilinear forms

$$(x \ddot{\ } y) = x_1y_1 + \cdots + x_ny_n - x_0y_0 \quad \text{and} \quad [u \ddot{\ } v] = u_1v_1 + \cdots + u_nv_n - u_0v_0,$$

with $(x \ddot{\ } x) = (y \ddot{\ } y) = -1$ (cf. Ratcliffe 1994/2006, § 3.2), the distance between two points X and Y in the same n-hemisphere of $\ddot{\mathrm{S}}^n$ is given by

$$]]XY[[= \cosh^{-1} |(x \ddot{\ } y)|, \tag{3.2.1}$$

the angle (from 0 to $\pi/2$) between two separating or tangent great hyperspheres $\breve{U}$ and $\breve{V}$ by

$$((\breve{U}\breve{V})) = \cos^{-1} \frac{|[u \ddot{\ } v]|}{\sqrt{[u \ddot{\ } u]}\sqrt{[v \ddot{\ } v]}}, \tag{3.2.2}$$

and the minimum distance between two separated great hyperspheres $\breve{U}$ and $\breve{V}$ by

$$]]\breve{U}\breve{V}[[= \cosh^{-1} \frac{|[u \ddot{\ } v]|}{\sqrt{[u \ddot{\ } u]}\sqrt{[v \ddot{\ } v]}}. \tag{3.2.3}$$

The distance from a point X to a great hypersphere $\breve{U}$ is given by

$$]]X\breve{U}((= \sinh^{-1} \frac{|\mathbf{(}x\mathbf{)[}u\mathbf{]}|}{\sqrt{\mathbf{[}u\,\ddot{}\,u\mathbf{]}}}. \tag{3.2.4}$$

The point O and the hyperplane $\breve{O}$ can be taken as the origin and the hyperplane at infinity of *Lorentzian* (or "pseudo-Euclidean") $(n+1)$-space $\mathrm{E}^{n,1}$, in which $\ddot{\mathrm{S}}^n$ appears as an n-hyperboloid of two sheets (a hyperbola if $n = 1$), asymptotic to the "light cone" $\mathbf{(}x\,\ddot{}\,x\mathbf{)} = 0$. Lorentzian space is homogeneous but not isotropic. The (not necessarily real) distance between two points X and Y with respective Cartesian coordinates $\mathbf{(}x\mathbf{)}$ and $\mathbf{(}y\mathbf{)}$ is given by

$$|X\,\ddot{}\,Y| = \sqrt{\mathbf{(}y-x\,\ddot{}\,y-x\mathbf{)}} = [(y_1-x_1)^2+\cdots+(y_n-x_n)^2-(y_0-x_0)^2]^{1/2}, \tag{3.2.5}$$

so that metrically $\ddot{\mathrm{S}}^n$ is a hypersphere with center O and imaginary radius i. The properties of such an "imaginary-spherical" geometry were anticipated by Johann Lambert (1728–1777) and extensively explored by Franz Taurinus (1794–1874), but it was Lobachevsky (1835, 1836) who first recognized it as a valid alternative to Euclidean and spherical geometry.

Just as the elliptic n-sphere S^n can be embedded in hyperbolic $(n+1)$-space as an n-perisphere with center O (and ideal median hyperplane $\breve{O}$), so the hyperbolic n-sphere $\ddot{\mathrm{S}}^n$ can be embedded in H^{n+1} as an n-pseudosphere with median hyperplane $\breve{O}$ (and ideal center O).

Either of the two n-hemispheres into which $\ddot{\mathrm{S}}^n$ is separated by the equatorial hypersphere $\mathring{\omega}$ (i.e., either sheet of the n-hyperboloid in $\mathrm{E}^{n,1}$ or the n-pseudosphere in H^{n+1}) will serve as an isometric model for hyperbolic n-space. When $n = 2$, the Lorentzian realization is the *hyperboloid model* of the hyperbolic plane (Ratcliffe 1994/2006, § 3.2; cf. Reynolds 1993). If antipodal points are identified, as by projecting from O to $\breve{O}$, the hyperbolic n-sphere $\ddot{\mathrm{S}}^n$ is transformed into extended hyperbolic n-space $\bar{\mathrm{H}}^n = \mathrm{P}\ddot{\mathrm{S}}^n = \ddot{\mathrm{S}}^n/\langle W\rangle$. Great hyperspheres of $\ddot{\mathrm{S}}^n$

project into hyperplanes of H^n, and the equatorial hypersphere $\mathring{\omega}$ of $\ddot{\mathrm{S}}^n$ becomes the absolute hypersphere ω of $\bar{\mathrm{H}}^n$.

Still another way to represent $\ddot{\mathrm{S}}^n$ is by Euclidean n-space E^n augmented by a single "exceptional" point that lies on every line, with some hyperplane $\check{O}$ taken to represent the equatorial hypersphere $\mathring{\omega}$. In this conformal "double half-space" model, the points and the k-planes or k-spheres of E^n lying in $\check{O}$ are the equatorial points and k-spheres of $\ddot{\mathrm{S}}^n$. Points that are mirror images with respect to $\check{O}$ are antipodal points of $\ddot{\mathrm{S}}^n$. Euclidean k-planes or k-spheres orthogonal to $\check{O}$ are great k-spheres of $\ddot{\mathrm{S}}^n$.

EXERCISES 3.2

1. Find the angle between the separating great circles $[-1, 1 \mid 1]$ and $[1, 2 \mid 1]$ on the hyperbolic sphere $\ddot{\mathrm{S}}^2$.
2. Find the distance between the separated great circles $[2, 0 \mid 1]$ and $[-2, \sqrt{3} \mid 2]$ on the hyperbolic sphere $\ddot{\mathrm{S}}^2$.

3.3 CONFORMAL MODELS

The elliptic and hyperbolic n-spheres can be projected into Euclidean n-space to provide inversive models for elliptic and hyperbolic n-space. Such mappings preserve circles and angular measure.

A. *Elliptic geometry.* Elliptic n-space eP^n can be conformally represented by a closed ball in E^n, i.e., a hypersphere Ω together with its interior. The k-planes of eP^n are diametral k-disks or caps of k-spheres intersecting Ω in great $(k-1)$-spheres, with diametrically opposite points of Ω being identified. When $n = 2$, this is Klein's "conformal disk" model of the elliptic plane.

To obtain explicit metrics for this and other Euclidean models, let the points of E^n have Cartesian coordinates $(\dot{x}) = (\dot{x}_1, \ldots, \dot{x}_n)$, and let

$(\dot{x}\,\dot{x}) = \dot{x}_1{}^2 + \cdots + \dot{x}_n{}^2$. In the elliptic "conformal ball" model, points of eP^n are represented by Euclidean points $(\dot{x})$ with $(\dot{x}\,\dot{x}) \leq 1$, where $(\dot{x})$ and $-(\dot{x})$ are identified if $(\dot{x}\,\dot{x}) = 1$. Each such point X also has normalized spherical coordinates

$$(x) = (x_1, \ldots, x_n, x_{n+1}),$$

where

$$x_i = \frac{2\dot{x}_i}{1 + (\dot{x}\,\dot{x})}\ (1 \leq i \leq n) \quad \text{and} \quad x_{n+1} = \frac{1 - (\dot{x}\,\dot{x})}{1 + (\dot{x}\,\dot{x})}. \tag{3.3.1}$$

(Optionally, the sign of the last coordinate can be reversed.) Each hyperplane $\check{U}$ has homogeneous spherical coordinates

$$[u] = [u_1, \ldots, u_n, u_{n+1}],$$

with $X \lozenge \check{U}$ if and only if $(x)[u] = 0$.

In terms of the bilinear form

$$(x\,y) = x_1y_1 + \cdots + x_ny_n + x_{n+1}y_{n+1},$$

with $(x\,x) = (y\,y) = 1$, the elliptic distance between two points X and Y is given by

$$[XY] = \cos^{-1} |(x\,y)|. \tag{3.3.2}$$

The angle $(\check{U}\check{V})$ between two hyperplanes $\check{U}$ and $\check{V}$ and the distance $[X\check{U})$ from a point X to a hyperplane $\check{U}$ are respectively equal to the spherical angle $((\check{U}\check{V}))$ and distance $[[X\check{U}))$ defined by (3.1.4) and (3.1.5).

For example (cf. Figure 3.3a), selected points of E^2 with Cartesian coordinates $(\dot{x}_1,\ \dot{x}_2) = (x,\ y)$ correspond to points of eP^2 with coordinates (x_1, x_2, x_3) as follows:

$$(0,\ 0) \mapsto (0,\ 0,\ 1), \quad (1,\ 0) \mapsto (1,\ 0,\ 0), \quad (-1,\ 0) \mapsto (-1,\ 0,\ 0),$$

$$(\tfrac{1}{2}, \tfrac{1}{2}) \mapsto (\tfrac{2}{3}, \tfrac{2}{3}, \tfrac{1}{3}), \quad (-\tfrac{1}{2}, -\tfrac{1}{2}) \mapsto (-\tfrac{2}{3}, -\tfrac{2}{3}, \tfrac{1}{3}),$$

$$(0, \sqrt{2} - 1) \mapsto (0, \tfrac{1}{2}\sqrt{2}, \tfrac{1}{2}\sqrt{2}).$$

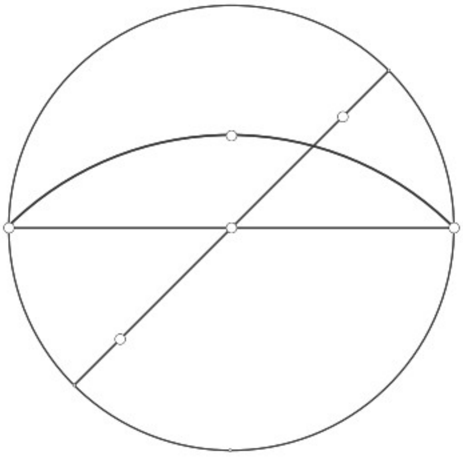

Figure 3.3a Conformal-disk model of eP^2

Coordinates $(1, 0, 0)$ and $(-1, 0, 0)$ represent the same point. Lines through distinct points of eP^2 have coordinates $[u_1, u_2, u_3]$ as follows:

$$(0,\ 0) \vee (1,\ 0) = [0,\ 1,\ 0], \quad (0,\ 0) \vee (\tfrac{1}{2}, \tfrac{1}{2}) = [1,\ -1,\ 0],$$
$$(1,\ 0) \vee (0, \sqrt{2} - 1) = [0,\ 1,\ -1].$$

Using Formula (3.3.2), we see that the elliptic distance between $(0, 0)$ and either $(½, ½)$ or $(-½, -½)$ is $\cos^{-1} ⅓$ and that the distance between $(½, ½)$ and $(-½, -½)$ is $\cos^{-1} 7/9$. The angle between $[0, 1, 0]$ and either $[1, -1, 0]$ or $[0, 1, -1]$ is $\pi/4$, and the angle between $[1, -1, 0]$ and $[0, 1, -1]$ is $\pi/3$.

B. *Hyperbolic geometry.* Hyperbolic n-space H^n can be conformally represented by an open ball in Euclidean n-space, i.e., the interior of a hypersphere Ω. The k-planes of H^n are diametral k-disks or caps of k-spheres orthogonal to Ω. When $n = 2$, this is the "conformal disk" model of the hyperbolic plane. Equivalently, either of the half-spaces into which E^n is separated by a hyperplane $\check{O}$ provides another conformal model. In this case, the k-planes of H^n are represented by Euclidean k-half-planes or k-hemispheres orthogonal to $\check{O}$. When $n = 2$, this is the *Poincaré model*, also called the "upper half-plane" model, of the hyperbolic plane (Poincaré 1882).

Like the projective model developed by Klein, these conformal representations of hyperbolic n-space were first described by Beltrami (1868b; cf. Milnor 1982, pp. 10–11; Stillwell 1996, pp. 35–38). The inversive and projective models are closely related: each arc orthogonal to the boundary circle in E^2 can be transformed into a corresponding chord, converting a disk model of H^2 that preserves angles into one that preserves collinearity.

In the hyperbolic "conformal ball" model (cf. Yaglom 1956, supp. 2; Ratcliffe 1994/2006, § 4.5), points of H^n are represented by Euclidean points $(\dot{x})$ with $(\dot{x}\,\dot{x}) < 1$. Each such point X also has normalized pseudospherical coordinates

$$(x) = (x_1, \ldots, x_n \,|\, x_0),$$

where

$$x_0 = \frac{1 + (\dot{x}\,\dot{x})}{1 - (\dot{x}\,\dot{x})} \quad \text{and} \quad x_i = \frac{2\dot{x}_i}{1 - (\dot{x}\,\dot{x})}\ (1 \le i \le n). \tag{3.3.3}$$

In the "upper half-space" model (cf. Ratcliffe 1994/2006, § 4.6), points of H^n are represented by Euclidean points $(\dot{x})$ with $\dot{x}_n > 0$. Each such point X also has normalized pseudospherical coordinates (x), where

$$x_0 = \frac{1 + (\dot{x}\,\dot{x})}{2\dot{x}_n}, \quad x_i = \frac{2\dot{x}_i}{2\dot{x}_n}\ (1 \le i \le n-1), \quad x_n = \frac{1 - (\dot{x}\,\dot{x})}{2\dot{x}_n}. \tag{3.3.4}$$

In either case, each hyperplane $\check{U}$ has homogeneous pseudospherical coordinates

$$[u] = [u_1, \ldots, u_n \,|\, u_0],$$

with ${u_1}^2 + \cdots + {u_n}^2 - {u_0}^2 > 0$. The point X and the hyperplane $\check{U}$ are incident if and only if $(x)[u] = 0$.

In terms of the bilinear form

$$(x\,\ddot{}\,y) = x_1y_1 + \cdots + x_ny_n - x_0y_0,$$

with $(x\,\ddot{}\,x) = (y\,\ddot{}\,y) = -1$, the hyperbolic distance between two points X and Y is given by

$$]XY[= \cosh^{-1} |(x\,\ddot{}\,y)|. \tag{3.3.5}$$

The angle $(\check{U}\check{V})$ between two intersecting or parallel hyperplanes $\check{U}$ and $\check{V}$, the minimum distance $)\check{U}\check{V}($ between two diverging hyperplanes $\check{U}$ and $\check{V}$, and the distance $]X\check{U}($ from a point X to a hyperplane $\check{U}$ are respectively equal to the pseudospherical angle $((\check{U}\check{V}))$ and distances $))\check{U}\check{V}(($ and $]]X\check{U}(($ defined by (3.2.2), (3.2.3), and (3.2.4).

For example (cf. Figure 3.3b), by (3.3.3) with $n = 2$, in the "conformal disk" model of the hyperbolic plane, points of E^2 with Cartesian coordinates (x, y) correspond to points of H^2 with coordinates $(x_1, x_2 \,|\, x_0)$ as follows:

$$(0,0) \mapsto (0,0\,|\,1), \quad (\tfrac{1}{2},0) \mapsto (\tfrac{4}{3},0\,|\,\tfrac{5}{3}), \quad (-\tfrac{1}{2},0) \mapsto (-\tfrac{4}{3},0\,|\,\tfrac{5}{3}),$$

$$(\tfrac{1}{2},\tfrac{1}{2}) \mapsto (2,2\,|\,3), \quad (-\tfrac{1}{2},-\tfrac{1}{2}) \mapsto (-2,-2\,|\,3),$$

$$(\tfrac{1}{5},\tfrac{2}{5}) \mapsto (\tfrac{1}{2},1\,|\,\tfrac{3}{2}), \quad (\tfrac{2}{5},\tfrac{1}{5}) \mapsto (1,\tfrac{1}{2}\,|\,\tfrac{3}{2}),$$

$$(-\tfrac{1}{5},-\tfrac{2}{5}) \mapsto (-\tfrac{1}{2},-1\,|\,\tfrac{3}{2}), \quad (-\tfrac{2}{5},-\tfrac{1}{5}) \mapsto (-1,-\tfrac{1}{2}\,|\,\tfrac{3}{2}).$$

Hyperbolic lines through certain pairs of points have coordinates $[u_1, u_2 \,|\, u_0]$ as follows:

$$(0,0) \vee (\tfrac{1}{2},0) = [0,1\,|\,0], \quad (0,0) \vee (\tfrac{1}{2},\tfrac{1}{2}) = [1,-1\,|\,0],$$

$$(\tfrac{1}{5},\tfrac{2}{5}) \vee (\tfrac{2}{5},\tfrac{1}{5}) = [1,1\,|\,-1], \quad (-\tfrac{1}{5},-\tfrac{2}{5}) \vee (-\tfrac{2}{5},-\tfrac{1}{5}) = [1,1\,|\,1].$$

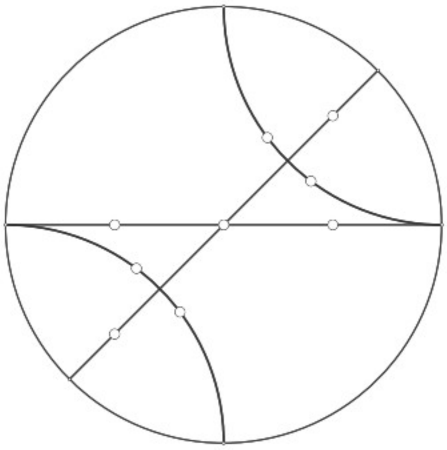

Figure 3.3b Conformal-disk model of H^2

Using Formula (3.3.5), we see that the hyperbolic distance between $(0, 0)$ and either (½, ½) or (−½, −½) is $\cosh^{-1} 3$ and that the distance between (½, ½) and (−½, −½) is $\cosh^{-1} 17$. The angle between $[0, 1 \,|\, 0]$ and $[1, -1 \,|\, 0]$ is $\pi/4$, and the angle between $[1, -1 \,|\, 0]$ and either $[1, 1 \,|\, -1]$ or $[1, 1 \,|\, 1]$ is $\pi/2$. The line $[0, 1 \,|\, 0]$ is parallel (in opposite directions) to both $[1, 1 \,|\, -1]$ and $[1, 1 \,|\, 1]$, and the angle between it and either of these lines is therefore 0. The lines $[1, 1 \,|\, -1]$ and $[1, 1 \,|\, 1]$ themselves are diverging, and the distance between them is $\cosh^{-1} 3$.

Inversion in the circle $x^2 + (y + 1)^2 = 2$ converts the "conformal disk" representation of H^2 into the "upper half-plane" model. Points (x, y) with $x^2 + y^2 < 1$ are interchanged with points (x', y') with $y' > 0$, where

$$x' = \frac{2x}{x^2 + (y + 1)^2}, \quad y' = \frac{2(y + 1)}{x^2 + (y + 1)^2} - 1. \tag{3.3.6}$$

The correspondence between Cartesian and hyperbolic point coordinates is now given by (3.3.4) with $n = 2$.

For example, the inversion given by (3.3.6) interchanges particular points in the unit disk with points in the upper half-plane as follows:

$$(0,0) \leftrightarrow (0,1), \quad (\tfrac{1}{2},0) \leftrightarrow (\tfrac{4}{5},\tfrac{3}{5}), \quad (-\tfrac{1}{2},0) \leftrightarrow (-\tfrac{4}{5},\tfrac{3}{5}),$$

$$(\tfrac{1}{2},\tfrac{1}{2}) \leftrightarrow (\tfrac{2}{5},\tfrac{1}{5}), \quad (-\tfrac{1}{2},-\tfrac{1}{2}) \leftrightarrow (-2,1),$$

$$(\tfrac{1}{5},\tfrac{2}{5}) \leftrightarrow (\tfrac{1}{5},\tfrac{2}{5}), \quad (-\tfrac{1}{5},\tfrac{2}{5}) \leftrightarrow (-\tfrac{1}{5},\tfrac{2}{5}),$$

$$(-\tfrac{1}{5},-\tfrac{2}{5}) \leftrightarrow (-1,2), \quad (-\tfrac{2}{5},-\tfrac{1}{5}) \leftrightarrow (-1,1).$$

The inversive-disk model of the hyperbolic plane is converted into the projective-disk (Beltrami-Klein) model by the mapping $(x,\ y) \mapsto (\xi,\ \eta)$, where

$$\xi = \frac{2x}{x^2 + y^2 + 1}, \quad \eta = \frac{2y}{x^2 + y^2 + 1}. \tag{3.3.7}$$

Each circular arc orthogonal to the unit circle $x^2 + y^2 = 1$ is mapped onto the chord with the same endpoints; each diameter is mapped onto itself. If we write $x = r\cos\theta$ and $y = r\sin\theta$, then the mapping (3.3.7) can be expressed in polar form as $(r,\ \theta) \mapsto (\rho,\ \theta)$, where $\rho = 2r/(r^2+1)$.

C. *Spherical and pseudospherical geometry.* Spherical n-space S^n can be conformally represented by a hypersphere of radius r in Euclidean $(n+1)$-space, and pseudospherical n-space $\ddot{\mathrm{S}}^n$ by a hypersphere of radius $r\mathrm{i}$ in Lorentzian $(n+1)$-space. For $n \geq 2$, the (Gaussian) *curvature* of S^n or $\ddot{\mathrm{S}}^n$, or of the derived elliptic or hyperbolic n-space, is the reciprocal of the square of the radius of this n-sphere. Thus S^n and eP^n have constant positive curvature $1/r^2$, while $\ddot{\mathrm{S}}^n$ and H^n have constant negative curvature $-1/r^2$; Euclidean n-space E^n is *flat*, with curvature 0.

For $n \geq 2$, the only simply connected n-manifolds of constant curvature are S^n, E^n, and H^n. Elliptic n-space eP^n is not simply connected, and pseudospherical n-space $\ddot{\mathrm{S}}^n$ is not connected.

For simplicity, all non-Euclidean distance formulas given in this section or elsewhere in the book assume a spatial curvature of ± 1. In spherical or elliptic n-space of curvature 1, a k-sphere of radius r or coradius $\check{r} = \pi/2 - r$ has the same curvature $\csc^2 r = \sec^2 \check{r}$ as a Euclidean k-sphere of radius $\sin r$. In pseudospherical or hyperbolic n-space of curvature -1, a k-perisphere of radius r has the same curvature $\operatorname{csch}^2 r$ as a Euclidean k-sphere of radius $\sinh r$; a k-horosphere has curvature 0; a k-pseudosphere of coradius $\check{r}$ has curvature $-\operatorname{sech}^2 \check{r}$.

Points on the elliptic sphere S^2, as the unit sphere of Euclidean 3-space, have normalized coordinates (x, y, z) with $x^2+y^2+z^2 = 1$. With the terrestrial (or celestial) sphere as a model, the antipodal points $(0, 0, 1)$ and $(0, 0, -1)$ are the "north pole" and "south pole" of S^2. Any great semicircle joining the poles is a "meridian," the one whose points have $y = 0$ and $x > 0$ being the "prime" meridian.

A point on S^2 can be given polar (or "geographic") coordinates (ϕ, θ), with $0 \leq \phi \leq \pi$ and $-\pi < \theta \leq \pi$ (see Figure 3.3c). The

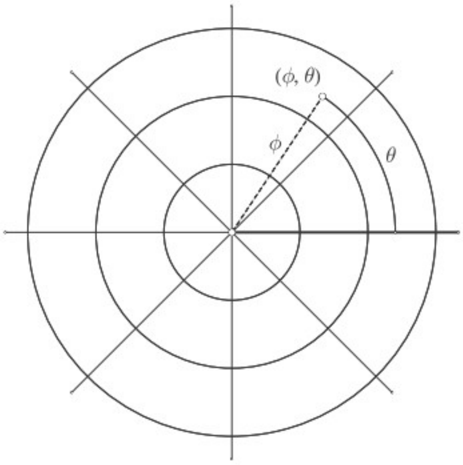

Figure 3.3c Polar coordinates

colatitude ϕ is the distance of the point from the north pole, while the *longitude* θ of a nonpolar point is the directed angle from the prime meridian to the meridian of the point. The longitude of either pole is arbitrary. The *latitude* of any point is the directed distance $\pi/2-\phi$ from the point to the "equator" $[0, 0, 1]$. A point on the elliptic sphere with polar coordinates (ϕ, θ) has normalized spherical coordinates (x, y, z), where

$$x = \sin\phi\cos\theta, \quad y = \sin\phi\sin\theta, \quad z = \cos\phi. \tag{3.3.8}$$

Similarly, ordinary points on the hyperbolic sphere $\ddot{\mathrm{S}}^2$ have normalized coordinates $(x, y \,|\, t)$ with $x^2 + y^2 - t^2 = -1$. The antipodal points $(0, 0 \,|\, 1)$ and $(0, 0 \,|\, {-1})$ are the "north pole" and "south pole" of $\ddot{\mathrm{S}}^2$. As with the elliptic sphere, a "meridian" is a great semicircle joining the poles, with points on the "prime" meridian having $y = 0$ and $x > 0$.

A point in either hemisphere of $\ddot{\mathrm{S}}^2$ can be given polar coordinates (p, θ), with $p \geq 0$ and $-\pi < \theta \leq \pi$. The *polaritude* p is the distance of the point from the pole in the same hemisphere, while the *longitude* θ of a nonpolar point is the directed angle from the prime meridian to the meridian of the point. The longitude of a pole is arbitrary. Antipodal points have the same polaritude and the same longitude. A point on the hyperbolic sphere with polar coordinates $(p,\ \theta)$ has normalized pseudospherical coordinates $(x, y \mid t)$, where

$$t = \pm\cosh p, \quad x = \sinh p\, \cos\theta, \quad y = \sinh p\, \sin\theta, \tag{3.3.9}$$

the sign of t depending on which hemisphere the point lies in. Since either hemisphere of $\ddot{\mathrm{S}}^2$ is an isometric model for H^2, polar coordinates $(p,\ \theta)$ can also be used for points in the hyperbolic plane.

EXERCISES 3.3

1. Show that in the "conformal disk" model of the elliptic plane, a line $[u_1,\ u_2,\ u_3]$ corresponds either to a circle with center $(-u_1/u_3,\ -u_2/u_3)$ and radius $\sqrt{u_1{}^2 + u_2{}^2 + u_3{}^2}/|u_3|$ or (if $u_3 = 0$) to the disk diameter with endpoints $(\pm u_2\sqrt{u_1{}^2 + u_2{}^2}, \mp u_1\sqrt{u_1{}^2 + u_2{}^2})$.

2. Show that in the "conformal disk" model of the hyperbolic plane, a line $[u_1,\ u_2 | u_0]$ corresponds either to a circle with center $(-u_1/u_0,\ -u_2/u_0)$ and radius $\sqrt{u_1{}^2 + u_2{}^2 - u_0{}^2}/|u_0|$ or (if $u_0 = 0$) to the disk diameter with endpoints , $(\pm u_2\sqrt{u_1{}^2 + u_2{}^2}, \mp u_1\sqrt{u_1{}^2 + u_2{}^2})$.

3. Find the point of H^2 corresponding to $(0, \sqrt{2} - 1)$ in the "conformal disk" model.

4. Verify the correspondences given in the text between Euclidean points $(x,\ y)$ and $(x',\ y')$ in the "conformal disk" and "upper half-plane" models of the hyperbolic plane.

5. Show that the mapping $(x,\ y) \mapsto (\xi,\ \eta)$ defined by (3.3.7) maps both the interior and the exterior of the unit circle onto the interior.

6. Find the points of E^2 in the projective-disk model for H^2 that correspond to the points $(0, 0)$, $(1/3, 0)$, $(1/2, 0)$, $(1/2, 1/2)$, and $(1/5, 2/5)$ in the inversive-disk model.

7. $\vdash$ The projective-disk model for H^2 is converted into the inversive-disk model by the mapping $(\xi,\ \eta) \mapsto (x,\ y)$, where

$$x = \frac{(1-\sqrt{1-\xi^2-\eta^2})\xi}{\xi^2+\eta^2}, \quad y = \frac{(1-\sqrt{1-\xi^2-\eta^2})\eta}{\xi^2+\eta^2}$$

if ξ and η are not both zero, with $(0,\ 0) \mapsto (0,\ 0)$.

8. $\vdash$ The distance between two points on S^2 with polar coordinates $(\phi_1,\ \theta_1)$ and $(\phi_2,\ \theta_2)$ is $\cos^{-1}[\cos\phi_1\ \cos\phi_2 + \sin\phi_1\ \sin\phi_2 \cos(\theta_2-\theta_1)]$.

3.4 TRIANGLES AND TRIGONOMETRY

The properties of Euclidean and spherical triangles have been studied since antiquity. Together with their elliptic and hyperbolic counterparts, these elementary geometric figures play a key role in the theory of metric spaces.

A. *Line segments and great arcs.* Any two points A and B in the affine plane A^2 or in the Euclidean or hyperbolic plane E^2 or H^2 lie on a unique line $\cdot AB\cdot$ and, by virtue of the relation of *intermediacy* (or "betweenness") introduced by Moritz Pasch in 1882, separate it into two infinite *rays* $\cdot A/B$ ("A away from B") and $\cdot B/A$ ("B away from A") and a finite *segment* AB (Coxeter 1942, p. 161), so that

$$\cdot AB\cdot = \cdot A/B \cup \{A\} \cup AB \cup \{B\} \cup \cdot B/A.$$

A ray is the same as an *open half-line*; the union $\cdot\overline{A}/B$ of a ray $\cdot A/B$ and its endpoint A is a *closed half-line*. A segment is the same as an *open interval*; the union $\overline{AB}$ of a segment AB and its endpoints A and B is a *closed interval*.

Two nonantipodal points A and B on the elliptic sphere S^2 lie on a unique great circle $\breve{C}$. The points A and B and their antipodes $\bar{A}$ and $\bar{B}$ separate $\breve{C}$ into four *proper* great arcs AB, $B\bar{A}$, $\bar{A}\bar{B}$, $\bar{B}A$—each shorter than a semicircle—with AB congruent to $\bar{A}\bar{B}$, $B\bar{A}$ congruent to $\bar{B}A$, and other pairs of supplementary lengths. The elliptic plane eP^2 is obtained by identifying antipodal points of S^2. Any two points A and B in eP^2 lie on a unique line $\cdot AB\cdot$, separating it into two segments AB and BA of supplementary lengths.

Any two ordinary points A and B in the same hemisphere of the hyperbolic sphere $\ddot{\mathrm{S}}^2$ lie on a unique great circle $\breve{C}$. The points A and B, together with their antipodes $\bar{A}$ and $\bar{B}$, separate $\breve{C}$ into two *proper* great arcs AB and $\bar{A}\bar{B}$, each lying entirely in one hemisphere, and two *improper* great arcs $A\bar{A}$ and $B\bar{B}$ crossing the equator. The hyperbolic plane H^2 is obtained by identifying antipodal points of $\ddot{\mathrm{S}}^2$, with antipodal pairs of proper great arcs projecting into segments and improper great arcs with antipodal ends projecting into rays.

B. *Metric triangles.* Any three noncollinear points A, B, and C in the affine plane A^2 or in the Euclidean or hyperbolic plane E^2 or H^2 define a unique *triangle* $\langle ABC\rangle$. With more structure than a projective triangle, which is just a configuration of three points and three lines, this is a set

$$\langle ABC\rangle = \{\varnothing; A, B, C; BC, CA, AB; ABC\},$$

partially ordered by dimensionality and incidence, consisting of eight geometric "entities": the *nullity* (the empty set $\varnothing$); three *vertices* (the points A, B, and C); three *sides* (the segments BC, CA, and AB); and the triangle's *body* (the interior region ABC).

Any three points A, B, and C on the elliptic sphere S^2 that do not lie on a great circle are the vertices of a unique triangle $\langle ABC\rangle$, each of whose sides BC, CA, and AB is a proper great arc and whose body ABC is contained within a hemisphere. The three points, together with their antipodes $\bar{A}$, $\bar{B}$, and $\bar{C}$, are the vertices of a tessellation of S^2 by eight spherical triangles, consisting of four antipodal pairs of congruent triangles, namely,

$$\langle ABC\rangle = \{\varnothing; A, B, C; BC, CA, AB; ABC\} \text{ and}$$
$$\langle \bar{A}\bar{B}\bar{C}\rangle = \{\varnothing; \bar{A}, \bar{B}, \bar{C}; \bar{B}\bar{C}, \bar{C}\bar{A}, \bar{A}\bar{B}; \bar{A}\bar{B}\bar{C}\},$$

$$\langle \bar{A}CB\rangle = \{\varnothing; \bar{A}, C, B; BC, B\bar{A}, \bar{A}C; \bar{A}CB\} \text{ and}$$

$$\langle A\bar{C}\bar{B}\rangle = \{\varnothing; A, \bar{C}, \bar{B}; \bar{B}\bar{C}, \bar{B}A, A\bar{C}; A\bar{C}\bar{B}\},$$

$$\langle C\bar{B}A\rangle = \{\varnothing; C, \bar{B}, A; \bar{B}A, CA, C\bar{B}; C\bar{B}A\} \text{ and}$$

$$\langle \bar{C}B\bar{A}\rangle = \{\varnothing; \bar{C}, B, \bar{A}; B\bar{A}, \bar{C}\bar{A}, \bar{C}B; \bar{C}B\bar{A}\},$$

$$\langle BA\bar{C}\rangle = \{\varnothing; B, A, \bar{C}; A\bar{C}, \bar{C}B, AB; BA\bar{C}\} \text{ and}$$

$$\langle \bar{B}\bar{A}C\rangle = \{\varnothing; \bar{B}, \bar{A}, C; \bar{A}C, C\bar{B}, \bar{A}\bar{B}; \bar{B}\bar{A}C\}.$$

Two triangles that have two vertices and one side in common, the other pair of vertices being antipodal and the other pairs of sides being supplementary—e.g., $\langle ABC\rangle$ and each of the three triangles $\langle \bar{A}BC\rangle$, $\langle C\bar{B}A\rangle$, $\langle BA\bar{C}\rangle$—are said to be a *colunar* pair. The region bounded by two great semicircles that is the union of the bodies and the common side of such a pair of triangles is called a *lune* (or "biangle").

In all cases, the body of a triangle is a bounded convex region, and in any of the metric spaces S^2, E^2, or H^2, each interior angle of a triangle has a radian measure between 0 and π. Triangles in the elliptic plane eP^2 also have these properties. Any three noncollinear points A, B, and C determine a tessellation of eP^2 by four triangles, any two of which are colunar (except that antipodal vertices are now coincident). All four triangles have the same vertices A, B, and C. If the sides of one triangle are labeled BC, CA, and AB and its body denoted by ABC—with the supplementary segments being CB, AC, and BA and the colunar regions being ACB, CBA, and BAC—then we have the triangles

$$\langle ABC\rangle = \{\varnothing; A, B, C; BC, CA, AB; ABC\},$$

$$\langle ACB\rangle = \{\varnothing; A, C, B; BC, BA, AC; ACB\},$$

$$\langle CBA\rangle = \{\varnothing; C, B, A; BA, CA, CB; CBA\},$$

$$\langle BAC\rangle = \{\varnothing; B, A, C; AC, CB, AB; BAC\}.$$

Three points A, B, and C in the same hemisphere of the hyperbolic sphere $\ddot{\mathrm{S}}^2$ that do not lie on a great circle and the three antipodal points $\bar{A}$, $\bar{B}$, and $\bar{C}$ are the vertices of an antipodal pair of triangles

$$\langle ABC\rangle = \{\varnothing; A, B, C; BC, CA, AB; ABC\} \text{ and}$$
$$\langle \bar{A}\bar{B}\bar{C}\rangle = \{\varnothing; \bar{A}, \bar{B}, \bar{C}; \bar{B}\bar{C}, \bar{C}\bar{A}, \bar{A}\bar{B}; \bar{A}\bar{B}\bar{C}\}.$$

Each side of either triangle is a proper great arc, and each of their bodies is a bounded convex region.

Because S^2, E^2, and H^2 are simply connected, any line or great circle separates the Euclidean or hyperbolic plane or the elliptic sphere into two half-planes or hemispheres. If A, B, and C are the vertices of a triangle, the (open) half-plane or hemisphere bounded by the line or great circle joining A and B that contains C may be denoted by $\cdot AB\cdot \uparrow C$ and the one that does not by $\cdot AB\cdot /C$. The body (interior) of $\langle ABC\rangle$ is then the intersection of $\cdot BC\cdot \uparrow A$, $\cdot CA\cdot \uparrow B$, and $\cdot AB\cdot \uparrow C$, and its exterior is the union of $\cdot BC\cdot /A$, $\cdot CA\cdot /B$, and $\cdot AB\cdot /C$.

The *area* of a triangle is the area of its body. If the interior angles at the vertices A, B, and C of a metric triangle $\langle ABC\rangle$ have the respective measures α, β, and γ, then the sum $\alpha + \beta + \gamma$ lies in the range 0 to 3π, with

$$\begin{aligned} 3\pi > \alpha + \beta + \gamma > \pi \quad & \text{for } \langle ABC\rangle \text{ in } \mathrm{S}^2 \text{ or } \mathrm{eP}^2;\\ \alpha + \beta + \gamma = \pi \quad & \text{for } \langle ABC\rangle \text{ in } \mathrm{E}^2;\\ 0 < \alpha + \beta + \gamma < \pi \quad & \text{for } \langle ABC\rangle \text{ in } \mathrm{H}^2 \text{ or } \ddot{\mathrm{S}}^2. \end{aligned} \tag{3.4.1}$$

The amount by which the angle sum $\alpha+\beta+\gamma$ exceeds or falls short of π for a non-Euclidean triangle $\langle ABC\rangle$ is its *spherical excess* or *hyperbolic defect* and (assuming a spatial curvature of ± 1) is equal to its area.

The area of a triangle is also a function of the lengths of its sides, which depend on the chosen unit of distance. Some writers treat non-Euclidean lengths and areas as if they were independent of each other and consequently arrive at mutually inconsistent formulas.

C. *The Triangle Inequality.* If the sides BC, CA, and AB of a metric triangle $\langle ABC\rangle$ have the respective lengths a, b, and c, then because lines in a plane or great circles on a sphere are geodesics and because ABC is a bounded convex region, it follows that for both Euclidean and non-Euclidean triangles we have the strict inequalities

$$b + c > a, \quad c + a > b, \quad a + b > c. \tag{3.4.2}$$

Moreover, most of the familiar Euclidean theorems about congruent triangles—in particular side-angle-side, angle-side-angle, and side-side-side—hold for non-Euclidean triangles as well. (However, angle-angle-side congruence does not generally hold either in the elliptic plane or on the elliptic sphere.) Since the interior angles of a non-Euclidean triangle determine not just its shape but its size, there is also an angle-angle-angle congruence theorem.

In the Euclidean and hyperbolic planes E^2 and H^2 and on the elliptic and hyperbolic spheres S^2 and $\ddot{\mathrm{S}}^2$, the length of a side AB of a triangle $\langle ABC\rangle$ is the same as the distance between the points A and B. This makes it easy to extend the Triangle Inequality

$$|AB| \leq |BC| + |CA|, \tag{3.4.3}$$

which holds for any three points A, B, and C in Euclidean n-space, to hyperbolic n-space and to the elliptic and hyperbolic n-spheres (in $\ddot{\mathrm{S}}^n$ the points must be restricted to the same n-hemisphere). If A, B, and C do not lie on a line or a great circle, they are the vertices of a unique triangle $\langle ABC\rangle$ and the conclusion follows from (3.4.2). Otherwise, we still have strict inequality except when C lies in the segment or proper great arc AB or, in the case of S^n, when A and B are antipodal, the only situations in which one distance equals the sum of the other two.

Because the total length of an elliptic line is π, the length of a side AB of a triangle in the elliptic plane eP^2 may be greater than the distance $[AB]$ between the points A and B (no distance can exceed $\pi/2$).

Consequently, the validity of the Triangle Inequality for three noncollinear points A, B, and C in eP^n does not immediately follow from the inequalities (3.4.2). Nevertheless, by considering triangles $\langle ABC\rangle$ with sides of various lengths less than, equal to, or greater than $\pi/2$, one can verify that $[AB] < [BC] + [CA]$ in every case. (I leave the details to the reader.) For three collinear points A, B, and C, either the sum of the three distances is π or else one of the distances is the sum of the other two; in either case, we have $[AB] \leq [BC] + [CA]$. Combining the two results, we find that the Triangle Inequality holds for any three points in elliptic n-space.* Thus distance in each of the geometries S^n, E^n, H^n, and eP^n has the essential properties that define a metric space.

D. *Trigonometry.* How the sides and the angles of a triangle are related depends on the curvature of the underlying space. For example, in a Euclidean triangle $\langle ABC\rangle$, the side lengths a, b, c and the corresponding angles α, β, γ satisfy the Law of Sines

$$\frac{\sin\alpha}{a} = \frac{\sin\beta}{b} = \frac{\sin\gamma}{c}. \tag{3.4.4}$$

On the elliptic sphere S^2 or in the elliptic plane eP^2, the formula is

$$\frac{\sin\alpha}{\sin a} = \frac{\sin\beta}{\sin b} = \frac{\sin\gamma}{\sin c}, \tag{3.4.5}$$

while on the hyperbolic sphere $\ddot{\mathrm{S}}^2$ or in the hyperbolic plane H^2 it is

$$\frac{\sin\alpha}{\sinh a} = \frac{\sin\beta}{\sinh b} = \frac{\sin\gamma}{\sinh c}. \tag{3.4.6}$$

---

* Two elliptic triangles whose corresponding sides have equal lengths are congruent. However, two triangles having equal distances between corresponding pairs of vertices need not be. Moreover, if A, B, and C are three points on a line such that none of the three distances $[BC]$, $[CA]$, and $[AB]$ is equal to the sum of the other two, then the three segments into which they separate the line can have the same lengths as the sides of a triangle, and the three distances can be equal to the distances between pairs of vertices of a triangle.

Two sides and the included angle of a Euclidean triangle $\langle ABC\rangle$ are related to the third side by the Law of Cosines

$$c^2 = a^2 + b^2 - 2ab\cos\gamma. \tag{3.4.7}$$

When the angle at C is a right angle, this reduces to the Pythagorean Theorem. On the elliptic sphere S^2 or in the elliptic plane eP^2, we have the dual formulas

$$\begin{aligned} \cos c &= \quad \cos a\,\cos b + \sin a\,\sin b\,\cos\gamma, \\ \cos\gamma &= -\cos\alpha\,\cos\beta + \sin\alpha\,\sin\beta\,\cos c. \end{aligned} \tag{3.4.8}$$

On the hyperbolic sphere $\ddot{\mathrm{S}}^2$ or in the hyperbolic plane H^2, the formulas are

$$\begin{aligned} \cosh c &= \cosh a\,\cosh b - \sinh a\,\sinh b\,\cos\gamma, \\ \cos\gamma &= -\cos\alpha\,\cos\beta + \sin\alpha\,\sin\beta\,\cosh c. \end{aligned} \tag{3.4.9}$$

In the hyperbolic plane we can also consider *asymptotic* triangles, with one or more absolute vertices, at which the interior angle is zero. Setting $\beta = \pi/2$ and $\gamma = 0$ in the last formula, we obtain the expression $\sin^{-1}\operatorname{sech} c$ for the angle of parallelism $\Pi(c) = \alpha$. The area of an asymptotic triangle is still finite and equal to the hyperbolic defect, so that a "tricuspal" triangle, with three absolute vertices, has an area of π.

Two Euclidean triangles whose corresponding angles are equal have the lengths of their sides proportional: the triangles are similar but not necessarily congruent. In the elliptic or hyperbolic plane, however, equality of angles implies equality of side lengths. Consequently, it is sometimes said that scale models are impossible in non-Euclidean geometry, but this is not entirely true. A spherical triangle with shorter sides can have the same angles as a plane triangle in elliptic 3-space, and a pseudospherical triangle with longer sides can have the same angles as a plane triangle in hyperbolic 3-space.

The n-dimensional analogue of a triangle, a polytope with $n + 1$ vertices and $n + 1$ sides (or "facets"), is called a *simplex*. A 3-simplex is a *tetrahedron*. The properties of simplexes and other polytopes will be discussed further in later chapters.

EXERCISES 3.4

1. The intermediacy relation "point X lies between points A and B" may be abbreviated as $/AXB/$. Extending the affine (or Euclidean) line $\cdot AB\cdot$ by the point at infinity P_∞, define $/AXB/$ in terms of separating pairs of points. Express the line segment AB and the rays $\cdot A/B$ and $\cdot B/A$ as segments of the circuit $\cdot AB\cdot \cup \{P_\infty\}$.

2. $\vdash$ The area of a spherical lune of angle θ is 2θ.

3. Show that the inequality $[AB] < [BC] + [CA]$ holds for any three noncollinear points A, B, and C in eP^2. (Consider triangles with sides of lengths less than, equal to, or greater than $\pi/2$.)

4. Show that the inequality $[AB] \leq [BC]+[CA]$ holds for any three collinear points A, B, and C in eP^2.

5. The area Δ of a Euclidean triangle with sides a and b and included angle γ is given by $\Delta = \frac{1}{2}ab \sin \gamma$. Combine this formula with the Law of Cosines (3.4.7) to obtain Heron's Formula $\Delta = \sqrt{s(s-a)(s-b)(s-c)}$, where $s = \frac{1}{2}(a+b+c)$ is the triangle's semiperimeter.

6. Find the area of a hyperbolic triangle having two angles of $\pi/4$ adjacent to a side of length $\cosh^{-1} 2$.

7. Prove the identity $\sin^{-1} \operatorname{sech} x = \cos^{-1} \tanh x$.

3.5 NON-EUCLIDEAN CIRCLES

The methods of integral calculus can be used to determine the arc lengths of portions of smooth curves and the areas of regions with nonrectilinear boundaries. In this section we describe some of the metric properties of circles in different geometries.

In the Euclidean plane, a circle with center (h, k) and radius r has equation $(x-h)^2 + (y-k)^2 = r^2$. Given a circle of radius r, an arc subtending a central angle of radian measure θ has length $s = r\theta$, so that the circle's circumference is $2\pi r$. The corresponding circular sector has area $\frac{1}{2}rs$, making the area of the whole circle equal to πr^2.

In the elliptic plane eP^2, a circle with center $\mathbf{(}h\mathbf{)} = (h_1,\ h_2,\ h_3)$ and radius r or, equivalently, with axis $\mathbf{[}h\mathbf{]} = [h_1,\ h_2,\ h_3]$ and coradius $\check{r} = \pi/2 - r$, has equation

$$|\mathbf{(}x\ h\mathbf{)}| = \cos r \quad \text{or} \quad |\mathbf{(}x\mathbf{)[}h\mathbf{]}| = \sin \check{r}, \tag{3.5.1}$$

where $\mathbf{(}x\ h\mathbf{)} = \mathbf{(}x\mathbf{)[}h\mathbf{]} = x_1h_1+x_2h_2+x_3h_3$ and where $\mathbf{(}x\ x\mathbf{)} = \mathbf{(}h\ h\mathbf{)} = 1$. The length of an arc of a circle of radius r subtending a central angle or axial distance of θ is $s = \theta \sin r = \theta \cos \check{r}$; the circumference is thus seen to be $2\pi \sin r = 2\pi \cos \check{r}$. A circular sector $V(r,\ s)$ of radius r and arc length s has area

$$|V(r,s)| = s \tan \tfrac{1}{2}r \quad (0 < r < \pi/2). \tag{3.5.2}$$

The area of the whole circle is $4\pi \sin^2 \tfrac{1}{2}r$. Complementary to such a sector is a *cosector* $U(\check{r},\ s)$ of coradius $\check{r}$ and arc length s, whose area is

$$|U(\check{r},s)| = s \tan \check{r} = \theta \sin \check{r} \quad (0 < \check{r} < \pi/2). \tag{3.5.3}$$

The sector and cosector together form a triangle with two right angles, a *great sector* of radius $\pi/2$ (see Figure 3.5a). The combined area is equal to the central angle or axial distance θ. Thus when $\theta = 1$, the

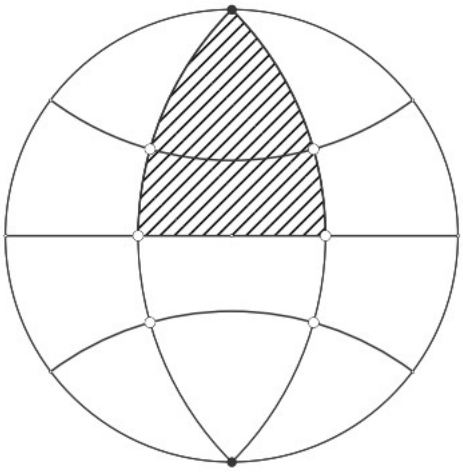

Figure 3.5a Circular sector and cosector in eP^2

area is 1. The above formulas also apply to small circles on the elliptic sphere S^2.

In the hyperbolic plane H^2, a pericycle—i.e., a proper circle—with center $\mathbf{(}h\mathbf{)} = (h_1,\ h_2 \,|\, h_0)$ and radius r has equation

$$|\mathbf{(}x\ddot{\ }h\mathbf{)}| = \cosh r, \tag{3.5.4}$$

where $\mathbf{(}x\ddot{\ }h\mathbf{)} = x_1h_1 + x_2h_2 - x_0h_0$, with coordinates normalized so that $\mathbf{(}x\ddot{\ }x\mathbf{)} = \mathbf{(}h\ddot{\ }h\mathbf{)} = -1$. An arc of such a pericycle subtending a central angle of θ has length $s = \theta\ \sinh r$, and the circumference is therefore $2\pi\ \sinh r$. A pericyclic sector $\ddot{V}(r,s)$ of radius r and arc length s (see Figure 3.5b) has area

$$|\ddot{V}(r,s)| = s\ \tanh \tfrac{1}{2}r \quad (r > 0). \tag{3.5.5}$$

The area of the whole pericycle is $4\pi\ \sinh^2 \tfrac{1}{2}r$.

A pseudocycle (equidistant curve) with axis $\mathbf{[}m\mathbf{]} = [m_1,\ m_2 \,|\, m_0]$ and coradius $\check{r}$ has equation

$$|\mathbf{(}x\mathbf{)[}m\mathbf{]}| = \sinh \check{r}, \tag{3.5.6}$$

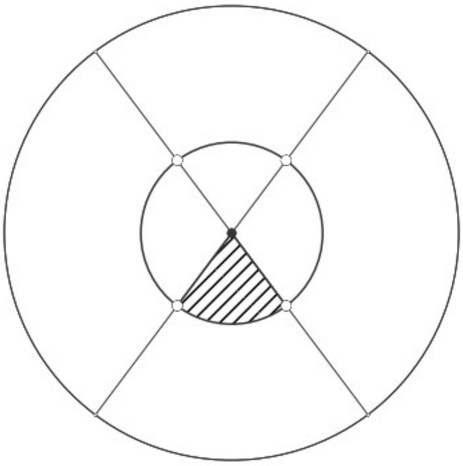

Figure 3.5b Pericyclic sector in H^2

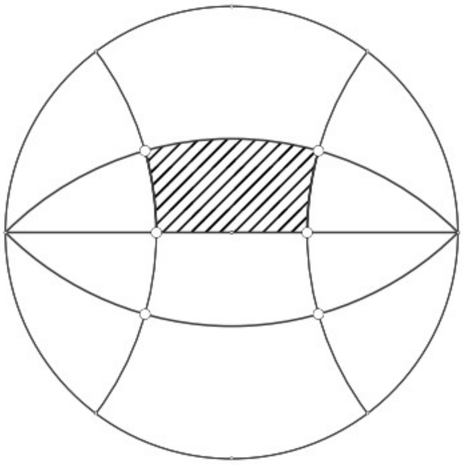

Figure 3.5c Pseudocyclic cosector in H^2

where $\mathbf{(}x\mathbf{)[}m\mathbf{]} = x_0m_0 + x_1m_1 + x_2m_2$, with coordinates normalized so that $\mathbf{(}x\ddot{\ }x\mathbf{)} = -1$ and $\mathbf{[}m\ddot{\ }m\mathbf{]} = 1$. An arc of such a pseudocycle subtending an axial distance of t has length $s = t \cosh \check{r}$. A pseudocyclic cosector $\ddot{U}(\check{r}, s)$ of coradius $\check{r}$ and arc length s (Figure 3.5c) has area

$$|\ddot{U}(\check{r}, s)| = s \tanh \check{r} = t \sinh \check{r} \quad (\check{r} > 0). \tag{3.5.7}$$

When the arc of a pseudocyclic cosector is replaced by the chord with the same endpoints, the resulting figure is the kind of quadrilateral used by Gerolamo Saccheri (1667–1733) in his attempted proof of Euclid's Fifth Postulate.

Whereas a pericycle has an ordinary point for its center and a pseudocycle has an ordinary line for its axis, the center of a horocycle (limiting curve) is an absolute point, and its axis is the absolute line through this point. Thus a horocycle cannot have an equation analogous to (3.5.4) or (3.5.6). However, all horocycles are congruent, so that, following Coxeter (1942, p. 250), we can deduce their metric properties from a conveniently chosen particular case.

The three points

$$P_\infty = (0,\ 1\,|\,1), \quad P_0 = (0,\ 0\,|\,1), \quad \text{and} \quad P_1 = (1, \tfrac{1}{2}\,|\,\tfrac{3}{2})$$

determine a horocycle whose center is the absolute point P_∞ and whose ordinary points are, for each real number x,

$$P_x = \left(x, \tfrac{1}{2}x^2\,\middle|\,\tfrac{1}{2}x^2 + 1\right).$$

The radial line joining P_x to the center and the tangent line at P_x are respectively

$$\check{R}_x = \left[1, x\,\middle|\,-x\right] \quad \text{and} \quad \check{T}_x = \left[x, \tfrac{1}{2}x^2 - 1\,\middle|\,-\tfrac{1}{2}x^2\right].$$

The horocyclic arc with endpoints P_x and P_y has length $s = |y - x|$, and a horocyclic sector $\ddot{W}(s)$ of arc length s (see Figure 3.5d) has area s. Thus the arc from P_0 to P_1 has length 1 and the corresponding sector has area 1. Moreover, the radial line at one end of a horocyclic arc of unit length is parallel to the tangent line at the other end. Thus $\check{R}_0$ is parallel to $\check{T}_1$ and $\check{R}_1$ is parallel to $\check{T}_0$.

The foregoing results for pericycles, pseudocycles, and horocycles also hold for small circles on the hyperbolic sphere $\ddot{\mathrm{S}}^2$.

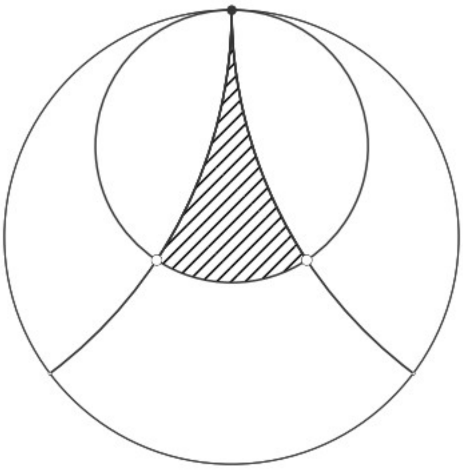

Figure 3.5d Horocyclic sector in H^2

EXERCISES 3.5

1. $\vdash$ The area of the elliptic plane is 2π.
2. Find the length of the chord of a pericycle of radius $\sinh^{-1} 2$ joining the ends of an arc of length π.
3. $\vdash$ The tangent lines at the ends of a horocyclic arc of unit length intersect at an angle of $\pi/3$.
4. Show that the isosceles asymptotic triangle $\langle P_0 P_1 P_\infty \rangle$ has area $\pi - 2 \tan^{-1} 2$.

3.6 SUMMARY OF REAL SPACES

The following diagram (Figure 3.6a) exhibits the relationships among the various real linear and circular geometries. A line joining two geometries indicates that the one below can be derived from the one above by selecting a quadric; by fixing an inversion, a polarity, or a hyperplane; or (for geometries joined by a double arrow) by identifying antipodal points.

y las circunferencias concéntricas de radios a y b se llaman, respectivamente, *círculo principal* y *círculo menor* de la elipse.

Una representación paramétrica sencilla de la hipérbola puede obtenerse como sigue. Tracemos dos circunferencias concéntricas que tengan su centro común en el origen y que sus radios sean $OA = a$ y $OB = b$, en que $a > b$, como se ve en la figura 128. A partir de O tracemos una recta cualquiera l que forme un ángulo θ con la parte positiva del eje X, y sea C el punto de intersección con la circunferencia de radio a. En C tracemos la tangente a la circunferencia; designemos por D el punto en que esta tangente corta al eje X. En B tracemos una perpendicular al eje X y sea E su punto de intersección con l. Por D y E tracemos rectas paralelas a los ejes Y y X, respectivamente; designemos por P el punto de intersección de estas rectas. Ahora vamos a obtener las ecuaciones paramétricas del lugar geométrico de $P(x, y)$, usando θ como parámetro. De los triángulos rectángulos OCD y OBE, tenemos

$$x = \overline{OD} = \overline{OC} \sec \theta = a \sec \theta$$

y

$$y = \overline{DP} = \overline{BE} = \overline{OB} \operatorname{tg} \theta = b \operatorname{tg} \theta .$$

Por tanto, las ecuaciones paramétricas del lugar geométrico de P son

$$x = a \sec \theta , \quad y = b \operatorname{tg} \theta , \tag{6}$$

y la ecuación rectangular puede hallarse fácilmente y es (véase el ejemplo 1 del Artículo 90)

$$\frac{x^2}{a^2} - \frac{y^2}{b^2} = 1 . \tag{7}$$

Por tanto, las ecuaciones (6) son una representación paramétrica de la hipérbola (7). El parámetro θ se llama *ángulo excéntrico* del punto P, y el círculo de radio a se llama *círculo auxiliar* de la hipérbola.

93. La cicloide. Sea P un punto cuya posición sea fija con relación a una curva C. Si la curva C rueda, sin resbalar, sobre una curva fija C', el lugar geométrico descrito por el punto P se llama *ruleta*.

Un caso importante de ruleta es la curva llamada *cicloide*. Una cicloide es el lugar geométrico descrito por cualquier punto fijo de una circunferencia que rueda, sin resbalar, sobre una recta fija. Deduciremos las ecuaciones paramétricas de la cicloide tomando la recta fija como eje X y una de las posiciones del punto móvil sobre el eje X como origen. Sea $P(x, y)$ un punto cualquiera del lugar geométrico, a el radio y C el centro de la circunferencia que rueda, como se indica en la figura 129. Tomaremos como parámetro el ángulo θ que gira la circunferencia al rodar partiendo de su posición inicial en el origen. Sean A y B, respectivamente, los pies de las perpendiculares bajadas de P y C al eje X. Tracemos PD perpendicular a BC. Como la circunferencia rueda, sin resbalar, desde O hasta B, tenemos

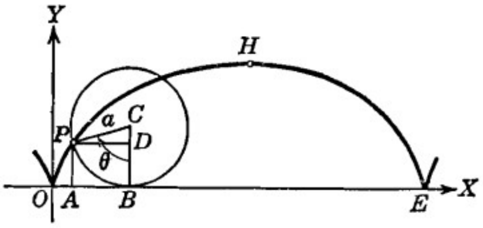

Fig. 129

$$\overline{OB} = \text{arco } \overline{PB}.$$

Si θ se mide en radianes, tenemos (Apéndice IC, 4)

$$\text{arco } \overline{PB} = a\theta .$$

Por tanto, de la figura 129,

$$x = \overline{OA} = \overline{OB} - \overline{AB} = a\theta - \overline{PD} = a\theta - a \operatorname{sen} \theta ,$$
$$y = \overline{AP} = \overline{BD} = \overline{BC} - \overline{DC} = a - a \cos \theta ,$$

de manera que las ecuaciones paramétricas de la cicloide son

$$x = a(\theta - \operatorname{sen} \theta), \quad y = a(1 - \cos \theta). \qquad (1)$$

Por el método empleado en el ejemplo del Artículo 91, podemos demostrar que la ecuación rectangular de la cicloide (1) es

$$x = a \text{ arc cos } \frac{a-y}{a} \mp \sqrt{2ay - y^2}, \qquad (2)$$

en donde debe tomarse el signo positivo o el negativo según que θ sea menor o mayor que π radianes en el arco comprendido entre $\theta = 0$ y $\theta = 2\pi$.

El punto medio H de cualquier arco de la cicloide se llama *vértice* del arco. Aquella porción OE de la recta fija comprendida entre los puntos extremos de un arco se llama ***base*** del arco; su longitud es, evidentemente, igual a $2\pi a$, que es la longitud de la circunferencia generatriz. Cada extremo de un arco, tal como O y E, se llama *pico* o *cúspide*.

A la cicloide también se le da a veces el nombre de *braquistocrona* o curva del más rápido descenso, porque, si se invierte la curva de la figura 129, se puede demostrar que es el recorrido descrito por una partícula que cae desde un punto dado a otro en el intervalo de tiempo *mínimo*. Además, si se sueltan dos partículas simultáneamente desde dos puntos cualesquiera del arco invertido de una cicloide, llegarán ambas al punto más bajo (el vértice) al *mismo* tiempo.

La cicloide es un caso especial de la ruleta conocida con el nombre de *trocoide*, que es el lugar geométrico descrito por un punto de un radio fijo de una circunferencia que rueda, sin resbalar, sobre una recta. Si el punto generador $P(x, y)$ está a una distancia b del centro del círculo rodante de radio a, si una posición del radio fijo es a lo largo del eje Y, y si la recta fija se toma como el eje X, puede demostrarse que las ecuaciones paramétricas de la trocoide son

$$x = a\theta - b \operatorname{sen} \theta, \quad y = a - b \cos \theta. \tag{3}$$

Se dice de la trocoide que es una *cicloide acortada* o *alargada* según que

$$b < a \text{ o } b > a.$$

Para $b = a$, las ecuaciones (3) se reducen a las ecuaciones paramétricas (1) de la cicloide.

94. Epicicloide e hipocicloide. Ahora consideremos dos tipos de ruletas que difieren de la cicloide en que la curva fija es una circunferencia en vez de una recta. Estas curvas, llamadas epicicloide e hipocicloide, son importantes en el diseño de dientes de engranajes.

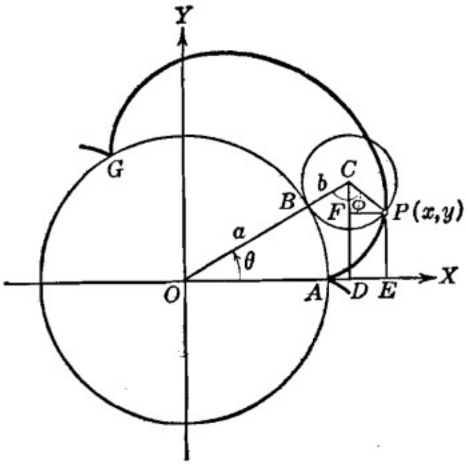

Fig. 130

Una *epicicloide* es el lugar geométrico descrito por un punto fijo cualquiera de una circunferencia que rueda exteriormente, sin resbalar, sobre una circunferencia fija. Deduciremos las ecuaciones paramétricas de la epicicloide en el caso en que la circunferencia fija tenga su centro en el origen y una posición del punto que describe la curva está sobre la parte positiva del eje X y sobre la circunferencia fija. Sea $P(x, y)$ un punto cualquiera del lugar geométrico; sean a y b, respectivamente, los radios de las circunferencias fija y rodante, y sea C el centro de la circunferencia rodante o generatriz, como se ve en la figura 130. Tomaremos como parámetro el ángulo θ que forma la recta de los centros OC con la parte positiva del eje X. Sea A el punto sobre el eje X que representa la posición inicial del punto P que describe la curva, y sea B el punto de tangencia de las dos circunferencias. Desde C y P bajemos las perpendiculares CD y PE, respectivamente, al eje X, y tracemos PF perpendicular a CD. Llamemos ϕ al ángulo OCP y β al ángulo PCF. Consideraremos ambos ángulos ϕ y θ medidos en radianes.

Como la circunferencia generatriz rueda, sin resbalar, de A a B, tenemos

$$\text{arco } AB = \text{arco } PB,$$

o sea,

$$a\theta = b\phi.$$

Por tanto, $\phi = \frac{a}{b}\theta$ y $\theta + \phi = \theta + \frac{a}{b}\theta = \frac{a+b}{b}\theta$. Tenemos, también,

$$\beta = \phi - \text{ángulo } OCD = \phi - \left(\frac{\pi}{2} - \theta\right) = \theta + \phi - \frac{\pi}{2}.$$

Por tanto,

$$\begin{aligned}\operatorname{sen}\beta = \operatorname{sen}\left(\theta + \phi - \frac{\pi}{2}\right) &= -\operatorname{sen}\left(\frac{\pi}{2} - [\theta + \phi]\right)\\ &= -\cos(\theta + \phi) = -\cos\frac{a+b}{b}\theta,\end{aligned}$$

y

$$\begin{aligned}\cos\beta = \cos\left(\theta + \phi - \frac{\pi}{2}\right) &= \cos\left(\frac{\pi}{2} - [\theta + \phi]\right)\\ &= \operatorname{sen}(\theta + \phi) = \operatorname{sen}\frac{a+b}{b}\theta.\end{aligned}$$

Para las coordenadas (x, y) del punto P, tenemos:

$$\begin{aligned} x &= \overline{OE} = \overline{OD} + \overline{DE} = \overline{OD} + \overline{FP} = \overline{OC} \cos\theta + \overline{CP} \operatorname{sen}\beta \\ &= (a+b)\cos\theta - b\cos\frac{a+b}{b}\theta, \\ y &= \overline{EP} = \overline{DF} = \overline{DC} - \overline{FC} = \overline{OC} \operatorname{sen}\theta - \overline{CP}\cos\beta \\ &= (a+b)\operatorname{sen}\theta - b\operatorname{sen}\frac{a+b}{b}\theta, \end{aligned}$$

de manera que las ecuaciones paramétricas de la epicicloide son

$$\left.\begin{aligned} x &= (a+b)\cos\theta - b\cos\frac{a+b}{b}\theta, \\ y &= (a+b)\operatorname{sen}\theta - b\operatorname{sen}\frac{a+b}{b}\theta. \end{aligned}\right\} \qquad (1)$$

Cada punto de la epicicloide que está sobre la circunferencia fija, tales como A y G, es un *pico;* la porción de curva comprendida entre dos picos sucesivos se llama *arco*. El número de picos y arcos depende de las magnitudes relativas de los radios a y b. Sea r la razón de a a b, de manera que $a = rb$. Si r es un número entero, la epicicloide será, evidentemente, una curva cerrada que tiene exactamente r picos y r arcos; se dice entonces que la curva es una *epicicloide de* r *picos*. Si r no es un número entero pero es racional, el punto trazador P dará la vuelta en torno de la circunferencia fija dos o más veces antes de regresar al punto de partida A; en este caso, los arcos de la curva de diferentes circuitos se cortarán. Si r es irracional, el punto trazador no regresa exactamente al punto de partida.

Cuando $a = b$, de manera que $r = 1$, tenemos la epicicloide de un pico o *cardioide* (véase el ejemplo 1 del Artículo 82 y el ejercicio 21 del grupo 41, Artículo 88). De las ecuaciones (1) se deducen las siguientes ecuaciones paramétricas de la cardioide:

$$x = 2a\cos\theta - a\cos 2\theta, \quad y = 2a\operatorname{sen}\theta - a\operatorname{sen} 2\theta. \qquad (2)$$

Una *hipocicloide* es el lugar geométrico de un punto fijo cualquiera de una circunferencia que rueda *interiormente*, sin resbalar, sobre otra circunferencia fija. Por un procedimiento semejante al empleado para la epicicloide, podemos demostrar que las ecuaciones paramétricas de la hipocicloide son

$$\left.\begin{aligned} x &= (a-b)\cos\theta + b\cos\frac{a-b}{b}\theta, \\ y &= (a-b)\operatorname{sen}\theta - b\operatorname{sen}\frac{a-b}{b}\theta, \end{aligned}\right\} \qquad (3)$$

en donde a y b son, respectivamente, los radios de las circunferencias fija y rodante, y el parámetro θ es el ángulo que la recta de los centros OC forma con la parte positiva del eje X, tal como puede verse en la figura 131. El lector debe observar que las ecuaciones paramétricas (3) de la hipocicloide pueden obtenerse reemplazando b por $-b$ en las ecuaciones paramétricas (1) de la epicicloide.

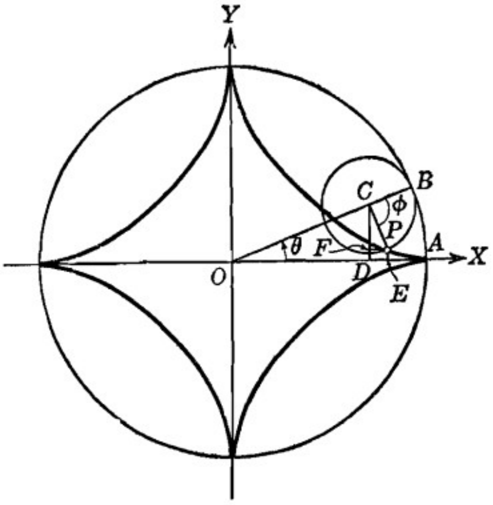

Fig. 131

Sea r la razón de a a b, de modo que $a = rb$. Si r es un número entero, tenemos una *hipocicloide de* r *picos*. La *hipocicloide de cuatro picos* está representada en la figura 131; esta curva se llama también *astroide*. Las ecuaciones paramétricas de la astroide pueden simplificarse de manera que tomen una forma muy simple. Así, para $b = \frac{a}{4}$, las ecuaciones paramétricas (3) se convierten en

$$\left.\begin{aligned} x &= \frac{3a}{4}\cos\theta + \frac{a}{4}\cos 3\theta, \\ y &= \frac{3a}{4}\operatorname{sen}\theta - \frac{a}{4}\operatorname{sen} 3\theta. \end{aligned}\right\}$$

Si en estas ecuaciones sustituímos los valores de $\cos 3\theta$ y $\operatorname{sen} 3\theta$ dados por las identidades trigonométricas

$$\cos 3\theta = 4\cos^3\theta - 3\cos\theta,$$

$$\operatorname{sen} 3\theta = 3\operatorname{sen}\theta - 4\operatorname{sen}^3\theta,$$

/4 & 3 ! @@@ A ! (!# !
3 $$ $ $)$ B ! !3 ! ==) *

obtenemos la forma simplificada de las ecuaciones paramétricas de la astroide,

$$x = a \cos^3 \theta , \quad y = a \operatorname{sen}^3 \theta . \tag{4}$$

Si tomamos la potencia dos tercios de ambos miembros de cada una de las ecuaciones (4) y sumamos, obtenemos como ecuación rectangular de la hipocicloide de cuatro picos

$$x^{2/3} + y^{2/3} = a^{2/3} . \tag{5}$$

EJERCICIOS. Grupo 43

Dibujar una figura para cada ejercicio.

1. De las ecuaciones paramétricas (2) del Artículo 92, demostrar que el tiempo en el cual alcanza el proyectil su altura máxima está dado por

$$t = \frac{v_0 \operatorname{sen} \alpha}{g}.$$

2. Si se conocen los ejes mayor y menor de una elipse, hallar un método para construir cualquier punto P de la elipse conociendo su ángulo excéntrico.

3. Dados el centro y el eje mayor de una elipse, hallar un procedimiento para construir el ángulo excéntrico de cualquier punto dado P de la elipse.

4. Sean P_1 y P_2 puntos extremos de dos diámetros conjugados de una elipse (véase el ejercicio 25 del grupo 29, Art. 63). Demostrar que los ángulos excéntricos de P_1 y P_2 difieren en 90° ó 270°.

5. Obtener las ecuaciones paramétricas (6) del Artículo 92 para una hipérbola, empleando una construcción en que $b > a$.

6. Sea l una recta dirigida hacia arriba, y sean α y β, respectivamente, los ángulos formados por l y las partes positivas de los ejes X y Y (ver el ejercicio 19 del grupo 14, Art. 37). Si l no es paralela a ninguno de los ejes coordenados y contiene al punto fijo $P_1(x_1, y_1)$, puede demostrarse que (ver el ejercicio 21 del grupo 14, Art. 37) la ecuación de l puede escribirse en la forma

$$\frac{x - x_1}{\cos \alpha} = \frac{y - y_1}{\cos \beta}.$$

De aquí, demostrar que una representación paramétrica de la recta l está dada por

$$x = x_1 + t \cos \alpha, \quad y = y_1 + t \cos \beta,$$

en donde el parámetro t representa la distancia variable del punto fijo $P_1(x_1, y_1)$ a cualquier punto $P(x, y)$ sobre l.

7. Discutir la recta cuyas ecuaciones paramétricas son

$$x = 3 + \frac{3}{5} t, \quad y = 4 + \frac{4}{5} t,$$

en donde el parámetro t tiene el significado establecido en el ejercicio 6.

8. Una recta cuya pendiente es $-\frac{5}{12}$ pasa por el punto $(2, -1)$. Hallar sus ecuaciones paramétricas en la forma dada en el ejercicio 6.

9. Demostrar la ecuación rectangular (2) de la cicloide dada en el Artículo 93.

10. Si los ejes coordenados son trasladados de tal manera que el nuevo origen sea el vértice H de la cicloide de la figura 129 del Artículo 93, demuéstrese que las ecuaciones paramétricas de la cicloide con respecto a los nuevos ejes están dadas por

$$x = a(\theta - \pi - \operatorname{sen} \theta), \quad y = -a(1 + \cos \theta).$$

11. Trazar la cicloide del ejercicio 10 cuando $a = 2$.

12. Deducir las ecuaciones paramétricas (3) de la trocoide dadas en el Artículo 93.

13. Obtener la ecuación rectangular de la trocoide a partir de las ecuaciones paramétricas (3) del Artículo 93.

14. Trazar la trocoide del ejercicio 12 cuando $a = 2$ y $b = 3$.

15. Trazar la epicicloide a partir de sus ecuaciones paramétricas (1) del Artículo 94 cuando $a = 3b$.

16. Deducir las ecuaciones paramétricas (2) de la cardioide, dadas en el Artículo 94, directamente a partir de una figura.

17. Deducir las ecuaciones paramétricas (3) de la hipocicloide, directamente de la figura 131.

18. Trazar la hipocicloide a partir de sus ecuaciones paramétricas (3) del Artículo 94 cuando $a = 3b$.

19. Demostrar, analíticamente, que cuando $a = 2b$ la hipocicloide (3) del Artículo 94 representa un diámetro de la circunferencia fija.

20. Si un hilo enrollado alrededor de una circunferencia fija se desenrolla manteniéndolo tirante en el plano de la circunferencia, cualquier punto fijo del hilo traza una curva llamada *evolvente de la circunferencia*. Hallar las ecuaciones paramétricas de la evolvente de la circunferencia $x^2 + y^2 = a^2$ bajo las siguientes condiciones: Si P es un punto cualquiera del lugar geométrico, sea el punto $A(a, 0)$ su posición inicial, y para cualquiera otra posición, sea T el punto de contacto de la tangente PT a la circunferencia. Tómese el ángulo $AOT = \theta$ como parámetro.

95. Resolución de problemas de lugares geométricos por el método paramétrico. Para ciertos lugares geométricos del tipo de curvas llamadas ruletas, hallamos que su representación paramétrica es preferible a su representación rectangular. Para muchas curvas, sin embargo, la ecuación rectangular es más deseable, pero esta ecuación puede determinarse a veces más convenientemente obteniendo primero las ecuaciones paramétricas a partir de las condiciones que el lugar geométrico debe satisfacer. Esto requiere la introducción de un parámetro, o posiblemente de dos o más parámetros, que deben eliminarse posteriormente. A este respecto, los parámetros son incidentales en la determinación de la ecuación rectangular y por esto se llaman a veces *variables auxiliares*. El lector debe notar que si se introducen n parámetros, es necesario tener $n+1$ ecuaciones para efectuar su eliminación y obtener la ecuación rectangular buscada. Si la ecuación rectangular de un lugar geométrico se obtiene mediante la introducción de uno o más parámetros, se suele decir que la resolución se ha efectuado por el *método paramétrico.*

Ejemplo 1. Hallar la ecuación del lugar geométrico del punto de intersección de dos rectas perpendiculares cualesquiera tangentes ambas a la elipse

$$b^2x^2 + a^2y^2 = a^2b^2.$$

Solución. Supongamos que el punto $P(x, y)$ (fig. 132) representa un punto cualquiera del lugar geométrico. Como las rectas son perpendiculares entre sí, podemos representar sus pendientes por m y $-\frac{1}{m}$, siendo la variable m el parámetro. Por el teorema 5 del Artículo 63 las ecuaciones de las tangentes son

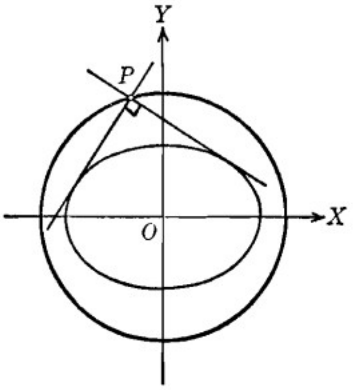

Fig. 132

$$y = mx \pm \sqrt{a^2m^2 + b^2}$$

y

$$y = -\frac{1}{m}x \pm \sqrt{\frac{a^2}{m^2} + b^2}.$$

Para obtener la ecuación rectangular requerida del lugar geométrico de P, debemos eliminar el parámetro m entre estas dos ecuaciones. Para esto, las escribiremos en las formas

$$y - mx = \pm\sqrt{a^2m^2 + b^2},$$

$$my + x = \pm\sqrt{a^2 + b^2m^2}.$$

Elevando al cuadrado ambos miembros de cada una de estas ecuaciones, y sumando, obtenemos

$$y^2 + m^2x^2 + m^2y^2 + x^2 = a^2m^2 + b^2 + a^2 + b^2m^2,$$

de donde

$$(m^2+1)(x^2+y^2) = (m^2+1)(a^2+b^2).$$

Si sustituímos estos valores de x', y' y x'' en la ecuación (4), obtenemos

$$\frac{2y}{\frac{15-4y}{3}} = \frac{6}{\frac{6x+4y-9}{3}}$$

la cual, después de simplificarla, nos da la ecuación buscada

$$6xy + 4y^2 + 3y - 45 = 0,$$

que representa una hipérbola. El estudiante debe trazar la gráfica correspondiente de este lugar geométrico.

Un tipo interesante de curvas, cuya ecuación se obtiene más fácilmente mediante el método paramétrico, son las llamadas *podarias* o *curvas pedales*, definidas de la siguiente manera: si desde un punto fijo Q se trazan perpendiculares a las tangentes a una curva C, el lugar geométrico de los pies de las perpendiculares es otra curva llamada *podaria de la curva* C *con respecto al punto* Q.

Ejemplo 3. Hallar la ecuación de la podaria de una parábola con respecto al vértice.

Solución. El problema no pierde generalidad si tomamos la forma canónica de la ecuación de la parábola, $y^2 = 4px$. Sea $P(x, y)$ (fig. 134) un punto cualquiera del lugar geométrico. Por el teorema 5 del Artículo 57, la ecuación de la tangente de pendiente m a la parábola $y^2 = 4px$ es

$$y = mx + \frac{p}{m}, \quad m \neq 0. \qquad (5)$$

Por ser OP perpendicular a la tangente (5), su ecuación es

$$y = -\frac{1}{m}x. \qquad (6)$$

La ecuación rectangular de la podaria se obtiene eliminando el parámetro m entre las ecuaciones (5) y (6). Para ello, de la ecuación (6) se obtiene $m = -\frac{x}{y}$, valor que sustituído en la ecuación (5) nos da:

$$y = -\frac{x^2}{y} - \frac{py}{x}.$$

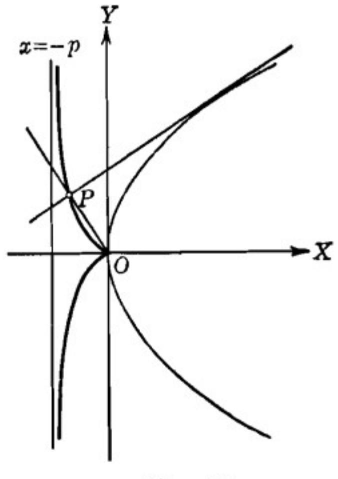

Fig. 134

Despejando y^2 obtenemos la ecuación rectangular buscada

$$y^2 = -\frac{x^3}{x+p},$$

que representa una cisoide con asíntota $x = -p$. (Véase el ejemplo 1 del Artículo 19 y el ejercicio 6 del grupo 41, Art. 88.)

EL PRODUCTO VECTORIAL Y APLICACIONES A LA TRIGONOMETRIA

A. EL CONCEPTO DE ANGULO

Hemos definido el ángulo entre dos vectores de un espacio vectorial euclidiano por su coseno, según la fórmula [13] del capítulo 2. Supuesto el ángulo comprendido entre 0° y 180°, su coseno lo determina sin ambigüedad. Sin embargo, conviene extender el dominio de los valores de los ángulos, por ejemplo, a valores negativos. Para ello es necesario definir una "orientación" en el espacio vectorial .

Consideremos un espacio vectorial de dimensión dos.

En la sección D del capítulo 3 vimos que dado un vector no nulo **U** existen siempre dos únicos versores ortogonales al mismo, los cuales son opuestos (o sea, difieren en el factor -1). Como ahora nos van a interesar únicamente las direcciones, o sea, las clases por la equivalencia "producto por un escalar", podemos suponer que **U** es un versor. Supongamos que se ha dado un criterio para asignar a todo versor **U** un único versor ortogonal, que indicaremos por $\mathbf{U}^\circ$, o sea, un criterio para elegir uno de los dos versores que existen ortogonales a **U**, cualquiera que sea este versor. Diremos que **U** y $\mathbf{U}^\circ$ son asociados.

Puesto que **U** y $\mathbf{U}^\circ$ forman una base, todo otro versor **V** será de la forma

$$\mathbf{V} = u\,\mathbf{U} + v\,\mathbf{U}^\circ, \text{ con } u^2 + v^2 = 1. \qquad [1]$$

Si

$$\mathbf{V}^\circ = u^\circ\,\mathbf{U} + v^\circ\,\mathbf{U}^\circ, \text{ con } u^{\circ 2} + v^{\circ 2} = 1 \qquad [2]$$

es el versor asociado a **V**, será

$$u\,u^\circ + v\,v^\circ = 0. \qquad [3]$$

De [1], [2], [3] se deduce

$$\begin{vmatrix} u & v \\ u^\circ & v^\circ \end{vmatrix}^2 = (uv^\circ - vu^\circ)^2 = (u^2+v^2)(u^{\circ 2}+v^{\circ 2}) - (uu^\circ + vv^\circ)^2 = 1$$

y por tanto

$$\begin{vmatrix} u & v \\ u^\circ & v^\circ \end{vmatrix} = \pm 1. \qquad [4]$$

Esto permite establecer la siguiente definición.

Definición. Dado un espacio vectorial de dimensión dos, se dice que el mismo está orientado si a cada versor **U** del espacio le está asignado un único versor asociado $\mathbf{U}^\circ$, ortogonal a **U**, y además si $(\mathbf{U}, \mathbf{U}^\circ)$ y $(\mathbf{V}, \mathbf{V}^\circ)$ son dos pares de versores asociados ligados por las relaciones [1] y [2], se cumple la igualdad

$$\begin{vmatrix} u & v \\ u^\circ & v^\circ \end{vmatrix} = 1. \qquad [5]$$

Según [13], capítulo 2, el ángulo α de los versores **U** y **V** (igual al ángulo de dos vectores cualesquiera proporcionales a **U** y **V**) está dado por la fórmula

$$\cos\alpha = \mathbf{U}\cdot\mathbf{V}. \qquad [6]$$

Si el espacio vectorial está orientado, definimos la función sen α por

$$\operatorname{sen}\alpha = \mathbf{U}^\circ\cdot\mathbf{V}. \qquad [7]$$

Multiplicando escalarmente ambos miembros de [1] primero por **U** y luego por $\mathbf{U}^\circ$, resulta $u = \cos\alpha$, $v = \operatorname{sen}\alpha$, de donde

$$\mathbf{V} = \cos\alpha\ \mathbf{U} + \operatorname{sen}\alpha\ \mathbf{U}^\circ. \qquad [8]$$

De aquí, elevando al cuadrado y teniendo en cuenta que por hipótesis **V** es un versor, resulta la relación fundamental

$$\cos^2\alpha + \operatorname{sen}^2\alpha = 1. \qquad [9]$$

Obsérvese que si hubieramos definido sen α a partir del cos α por esta relación [9] hubiera quedado indeterminado el signo, lo que no ocurre con la definición [7].

La condición [5] se escribe

$$v^\circ \cos\alpha - u^\circ \operatorname{sen}\alpha = 1$$

que junto con [2] obliga a que sea

$$u^\circ = -\operatorname{sen}\alpha, \quad v^\circ = \cos\alpha$$

y por tanto

$$\mathbf{V}^\circ = -\operatorname{sen}\alpha\ \mathbf{U} + \cos\alpha\ \mathbf{U}^\circ. \qquad [10]$$

Con todo esto podemos ya pasar a definir los ángulos negativos. Para ello se aceptan como *postulados* las *relaciones de Chasles*:

$$\left.\begin{aligned} \operatorname{ang}(\mathbf{U},\mathbf{V}) + \operatorname{ang}(\mathbf{V},\mathbf{U}) &= 0 \\ \operatorname{ang}(\mathbf{U},\mathbf{V}) + \operatorname{ang}(\mathbf{V},\mathbf{W}) + \operatorname{ang}(\mathbf{W},\mathbf{U}) &= 0 \end{aligned}\right\} \qquad [11]$$

donde **U**, **V** y **W** son tres versores cualesquiera del espacio vectorial de dimensión dos que estamos considerando.

De la primera relación [11] se deduce que si α es el ángulo entre **U** y **V**, el ángulo $-\alpha$ será el que forman **V** y **U**. Según [6] y [7] es

$$\cos(-\alpha) = \mathbf{V}\cdot\mathbf{U} = \mathbf{U}\cdot\mathbf{V} = \cos\alpha, \quad \operatorname{sen}(-\alpha) = \mathbf{V}^\circ\cdot\mathbf{U} = -\operatorname{sen}\alpha$$

donde la última igualdad resulta de [10] al multiplicar escalarmente por **U**.

Pongamos $\alpha = \operatorname{ang}(\mathbf{U},\mathbf{V})$ y $\beta = \operatorname{ang}(\mathbf{U},\mathbf{W})$, con lo cual el versor **W** será de la forma [8] aplicada a **W**, o sea

$$\mathbf{W} = \cos\beta\ \mathbf{U} + \operatorname{sen}\beta\ \mathbf{U}^\circ.$$

Según las relaciones [11] será $\operatorname{ang}(\mathbf{V},\mathbf{W}) = \beta - \alpha$ y por tanto aplicando las definiciones [6] y [7] y las fórmulas [8], [12] y [10] resulta

$$\cos(\beta - \alpha) = \mathbf{V}\cdot\mathbf{W} = \cos\alpha\ \cos\beta + \operatorname{sen}\alpha\ \operatorname{sen}\beta$$

$$\operatorname{sen}(\beta - \alpha) = \mathbf{V}^\circ\cdot\mathbf{W} = \operatorname{sen}\beta\ \cos\alpha - \cos\beta\ \operatorname{sen}\alpha$$

Para las fórmulas de adición basta substituir α por $-\alpha$.

B. TRIGONOMETRIA PLANA

Las fórmulas trigonométricas referentes a los triángulos del plano resultan muy fácilmente como relaciones vectoriales.

Sea el triángulo ABC y llamemos a, b y c a las longitudes de sus lados, o sea, a los módulos de los vectores B-C, C-A y A-B, respectivamente. Sean α, β y γ los ángulos correspondientes a los vértices A, B y C.

Elevando al cuadrado ambos miembros de la identidad

$$B - A = (B - C) - (A - C)$$

y puesto que $(B-C)\cdot(A-C) = a\, b \cos\gamma$, resulta

$$c^2 = a^2 + b^2 - 2\, a\, b \cos\gamma$$

que es la llamada fórmula del coseno.

Supongamos ahora que el espacio vectorial asociado al plano euclidiano está orientado. Sea $\mathbf{C}$ el versor asociado correspondiente al vector B - A, o sea, $\mathbf{C}\cdot(B - A) = 0$.

Según [7] y siendo $|C - A| = b$, se tiene

$$b \operatorname{sen}\alpha = \mathbf{C}\cdot(C - A) = \mathbf{C}\cdot(C - B + B - A) = \mathbf{C}\cdot(C - B) = a \operatorname{sen}\beta$$

de donde

$$\frac{a}{\operatorname{sen}\alpha} = \frac{b}{\operatorname{sen}\beta}$$

De igual manera se obtiene que estos cocientes son iguales a $c/\operatorname{sen}\gamma$. Por tanto

$$\frac{a}{\operatorname{sen}\alpha} = \frac{b}{\operatorname{sen}\beta} = \frac{c}{\operatorname{sen}\gamma}$$

que es la llamada fórmula del seno.

C. EL PRODUCTO VECTORIAL

En el espacio euclidiano de tres dimensiones, además del producto escalar de vectores, es útil considerar el llamado producto vectorial.

Sean

$$\mathbf{A} = a_1\,\mathbf{I} + a_2\,\mathbf{J} + a_3\,\mathbf{K}, \quad \mathbf{B} = b_1\,\mathbf{I} + b_2\,\mathbf{J} + b_3\,\mathbf{K}$$

dos vectores del espacio, expresados mediante la base **I, J, K.** Todo vector $\mathbf{C} = c_1\,\mathbf{I} + c_2\,\mathbf{J} + c_3\,\mathbf{K}$ que sea ortogonal a **A** y **B** debe cumplir las condiciones

$$\mathbf{C}\cdot\mathbf{A} = c_1\,a_1 + c_2\,a_2 + c_3\,a_3 = 0,$$

$$\mathbf{C}\cdot\mathbf{B} = c_1\,b_1 + c_2\,b_2 + c_3\,b_3 = 0. \qquad [12]$$

De estas ecuaciones se deduce

$$c_1 = \frac{a_2 b_3 - a_3 b_2}{a_1 b_2 - a_2 b_1}\,c_3, \quad c_2 = \frac{a_3 b_1 - a_1 b_3}{a_1 b_2 - a_2 b_1}\,c_3$$

o sea

$$\frac{c_1}{a_2\,b_3 - a_3\,b_2} = \frac{c_2}{a_3\,b_1 - a_1\,b_3} = \frac{c_3}{a_1\,b_2 - a_2\,b_1}$$

Consideremos, además, la identidad

$$(a_2\,b_3 - a_3\,b_2)^2 + (a_3\,b_1 - a_1\,b_3)^2 + (a_1\,b_2 - a_2\,b_1)^2$$

$$= (a_1^2 + a_2^2 + a_3^2)(b_1^2 + b_2^2 + b_3^2) - (a_1\,b_1 + a_2\,b_2 + a_3\,b_3)^2. \qquad [13]$$

El vector de componentes

$$a_2\,b_3 - a_3\,b_2, \quad a_3\,b_1 - a_1\,b_3, \quad a_1\,b_2 - a_2\,b_1 \qquad [14]$$

según [12] es ortogonal a **A** y **B**, o sea, es ortogonal al plano que ellos determinan (supuestos llevados a partir de un mismo origen) y según [13] tiene por módulo $(a^2b^2 - a^2b^2\cos^2\alpha)^{1/2} = ab\,|\mathrm{sen}\,\alpha|$, siendo a y b los módulos de **A**, **B** y α el ángulo que estos vectores forman entre sí. Esto nos dice que el vector [14] a pesar de haber sido definido mediante las componentes **A** y **B** respecto a cierta base **I, J, K** tiene la dirección y el módulo independientes de esta base, o sea, está vinculado intrínsecamente a los vectores dados **A** y **B**. No ocurre lo mismo con el sentido. Cambiando la base **I, J, K** y tomando las mismas expresiones [14] con las componentes de **A** y **B** en la nueva base, puede ocurrir que el vector obtenido tenga el sentido opuesto al anterior, o sea, que difiera en un factor -1. Por esto se dice que las expresiones [14] son componentes de un pseudo vector, el cual se llama el producto vectorial de **A** y **B** y se representa $\mathbf{A}\wedge\mathbf{B}$. La regla práctica para acordarse de las componentes [14] es considerarlas como resultado del desarrollo del determinante

$$\mathbf{A} \wedge \mathbf{B} = \begin{vmatrix} \mathbf{I} & \mathbf{J} & \mathbf{K} \\ a_1 & a_2 & a_3 \\ b_1 & b_2 & b_3 \end{vmatrix} . \qquad [15]$$

Mientras mantengamos una base **I**, **J**, **K** fija, el producto vectorial actúa como un vector bien definido por [15] y por consiguiente se opera con él lo mismo que con los vectores. Es únicamente al cambiar de base que puede ocurrir que cambie el sentido, o sea el signo del producto vectorial, pero como su dirección y su módulo no cambian resulta un producto muy útil desde el punto de vista de las aplicaciones geométricas.

D. PRODUCTO MIXTO DE TRES VECTORES Y DOBLE PRODUCTO VECTORIAL

Se llama producto mixto de tres vectores **A**, **B** y **C** al escalar

$$(\mathbf{A}\ \mathbf{B}\ \mathbf{C}) = (\mathbf{A} \wedge \mathbf{B})\cdot\mathbf{C} = \begin{vmatrix} a_1 & a_2 & a_3 \\ b_1 & b_2 & b_3 \\ c_1 & c_2 & c_3 \end{vmatrix} .$$

De aquí se deduce, recordando la propiedad de los determinantes de cambiar de signo al permutar dos filas entre sí,

$$(\mathbf{A}\ \mathbf{B}\ \mathbf{C}) = (\mathbf{B}\ \mathbf{C}\ \mathbf{A}) = (\mathbf{C}\ \mathbf{A}\ \mathbf{B}) = -(\mathbf{B}\ \mathbf{A}\ \mathbf{C}) = -(\mathbf{A}\ \mathbf{C}\ \mathbf{B}) = -(\mathbf{C}\ \mathbf{B}\ \mathbf{A}).$$

Pasando a las componentes respecto de una determinada base, se pueden comprobar las siguientes identidades

$$(\mathbf{A} \wedge \mathbf{B}) \wedge \mathbf{C} = (\mathbf{A}\cdot\mathbf{C})\ \mathbf{B} - (\mathbf{B}\cdot\mathbf{C})\ \mathbf{A},$$

$$(\mathbf{A} \wedge \mathbf{B})\cdot(\mathbf{C} \wedge \mathbf{D}) = (\mathbf{A}\cdot\mathbf{C})(\mathbf{B}\cdot\mathbf{D}) - (\mathbf{B}\cdot\mathbf{C})(\mathbf{A}\cdot\mathbf{D}) \text{ (identidad de Lagrange)}$$

$$(\mathbf{A} \wedge \mathbf{B}) \wedge (\mathbf{C} \wedge \mathbf{D}) = (\mathbf{A}\ \mathbf{B}\ \mathbf{D})\ \mathbf{C} - (\mathbf{A}\ \mathbf{B}\ \mathbf{C})\ \mathbf{D}.$$

Mediante artificios adecuados estas identidades pueden demostrarse de manera más simple, como puede verse en cualquier texto clásico de cálculo vectorial.

E. TRIGONOMETRIA ESFERICA

Vamos a ver como las relaciones anteriores permiten obtener las fórmulas clásicas de la trigonometría esférica.

Fórmula del coseno. Consideremos los versores **A**, **B** y **C**. Supuestos llevados a partir de un mismo origen, sus extremos serán los vértices de un triángulo esférico A B C; llamemos a, b y c a los lados de este triángulo y α, β y γ a sus ángulos, de manera que será

$$\mathbf{A}\cdot\mathbf{B} = \cos c, \quad \mathbf{A}\cdot\mathbf{C} = \cos b, \quad \mathbf{C}\cdot\mathbf{B} = \cos a. \qquad [16]$$

En la identidad de Lagrange

$$(\mathbf{A} \wedge \mathbf{C})\cdot(\mathbf{B} \wedge \mathbf{C}) = (\mathbf{A}\cdot\mathbf{B})\,(\mathbf{C}\cdot\mathbf{C}) - (\mathbf{A}\cdot\mathbf{C})(\mathbf{C}\cdot\mathbf{B})$$

el primer miembro es el producto de $|\mathbf{A} \wedge \mathbf{C}| = \operatorname{sen} b$ por $|\mathbf{B} \wedge \mathbf{C}| = \operatorname{sen} a$, por el coseno del ángulo que forman dos vectores ortogonales a los planos **A, C** y **B, C**, es decir, por cos γ. Los factores del segundo miembro están dados por [16]. Sustituyendo, resulta

$$\cos c = \cos a \;\; \cos b + \operatorname{sen} a \;\; \operatorname{sen} b \;\; \cos \gamma$$

que es la fórmula del coseno de la trigonometría esférica.

Fórmula del seno. Apliquemos ahora la fórmula

$$(\mathbf{A} \wedge \mathbf{C}) \wedge (\mathbf{B} \wedge \mathbf{C}) = (\mathbf{A}\ \mathbf{C}\ \mathbf{C})\ \mathbf{B} - (\mathbf{A}\ \mathbf{C}\ \mathbf{B})\ \mathbf{C}$$

que por ser $(\mathbf{A}\ \mathbf{C}\ \mathbf{C}) = 0$ se reduce a

$$(\mathbf{A} \wedge \mathbf{C}) \wedge (\mathbf{B} \wedge \mathbf{C}) = (\mathbf{A}\ \mathbf{B}\ \mathbf{C})\ \mathbf{C}.$$

Igualando los módulos de los dos miembros de esta igualdad resulta

$$\operatorname{sen} a \operatorname{sen} b \operatorname{sen} \gamma = |(\mathbf{A}\ \mathbf{B}\ \mathbf{C})|.$$

Por permutación circular de los versores **A**, **B** y **C** puesto que

$$|(\mathbf{ABC})| = |(\mathbf{BCA})| = |(\mathbf{CAB})|, \text{ resulta}$$

$$\operatorname{sen} a \;\; \operatorname{sen} b \;\; \operatorname{sen} \gamma = \operatorname{sen} b \;\; \operatorname{sen} c \;\; \operatorname{sen} \alpha = \operatorname{sen} c \;\; \operatorname{sen} a \;\; \operatorname{sen} \beta$$

que puede escribirse

$$\frac{\text{sen } a}{\text{sen } \alpha} = \frac{\text{sen } b}{\text{sen } \beta} = \frac{\text{sen } c}{\text{sen } \gamma}$$

que es la fórmula del seno de la trigonometría esférica.

Capítulo VIII

Integrales abelianas

A finales del siglo XVII, Jakob Bernoulli introdujo el término "lemniscata" para referirse a las curvas con forma de 8 (el lemnisco era la cinta que adornaba las coronas con que se distinguía a los atletas en la antigua Grecia). Entre ellas se encuentra la que ahora se conoce como lemniscata de Bernoulli.

Del mismo modo que una elipse puede definirse como el conjunto de los puntos del plano tales que la suma de sus distancias a dos focos es constante, podemos considerar el conjunto de los puntos del plano tales que el producto de sus distancias a dos focos sea constante. Eligiendo adecuadamente el sistema de referencia, no perdemos generalidad si suponemos que los focos tienen coordenadas $(\pm c, 0)$. Si $(x, y) \in \mathbb{R}^2$ es un punto de módulo $\rho = \sqrt{x^2 + y^2}$, su distancia a cada foco es

$$\begin{aligned} r_1^2 &= (x+c)^2 + y^2 = \rho^2 + 2cx + c^2, \\ r_2^2 &= (x-c)^2 + y^2 = \rho^2 - 2cx + c^2, \end{aligned}$$

luego el punto está en en el conjunto si cumple

$$r_1^2 r_2^2 = (\rho^2 + c^2)^2 - 4c^2x^2 = \rho^4 + 2c^2\rho^2 - 4c^2x^2 + c^4 = d^4,$$

para una constante $d > 0$. Si $d < c$, estos puntos forman una curva con dos componentes conexas, cada una de las cuales rodea a uno de los focos. Si $d > c$ obtenemos una curva conexa que rodea a ambos focos. En cambio, si $d = c$ obtenemos una figura en forma de 8, es decir, una lemniscata, que es precisamente la *lemniscata de Bernoulli.* En este caso la ecuación se reduce a

$$\rho^4 + 2c^2\rho^2 - 4c^2x^2 = 0,$$

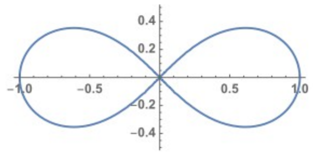
o, equivalentemente,

$$(x^2 + y^2)^2 = 2c^2(y^2 - x^2).$$

El valor de c es irrelevante, en el sentido de que, aplicando una homotecia, podemos hacer que $c = 1/\sqrt{2}$, con lo que $2c^2 = 1$, con lo que la ecuación se reduce a

$$\rho^4 + \rho^2 - 2x^2 = 0, \qquad \text{o} \qquad (x^2 + y^2)^2 = y^2 - x^2.$$

Así pues, salvo un cambio de escala, toda lemniscata de Bernoulli tiene el aspecto que muestra la figura siguiente:



Es fácil ver que una parametrización de la lemniscata es:

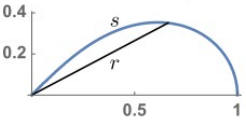
$$x = \pm\frac{1}{\sqrt{2}}\sqrt{\rho^2+\rho^4}, \qquad y = \pm\frac{1}{\sqrt{2}}\sqrt{\rho^2-\rho^4}.$$

Un simple cálculo nos da que el elemento de longitud es

$$ds = \frac{d\rho}{\sqrt{1-\rho^4}}.$$

Así pues, la longitud del arco de lemniscata comprendido entre el origen y un punto situado a distancia $0 < r < 1$ (unidos por el camino más corto) es

$$s(r) = \int_0^r \frac{d\rho}{\sqrt{1-\rho^4}}.$$



En 1718, el conde Fagnano descubrió una curiosa propiedad sobre el arco de una lemniscata. Probablemente, trató de explotar la analogía entre esta integral y la bien conocida

$$\operatorname{arcsen} r = \int_0^r \frac{d\rho}{\sqrt{1-\rho^2}}.$$

Esta integral se racionaliza con el cambio de variable

$$\rho = \frac{2\tau}{1+\tau^2},$$

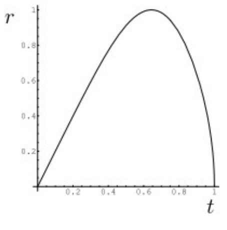
por lo que parece razonable aplicar a nuestra integral el cambio

$$\rho^2 = \frac{2\tau^2}{1+\tau^4}.$$

Un simple cálculo nos da que

$$s(r) = \int_0^r \frac{d\rho}{\sqrt{1-\rho^4}} = \sqrt{2}\int_0^t \frac{d\tau}{\sqrt{1+\tau^4}}, \qquad r^2 = \frac{2t^2}{1+t^4}.$$

En lo que se refiere al cálculo de la integral no hemos ganado nada, pero Fagnano se dio cuenta de



que si ahora aplicamos el mismo cambio pero con un signo negativo en el denominador, obtenemos

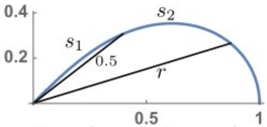
$$s(r) = \int_0^r \frac{d\rho}{\sqrt{1-\rho^4}} = 2\int_0^t \frac{d\tau}{\sqrt{1-\tau^4}} = 2s(t),$$

donde

$$r^2 = \frac{2\frac{2t^2}{1-t^4}}{1+\left(\frac{2t^2}{1-t^4}\right)^2} = \frac{4t^2(1-t^4)}{(1+t^4)^2}.$$

Esto tiene una interpretación geométrica: si señalamos un punto de la lemniscata a una distancia $0 < t < 1$ del origen, entonces el punto situado a la distancia r dada por la fórmula anterior determina un arco de doble longitud. (En realidad es necesario suponer que t no exceda del punto donde $r(t)$ deja de ser inyectiva, lo cual equivale a que al duplicar el arco no sobrepasemos el cuadrante). La sencilla relación entre r y t permite, por ejemplo, duplicar un arco de lemniscata con regla y compás. También podemos expresar t en función de r, lo que nos da un método para bisecar un arco de lemniscata.

Así, en la figura, el arco s_1, correspondiente a $t = 0.5$, tiene la misma longitud que s_2, cuyo extremo derecho corresponde a $r = 4\sqrt{15}/17$, dado por la relación precedente.



En 1751, Euler llegó más lejos que Fagnano. En primer lugar, vio que la analogía con el arco seno podía aprovecharse más aún. La relación

$$\operatorname{sen}(x+y) = \operatorname{sen} x \cos y + \cos x \operatorname{sen} y$$

puede expresarse en la forma

$$u\sqrt{1-v^2} + v\sqrt{1-u^2} = \operatorname{sen}(x+y), \qquad u = \operatorname{sen} x, \quad v = \operatorname{sen} y,$$

o también,

$$\int_0^u \frac{d\rho}{\sqrt{1-\rho^2}} + \int_0^v \frac{d\rho}{\sqrt{1-\rho^2}} = \int_0^r \frac{d\rho}{\sqrt{1-\rho^2}}, \qquad r = u\sqrt{1-v^2} + v\sqrt{1-u^2}.$$

Aquí hay que entender que u y v son números positivos suficientemente pequeños. Euler consiguió probar una fórmula análoga para la lemniscata, a saber:

$$\int_0^u \frac{d\rho}{\sqrt{1-\rho^4}} + \int_0^v \frac{d\rho}{\sqrt{1-\rho^4}} = \int_0^r \frac{d\rho}{\sqrt{1-\rho^4}}, \quad r = \frac{u\sqrt{1-v^4} + v\sqrt{1-u^4}}{1+u^2v^2}.$$

Esta fórmula se particulariza a la de Fagnano cuando $u = v$, y permite sumar fácilmente dos arcos de lemniscata suficientemente pequeños como para que la suma no exceda un cuadrante.

Más aún, Euler generalizó su resultado probando que sigue siendo cierto si cambiamos el polinomio $P(u) = 1 - u^4$ por $P(u) = 1 + au^2 - u^4$, para cualquier valor de a.

Los resultados de Euler fueron notablemente generalizados por Abel, quien estudió el comportamiento de las integrales de la forma

$$\int R(x, y)\, dx,$$

donde $R(X, Y)$ es una función racional e $y(x)$ es una función algebraica determinada por una relación polinómica $P(x, y) = 0$. Estas integrales se conocen como integrales abelianas. En términos más modernos, podemos definir las integrales abelianas como las integrales curvilíneas de formas diferenciales meromorfas sobre superficies de Riemann. Por ejemplo, para interpretar como integral abeliana la integral que da la longitud de arco de la lemniscata consideramos la curva proyectiva S dada por $Y^2 = 1 - X^4$ y, en ella, la forma $\omega = dx/y$. Así,

$$s(r) = \int_\sigma \omega, \qquad \text{donde } \sigma(\rho) = (\rho, \sqrt{1 - \rho^4}).$$

Dedicamos este capítulo a estudiar las integrales abelianas. Ello nos llevará a unos resultados generales de los cuales no sólo se deducen los hechos que acabamos de comentar, sino también resultados de gran interés teórico. Por ejemplo, vamos a determinar la estructura del grupo de clases de grado 0 de una curva proyectiva.

8.1 Homología y cohomología

Vamos a recordar y generalizar al caso complejo algunos resultados sobre topología algebraica y geometría diferencial que vamos a necesitar. Antes de entrar en materia, recordemos el comportamiento de las integrales curvilíneas sobre un abierto $U \subset \mathbb{C}$ simplemente conexo. Si $f : U \longrightarrow \mathbb{C}$ es una función holomorfa, el teorema de Cauchy [VC 1.34] afirma que la integral de f a lo largo de un arco cerrado es nula. Ello se debe esencialmente a que los arcos cerrados son homotópicos a un punto y las integrales no se alteran al transformar homotópicamente los arcos. Como consecuencia, fijado $P \in U$, la integral

$$\int_P^z f(\zeta)\, d\zeta \tag{8.1}$$

no depende del arco sobre el que se calcula y determina una función holomorfa en U, una primitiva de f, de hecho (véase la prueba de [VC 3.8]).

Si f es una función meromorfa, entonces ya no podemos aplicar el teorema de Cauchy, sino que en su lugar tenemos el teorema de los residuos [VC 3.14], que dice que la integral a lo largo de un arco cerrado será una combinación lineal entera de los residuos de f multiplicados por $2\pi i$. Pese a ello podemos hablar aún de la integral (8.1), si bien ahora se trata de una integral multiforme meromorfa, en el sentido de que en un entorno (simplemente conexo) de cada punto z_0 que no sea un polo de f podemos determinar ramas uniformes meromorfas de la integral (la rama dependerá del camino elegido para unir P con z_0). Un caso típico es la integral

$$\int_1^z \frac{d\zeta}{\zeta},$$

que determina la función logaritmo en $\mathbb{C} \setminus \{0\}$.

Si pasamos a considerar integrales de formas diferenciales en una superficie de Riemann, en primer lugar nos encontramos con que, salvo en el caso trivial de la esfera, ya no estamos en un espacio simplemente conexo, por lo que el teorema de Cauchy no es válido ni siquiera para integrales de formas holomorfas. Por ejemplo, si integramos una forma holomorfa en un toro a lo largo de un arco que una dos puntos, el resultado dependerá del número de vueltas que demos al toro. De hecho hay dos clases de vueltas distintas: las que damos transversalmente, alrededor del "tubo" y las que damos longitudinalmente, a lo largo del "tubo". Los valores que toma la integral sobre dos arcos cerrados que den una única vuelta transversal y longitudinal respectivamente se llaman periodos de la integral, y de nuevo sucede que la integral entre dos puntos está bien definida módulo estos dos periodos.

Si el integrando es una forma meromorfa, además de los periodos en el sentido anterior tenemos también periodos polares, como en el caso plano (salvo que la forma tenga residuos nulos, es decir, salvo que sea de segunda clase).

Homología y cohomología compleja Vamos a precisar las ideas precedentes, para lo cual consideramos en principio una variedad diferencial S de dimensión $2n$, en las mismas condiciones que en la sección A.5 de [VC]. De acuerdo con lo expuesto allí, para cada $P \in S$, podemos considerar el espacio tangente real $T_P(S)$, que es un $\mathbb{R}$-espacio vectorial de dimensión $2n$, y también el espacio $T_P(S, \mathbb{C}) \cong \mathbb{C} \otimes_{\mathbb{R}} T_P(S)$, que es un $\mathbb{C}$-espacio vectorial de dimensión $2n$.

Consideramos ahora [GD 3.24] los espacios $\Lambda^p(S) = \Lambda^p(S, \mathbb{R})$ de las p-formas diferenciales en S. Definimos

$$\Lambda^p(S, \mathbb{C}) = \mathbb{C} \otimes_{\mathbb{R}} \Lambda^p(S, \mathbb{R}) = \{\omega_1 + i\omega_2 \mid \omega_1, \omega_2 \in \Lambda^p(S, \mathbb{R})\}.$$

En particular, $\Lambda^0(S, \mathbb{C})$ es el espacio de todas las funciones diferenciables $f : S \longrightarrow \mathbb{C}$. Similarmente, cada $\omega \in \Lambda^1(S, \mathbb{C})$ puede verse como una función que a cada $P \in S$ le asigna una 1-forma $\omega_P \in \mathbb{C} \otimes_{\mathbb{R}} T_P(S)^* \cong T_P(S, \mathbb{C})^*$.

Nota Nos va a bastar con este hecho, pero, en general, es claro que, si V es un $\mathbb{R}$-espacio vectorial de dimensión finita, todo tensor covariante $\alpha \in \mathcal{T}_s^0(\mathbb{C} \otimes_R V)$ [GD A.1], es decir, toda aplicación $\mathbb{C}$-multilineal

$$\alpha : (\mathbb{C} \otimes_{\mathbb{R}} V) \times \cdots \times (\mathbb{C} \otimes_{\mathbb{R}} V) \longrightarrow \mathbb{C}$$

está determinada por su acción sobre los elementos de B^s, donde B es una base de V, por lo que cada $\alpha \in \mathcal{T}_s^0(V)$ tiene una extensión única $\bar{\alpha} \in \mathcal{T}_s^0(\mathbb{C} \otimes_{\mathbb{R}} V)$, lo que nos da un isomorfismo natural $\mathbb{C} \otimes_{\mathbb{R}} \mathcal{T}_s^0(V) \cong \mathcal{T}_s^0(\mathbb{C} \otimes_{\mathbb{R}} V)$ dado por $z \otimes \alpha \mapsto z\bar{\alpha}$.

Este isomorfismo se restringe a un isomorfismo $\mathbb{C}\otimes_{\mathbb{R}}\Lambda^s(V)\cong\Lambda^s(\mathbb{C}\otimes_{\mathbb{R}}V)$. Si aplicamos esto al caso en que $V=T_P(S)$, vemos que cada $\omega\in\Lambda^p(S,\mathbb{C})$ puede identificarse con una aplicación que a cada $P\in S$ le asigna una forma constante $\omega_P\in\Lambda^p(T_P(S,\mathbb{C}))$. ■

Podemos definir de forma natural el producto de una función $f\in\Lambda^0(S,\mathbb{C})$ por una forma $\omega\in\Lambda^p(S,\mathbb{C})$.

Definimos $d:\Lambda^p(S,\mathbb{C})\longrightarrow\Lambda^{p+1}(S,\mathbb{C})$ mediante $d(\omega_1+i\omega_2)=d\omega_1+id\omega_2$.

Notemos que si $f\in\Lambda^0(S,\mathbb{C})$, la diferencial que acabamos de definir es la misma que ya teníamos definida en la sección A.5 de [VC]. Allí se muestra que si S es el dominio de una carta de coordenadas $z_1,\ldots,z_n$, entonces, para cada punto $P\in S$, las diferenciales $dz_i|_P$, $d\bar{z}_i|_P$ forman una base de $T_P(S,\mathbb{C})^*$, concretamente, la base dual de los vectores tangentes $\partial_{z_i}|_P$, $\partial_{\bar{z}_i}|_P$. En particular, si $f\in\Lambda^0(S,\mathbb{C})$, se cumple que

$$df=\sum_{i=1}^n\frac{\partial f}{\partial z_i}\,dz_i+\sum_{i=1}^n\frac{\partial f}{\partial\bar{z}_i}\,d\bar{z}_i.$$

El operador d cumple trivialmente $d\circ d=0$, luego define grupos de cohomología $H^p(S,\mathbb{C})$ análogamente al caso real [GD 6.11], es decir, como el cociente del espacio de las p-formas cerradas (con diferencial nula) sobre el subespacio de las p-formas exactas. Es claro que la asignación $[\omega_1]+i[\omega_2]\mapsto[\omega_1+i\omega_2]$ determina un isomorfismo natural

$$\mathbb{C}\otimes_{\mathbb{R}}H^p(S,\mathbb{R})\cong H^p(S,\mathbb{C}).$$

Por otra parte, si fijamos un anillo conmutativo y unitario $\mathbb{A}$ (que en la práctica será siempre $\mathbb{Z}$, $\mathbb{R}$ o $\mathbb{C}$), podemos considerar [TA 9.6] los $\mathbb{A}$-módulos $C_p(S,\mathbb{A})$ de cadenas de símplices singulares diferenciables (para la diferenciabilidad véase el final de la sección 9.2 de [TA]), con los que podemos definir los grupos de homología singular $H_p(S,\mathbb{A})$. Según [TA 12.21], existe un isomorfismo natural

$$H_p(S,\mathbb{C})\cong\mathbb{C}\otimes_{\mathbb{R}}H_p(S,\mathbb{R}).$$

Definimos la integral de una forma $\omega=\omega_1+i\omega_2\in\Lambda^p(S,\mathbb{C})$ sobre un símplice $\sigma\in C_p(S,\mathbb{C})$ mediante

$$\int_\sigma\omega=\int_\sigma\omega_1+i\int_\sigma\omega_2.$$

(La integral de una forma diferencial real sobre un símplice está definida antes de [TA 13.12].) Por linealidad, la integral se extiende a una forma bilineal

$$\int:C_p(S,\mathbb{C})\times\Lambda^p(S,\mathbb{C})\longrightarrow\mathbb{C}.$$

La versión compleja del teorema de Stokes [TA 13.13] se sigue inmediatamente de la versión real, es decir, si $c\in C_{p+1}(S,\mathbb{C})$ y $\omega\in\Lambda^p(S,\mathbb{C})$, entonces

$$\int_c d\omega=\int_{\partial c}\omega.$$

Esto nos permite definir una forma bilineal

$$\int^* : H_p(S, \mathbb{C}) \times H^p(S, \mathbb{C}) \longrightarrow \mathbb{C}.$$

Si $\phi : S \longrightarrow T$ es una aplicación diferenciable, tenemos definidas las retracciones $\phi^* : \Lambda^p(T, \mathbb{R}) \longrightarrow \Lambda^p(S, \mathbb{R})$ (véase el final de la sección 6.2 de GD]), que nos permiten definir aplicaciones lineales $\phi^* : \Lambda^p(T, \mathbb{C}) \longrightarrow \Lambda^p(S, \mathbb{C})$ mediante

$$\phi^*(\omega_1 + i\omega_2) = \phi^*(\omega_1) + i\phi^*(\omega_2).$$

El teorema [GD 3.48] se traduce inmediatamente a su análogo complejo, es decir, a que $\phi^* \circ d = d \circ \phi^*$, por lo que ϕ^* induce una aplicación lineal $\phi^* : H^p(T, \mathbb{C}) \longrightarrow H^p(S, \mathbb{C})$.

Por otra parte, ϕ induce aplicaciones lineales $\phi^\sharp : C_1(S, \mathbb{C}) \longrightarrow C_1(T, \mathbb{C})$ (véase [TA 9.6]), que a su vez inducen aplicaciones $\phi_* : H_1(S, \mathbb{C}) \longrightarrow H_1(T, \mathbb{C})$ (véase la sección 9.3 de [TA]).

El teorema [TA 13.12] se generaliza trivialmente al caso complejo, de modo que, para todo $c \in C_p(S, \mathbb{C})$ y toda $\omega \in \Lambda^p(S, \mathbb{C})$, se cumple

$$\int_{\phi^\sharp(c)} \omega = \int_c \phi^*(\omega)$$

y, a su vez,

$$\int^*_{\phi_*([c])} [\omega] = \int^*_{[c]} \phi^*([\omega]).$$

También es fácil probar las relaciones

$$\phi^*(f\omega) = (\phi \circ f)\phi^*(\omega), \qquad \phi^*(\omega)_P(v) = \omega_{\phi(P)}(d_P\phi(v)), \quad \omega \in \Lambda^1(S, \mathbb{C}).$$

Formas holomorfas A partir de este momento suponemos que S es una variedad analítica compacta de dimensión 1 (con lo que en particular sigue siendo una variedad diferencial de dimensión 2, como hasta ahora con $n = 1$). En tal caso, según [VC A.38], podemos descomponer $T_P(S, \mathbb{C})$ como suma directa de un espacio tangente holomorfo y otro antiholomorfo, ambos de dimensión compleja 1:

$$T_P(S, \mathbb{C}) = T_P^h(S) \oplus T_P^a(S).$$

Además, según [VC A.39], podemos identificar $T_p(S)$ con $T_P^h(S)$ de forma natural.

Si $\omega \in \Lambda^1(S, \mathbb{C})$ y $U \subset S$ es el dominio de una carta z, tenemos que $\omega|_U = f\,dz + g\,d\bar{z}$, para ciertas funciones f, $g \in \Lambda^0(U)$ unívocamente determinadas.

Llamaremos *formas diferenciales holomorfas* en S a las que cumplan que $g = 0$ y $f \in \mathcal{H}(U)$ para todo abierto coordenado U, es decir, a las que cumplen $\omega|_U = f\,dz$, para cierta función f holomorfa en U. Es fácil ver que, para que esto suceda, basta con que se cumpla para un atlas analítico de S. Llamaremos $\Lambda^1(S)$ al espacio de todas las formas diferenciales holomorfas en S.

Así, si $\omega \in \Lambda^1(S)$, para cada $P \in S$ se cumple que ω_P se anula sobre los vectores tangentes antiholomorfos (pues una base de $T_P^a(S)$ es $\partial_{\bar{z}}$, donde z es una carta alrededor de P).

Se comprueba fácilmente que si $\phi : S \longrightarrow T$ es una aplicación holomorfa entre variedades analíticas, entonces ϕ^* se restringe a una aplicación lineal

$$\phi^* : \Lambda^1(T) \longrightarrow \Lambda^1(S),$$

con lo que Λ^1 es un funtor contravariante.

Observemos ahora que si $\sigma : [0,1] \longrightarrow U \subset \mathbb{C}$ es un 1-símplice en un abierto de $\mathbb{C}$, entonces la integral $\int_\sigma f\,dz$ coincide con la integral curvilínea usual en variable compleja.

En efecto, teniendo en cuenta que $\sigma = \sigma^\sharp(I)$, donde I es la identidad en $[0,1]$ y el análogo complejo a [TA 13.12], tenemos que

$$\int_\sigma f\,dz = \int_I \sigma^*(f\,dz) = \int_I (\sigma \circ f)\,d(\sigma \circ z) = \int_I (\sigma \circ f)\,d\sigma,$$

donde hemos usado que z no es sino la identidad en U. Si t es la identidad en $[0,1]$ (vista ahora como carta de $[0,1]$), entonces $d\sigma = d\sigma(\partial_t)\,dt = \sigma'(t)\,dt$, luego, por la definición de integral sobre un 1-símplice:

$$\int_\sigma f\,dz = \int_0^1 f(\sigma(t))\,\sigma'(t)\,dt.$$

Todas las formas holomorfas son cerradas. En efecto, si $\omega \in \Lambda^1(S)$ y $P \in S$, tomamos una carta z en un entorno U de P, de modo que

$$\omega|_U = f\,dz = \operatorname{Re} f\,dx - \operatorname{Im} f\,dy + i(\operatorname{Im} f\,dx + \operatorname{Re} f\,dy),$$

para una cierta función homomorfa f. Teniendo en cuenta que la diferencial es un operador local, vemos que

$$d\omega|_U = \left(-\frac{\partial \operatorname{Re} f}{\partial y} - \frac{\partial \operatorname{Im} f}{\partial x}\right) dx \wedge dy + i\left(-\frac{\partial \operatorname{Im} f}{\partial y} + \frac{\partial \operatorname{Re} f}{\partial x}\right) dx \wedge dy.$$

Como f satisface las ecuaciones de Cauchy-Riemann, concluimos que $d\omega = 0$.

Por otra parte, si una forma holomorfa ω cumple $\omega = dg$, para cierta función $g \in \Lambda^0(S, \mathbb{C})$, de hecho ha de ser $g \in \mathcal{H}(S)$.

En efecto, en un entorno coordenado U de un punto arbitrario tenemos que

$$\omega|_U = dg|_U = \frac{\partial \operatorname{Re} g}{\partial x}\,dx + \frac{\partial \operatorname{Re} g}{\partial y}\,dy + i\frac{\partial \operatorname{Im} g}{\partial x}\,dx + i\frac{\partial \operatorname{Im} g}{\partial y}\,dy$$

y también

$$\omega|_U = f\,dz = \operatorname{Re} f\,dx - \operatorname{Im} f\,dy + i(\operatorname{Im} f\,dx + \operatorname{Re} f\,dy),$$

para una cierta función holomorfa f. Comparando ambas expresiones concluimos que g cumple las ecuaciones de Cauchy-Riemann, luego es una función holomorfa.

Esto implica que si definimos $\mathcal{H}^1(S)$ como el cociente del espacio $\Lambda^1(S)$ de las formas holomorfas en S sobre el subespacio de las diferenciales de funciones holomorfas, la aplicación $[\omega] \mapsto [\omega]$ es un monomorfismo de $\mathcal{H}^1(S)$ en $H^1(S, \mathbb{C})$. En general no es un isomorfismo.

También es claro que si $\phi : S \longrightarrow T$ es una aplicación holomorfa entre variedades analíticas, entonces $\phi^* : \Lambda^1(T) \longrightarrow \Lambda^1(S)$ induce una aplicación lineal $\phi^* : \mathcal{H}^1(T) \longrightarrow \mathcal{H}^1(S)$, con lo que $\mathcal{H}^1$ es también un funtor contravariante.

Notemos que estos hechos generalizan el teorema de Cauchy sobre integrales curvilíneas. En efecto, si c es una 2-cadena en una superficie analítica S y ω es una forma diferencial holomorfa en S, entonces

$$\int_{\partial c} \omega = \int_c d\omega = \int_c 0 = 0.$$

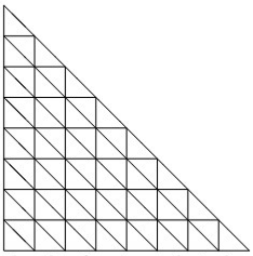
El teorema de Cauchy clásico se sigue de aquí porque si S es simplemente conexa entonces $H_1(S) = 0$, es decir, todo ciclo es una frontera.

Supongamos ahora que S puede cubrirse por una carta z y que $\omega = f\,dz$ es una forma diferencial meromorfa en S (que, por consiguiente, es una forma holomorfa en S menos un número finito de puntos). Sea $\tilde{f} = z^{-1} \circ f$ la lectura de f en la carta. Es claro entonces que $\omega = z^*(\tilde{f}\,dz)$, donde en el segundo miembro z es la identidad en $\mathbb{C}$. Para cada $x \in S$, el desarrollo de f en potencias de $z - z(x)$ es el mismo que el de $\tilde{f}$, luego, en particular, $\operatorname{Res}_x \omega = \operatorname{Res}_{z(x)} \tilde{f}$. Esto nos permite traducir el teorema de los residuos a integrales en variedades:

Supongamos que $\sigma : \Delta_2 \longrightarrow S$ es un 2-símplice positivamente orientado que se extienda a un difeomorfismo y cuya frontera no contenga polos de ω. Entonces

$$\int_{\partial\sigma} \omega = \int_{\partial\sigma} z^\sharp(\tilde{f}\,dz) = \int_{z_\sharp(\partial\sigma)} \tilde{f}\,dz = \int_{\partial(\sigma\circ z)} \tilde{f}\,dz = 2\pi i \sum_x \operatorname{Res}_x \omega,$$

donde x recorre los polos de ω contenidos en la imagen de σ (que se corresponden con los polos de $\tilde{f}$ contenidos en la imagen de $\sigma \circ z$).



Un poco más laxamente: si $\sigma : \Delta_2 \longrightarrow S$ es un 2-símplice arbitrario y ω es una forma meromorfa que no tenga polos en la imagen de c, por el lema del cubrimiento de Lebesgue [TA 1.1], podemos subdividir Δ_2 en triángulos suficientemente pequeños como para que sus imágenes por σ estén contenidas en dominios de cartas de S. Además podemos retocar levemente la subdivisión para que ningún polo de ω se encuentre sobre los lados de los triángulos obtenidos. Entonces la integral de ω sobre $\partial\sigma$ es igual a la suma de las integrales de ω sobre las fronteras de todos los triángulos pequeños, pues las integrales sobre los lados interiores se cancelan dos a dos y las de los lados exteriores se suman hasta formar $\partial\sigma$.

Al igual que hemos visto antes (aunque sin suponer que los triángulos sean biyectivos) la integral de ω sobre cada uno de estos triángulos equivale a la integral de otra función $\tilde{f}$ sobre un ciclo en un abierto de $\mathbb{C}$, cuyos residuos se corresponden con (algunos de) los de ω. El teorema de los residuos nos da que la integral

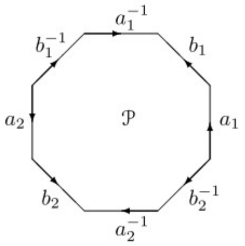
$$\int_{\partial\sigma} \omega$$

es combinación lineal entera de los *periodos polares* $2\pi i \operatorname{Res}_P \omega$ de ω. Por linealidad lo mismo vale para integrales sobre fronteras arbitrarias.

Superficies de Riemann Supongamos ahora que S es una superficie de Riemann compacta (en tendiendo que las superficies de Riemann son conexas por defiinición). En virtud del teorema de clasificación de las superficies compactas, toda superficie de Riemann, como espacio topológico, puede obtenerse como cociente de un polígono regular $\mathcal{P}$ de $4g$ lados identificándolos dos a dos en la forma

$$a_1b_1a_1^{-1}b_1^{-1}a_2b_2a_2^{-1}b_2^{-1}\cdots a_gb_ga_g^{-1}b_g^{-1}.$$

(Véase la discusión previa a [VC A.25].) Sea $\phi : \mathcal{P} \longrightarrow S$ la aplicación continua y suprayectiva (inyectiva en el interior de $\mathcal{P}$) que identifica los lados de $\mathcal{P}$ en la forma indicada. Por ejemplo, la figura muestra el polígono cuyo cociente es la superficie de género 2:



Cada arco a_k (recorrido en el sentido de la flecha) se corresponde en S con el mismo arco que a_k^{-1}, e igualmente con los b_k. En general, todos los vértices de $\mathcal{P}$ se identifican con un mismo punto de S, y así, en S tenemos $2g$ arcos cerrados $a_1, b_1, \ldots, a_g, b_g$.

En la prueba del teorema de clasificación se ve que el polígono $\mathcal{P}$ se construye a partir de una triangulación de S. Pero en la prueba de la fórmula de Hurwitz [VC A.25] (véase la nota posterior) se ve que si partimos de una triangulación diferenciable de una esfera podemos construir una triangulación diferenciable de cualquier superficie de Riemann, es decir, una triangulación formada por triángulos $\sigma : \Delta_2 \longrightarrow S$ que se extienden a difeomorfismos de un entorno simplemente conexo de Δ_2 en un entorno de la imagen.

Añadiendo este hecho a la prueba del teorema de clasificación se ve que la aplicación $\phi : \mathcal{P} \longrightarrow S$ se puede tomar diferenciable a trozos, es decir, que se puede triangular $\mathcal{P}$ de modo que ϕ coincida con un difeomorfismo en cada triángulo.

Si además elegimos los triángulos de $\mathcal{P}$ de forma que conserven la orientación, tenemos que los lados interiores (compartidos por dos triángulos contiguos) se recorren necesariamente en sentidos opuestos, por lo que constituyen 1-cadenas homólogas en $\mathcal{P}$. Esto nos permite ver a la triangulación de $\mathcal{P}$ como una cadena $\zeta_{\mathcal{P}} \in C_2(\mathcal{P}, \mathbb{Z})$ cuya frontera es homóloga al ciclo

$$a_1 + b_1 - a_1^{-1} - b_1^{-1} + a_2 + \cdots$$

El hecho de que ϕ sea diferenciable a trozos hace que $\zeta_S = \phi^\sharp(\zeta_{\mathcal{P}})$ (que no es sino la triangulación de S) sea también una cadena en S, cuya frontera es ahora

$$a_1 + b_1 - a_1 - b_1 + \cdots = 0.$$

Se demuestra que las clases de los ciclos $a_1, b_1, \ldots, a_g, b_g$ forman una base de $H_1(S, \mathbb{Z})$. En lo sucesivo, salvo que indiquemos lo contrario, cuando hablemos de una base de $H_1(S)$ se entenderá que es una base obtenida de esta forma a partir de un polígono.

La cohomología de las formas holomorfas es especialmente simple: observemos que las únicas funciones holomorfas en S son las constantes, luego no existen formas diferenciales holomorfas exactas (salvo la forma nula). Esto significa que $\mathcal{H}^1(S) = \Lambda^1(S)$ (sin ninguna identificación).

8.2 Integración de formas meromorfas

En 7.24 hemos distinguido tres clases de diferenciales en un cuerpo de funciones algebraicas K. En particular, si K es el cuerpo de funciones meromorfas de una superficie de Riemann S, entonces los divisores primos de K se identifican con los puntos de S y las formas diferenciales de K son las formas diferenciales meromorfas en S. Las diferenciales que hemos llamado de primera clase son simplemente las diferenciales holomorfas, mientras que las diferenciales de segunda clase son las que tienen integral nula sobre las fronteras en S pues, según hemos visto en la sección anterior, la integral de una forma meromorfa ω sobre una frontera es una combinación lineal entera de sus periodos polares, es decir, de los números $2\pi i \operatorname{Res}_P \omega$.

Sea ω una forma diferencial en una superficie de Riemann S y sea $a_1, \ldots, a_g$, $b_1, \ldots, b_g$ una base de $H_1(S)$ en las condiciones de la sección anterior, es decir, obtenida a partir de una identificación $\phi : \mathcal{P} \longrightarrow S$, donde $\mathcal{P}$ es un polígono de $4g$ lados. Podemos suponer que los ciclos a_k, b_k no pasan por polos de ω (por ejemplo, porque existe un difeomorfismo de S en sí misma que transforma cualquier conjunto finito de puntos prefijado en cualquier otro [GD 1.25]).

Llamaremos *periodos cíclicos* (o simplemente periodos) de ω (respecto a la base fijada) a los números complejos

$$A_k = \int_{a_k} \omega, \qquad B_k = \int_{b_k} \omega, \qquad k = 1, \ldots, g.$$

Si z es un ciclo en S, tenemos que su clase de homología se expresa como

$$[z] = \sum_{k=1}^{g} (m_k[a_k] + n_k[b_k]), \tag{8.2}$$

para ciertos $m_k, n_k \in \mathbb{Z}$, luego

$$z = \sum_{k=1}^{g} (m_k a_k + n_k b_k) + \partial c,$$

para cierta 2-cadena c en S. Consecuentemente,

$$\int_z \omega = \sum_{k=1}^{g} (m_k A_k + n_k B_k) + \int_{\partial c} \omega.$$

Por el teorema de los residuos, la última integral es combinación lineal entera de los periodos polares de ω. En resumen:

Teorema 8.1 *Si S es una superficie de Riemann de género $g \geq 1$ y ω es una forma diferencial meromorfa en S, entonces las integrales de ω sobre ciclos en S recorren el grupo generado por los periodos (polares y cíclicos) de ω.*

Notemos que ciertamente se recorre todo el grupo porque integrando sobre una pequeña circunferencia alrededor de un polo obtenemos el correspondiente periodo polar. Este teorema muestra que, aunque los periodos de ω dependen de la elección de la base de homología respecto a la que se calculan, el grupo de periodos es independiente de ella.

Fijado un punto $O \in S$, la integral

$$\int_O^P \omega$$

define una función holomorfa multiforme en S menos los polos de ω. Dos valores de la integral en un mismo punto P (calculados con arcos distintos de extremos O y P) se diferencian en un elemento del grupo de periodos de ω.

En el estudio de las integrales abelianas será fundamental una fórmula que vamos a deducir a continuación. Fijemos una forma diferencial ω de primera clase y una forma η arbitraria. Tomamos una base de homología a_k, b_k construida a partir de una identificación $\phi : \mathcal{P} \longrightarrow S$, donde $\mathcal{P}$ es un polígono en forma canónica. Podemos exigir que los ciclos no pasen por polos de η. Llamemos

$$A_k = \int_{a_k} \omega, \quad B_k = \int_{B_k} \omega, \quad A_k' = \int_{a_k} \eta, \quad B_k' = \int_{b_k} \eta.$$

Sea $D \subset S$ la imagen por ϕ del interior de $\mathcal{P}$, que es un abierto simplemente conexo en S. Si P_1 y P_2 son puntos de D, podemos definir

$$\int_{P_1}^{P_2} \omega$$

como la integral sobre cualquier arco en D que una P_1 con P_2. Fijado un punto $O \in D$, la función $g : D \longrightarrow \mathbb{C}$ dada por

$$g(P) = \int_O^P \omega$$

es holomorfa (uniforme) en D.

Sea ζ_S una triangulación (orientada) de S diferenciable a trozos (vista como 2-cadena en S). Podemos suponer que los lados de los triángulos no pasan por polos de η. Sabemos que $\partial\zeta_S = 0$, lo cual significa que cada arista es compartida por dos triángulos, pero recorrida en sentidos opuestos. Observemos ahora que si $\sigma : \Delta_2 \longrightarrow S$ es uno de los triángulos, entonces la restricción de g al interior de su imagen se extiende a una función holomorfa en un entorno de $\sigma[\Delta_2]$. En efecto, basta considerar un abierto simplemente conexo U que contenga a $\sigma[\Delta_2]$. Fijado un punto P_1 en el interior de $\sigma[\Delta_2]$, tenemos que, para cualquier otro punto P en dicho interior,

$$g(P) = \int_O^{P_1} \omega + \int_{P_1}^P \omega,$$

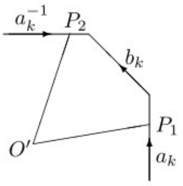
donde la segunda integral se calcula respecto de cualquier arco contenido en U que una P_1 con P, pero esta integral define una función holomorfa en U, que nos permite definir la extensión holomorfa que buscábamos. Obviamente esta extensión es única.

La construcción muestra que si $P \in \sigma[\Delta_2]$, entonces

$$g(P) = \int_O^P \omega,$$

donde la integral se calcula sobre cualquier arco que una O con P y que esté contenido en D salvo a lo sumo en su extremo final.

Consideremos ahora un punto P situado sobre la arista común de dos triángulos σ_1 y σ_2 y vamos a calcular la relación entre los valores $g_1(P)$ y $g_2(P)$. Si $P \in D$ tenemos $g_1(P) = g_2(P) = g(P)$. En caso contrario P es la imagen por ϕ de dos puntos P_1 y P_2 situados en la frontera de $\mathcal{P}$, tal y como muestra la figura.



(En realidad la figura ilustra una posibilidad. La otra es que P_1 y P_2 estén sobre dos lados b_k y b_k^{-1}, en cuyo caso la flecha del lado intermedio tendría sentido opuesto.) Llamamos O' al punto de $\mathcal{P}$ que se corresponde con O.

La poligonal γ que va de O' a P_1, de P_1 a P_2 sobre la frontera de $\mathcal{P}$ y de P_2 a O' es un ciclo en $\mathcal{P}$, y como éste es simplemente conexo, γ es una frontera. Por consiguiente, su imagen $\phi^\sharp(\gamma)$ es una frontera en S, luego

$$0 = \int_{\phi^\sharp(\gamma)} \omega = g_1(P) + B_k - g_2(P),$$

donde hemos usado que las integrales sobre los dos fragmentos de a_k y a_k^{-1} se cancelan porque, en S, son integrales de la misma forma ω sobre el mismo arco recorrido en sentidos opuestos. Así pues, $g_1(P) - g_2(P) = -B_k$.

Similarmente, si P_1 está en b_k y P_2 en b_k^{-1}, resulta $g_1(P) - g_2(P) = A_k$.

Sea $\zeta_S = \sigma_1 + \cdots + \sigma_r$ la triangulación que hemos tomado. Definimos

$$\Sigma = \sum_{j=1}^{r} \int_{\partial\sigma_j} g_j\eta, \tag{8.3}$$

donde g_j es la extensión de g al triángulo σ_j.

Cada lado interior a D es recorrido dos veces en sentidos opuestos y, sobre ellos, la función g_j es la misma en ambos casos (pues coincide con la función g definida sobre D), luego las integrales se cancelan, y sólo quedan los términos correspondientes a lados contenidos en los arcos a_k y b_k. Éstos no se cancelan, porque para cada punto $P = \phi(P_1) = \phi(P_2)$ situado sobre uno de estos lados, con P_1 sobre a_k (o b_k) y P_2 sobre a_k^{-1} (o b_k^{-1}), la función g_j toma valores diferentes, digamos $g^+(P)$ cuando recorremos a_k o b_k positivamente y $g^-(P)$ cuando lo hacemos negativamente. El resultado es

$$\begin{aligned} S &= \sum_{k=1}^{g} \left(\int_{a_k} g^+\eta + \int_{b_k} g^+\eta - \int_{a_k} g^-\eta - \int_{b_k} g^-\eta \right) \\ &= \sum_{k=1}^{g} \left(\int_{b_k} (g^+ - g^-)\eta + \int_{a_k} (g^+ - g^-)\eta \right). \end{aligned}$$

Pero hemos visto que $g^+(P) - g^-(P) = A_k$ sobre b_k y $g^+(P) - g^-(P) = -B_k$ sobre a_k. Por consiguiente,

$$\Sigma = \sum_{k=1}^{g} (A_k B_k' - B_k A_k').$$

Por otra parte, podemos evaluar Σ calculando la integral sobre cada triángulo. Observemos que $g_j\eta$ es una forma diferencial meromorfa en un entorno (simplemente conexo) de cada uno de ellos. Subdividiendo la triangulación si es preciso, no perdemos generalidad si suponemos que dicho entorno es el dominio de una carta. Así, aplicando el teorema de los residuos vemos que

$$\Sigma = 2\pi i \sum_P \operatorname{Res}_P(g\eta),$$

donde P recorre los polos de η y g es ahora la función holomorfa (fija) definida en D. Si suponemos que η es una diferencial de tercera clase, entonces se cumple $\operatorname{Res}_P(g\eta) = g(P)\operatorname{Res}_P \eta$, pues si $g(P) = 0$ entonces $g\eta$ es holomorfa en P y su residuo es nulo.

En resumen, si ω es una diferencial de primera clase y η de tercera clase, sus periodos cíclicos A_k, B_k, A'_k, B'_k y los periodos polares de η (es decir, los números $2\pi i \operatorname{Res}_P \eta$) satisfacen la relación:

$$\sum_{k=1}^{g} (A_k B'_k - B_k A'_k) = 2\pi i \sum_P g(P) \operatorname{Res}_P \eta. \tag{8.4}$$

Si η es también una diferencial de primera clase, el segundo miembro es nulo, con lo que obtenemos el siguiente caso particular:

Teorema 8.2 (Primeras relaciones de Riemann) *Sean ω y η dos diferenciales de primera clase en una superficie de Riemann S de género $g \geq 1$, sean A_k, B_k los periodos de ω y A'_k, B'_k los periodos de η. Entonces*

$$\sum_{k=1}^{g} (A_k B'_k - B_k A'_k) = 0.$$

Más importante es la relación siguiente, pues de ella se deduce que si dos diferenciales de primera clase tienen los mismos A-periodos (o los mismos B-periodos) entonces son iguales:

Teorema 8.3 (Segundas relaciones de Riemann) *Si A_k y B_k son los periodos de una diferencial de primera clase no nula ω en una superficie de Riemann S de género $g \geq 1$, entonces*

$$i \sum_{k=1}^{g} (A_k \bar{B}_k - B_k \bar{A}_k) > 0.$$

Demostración: Consideramos

$$\Sigma' = \sum_{j=1}^{r} \int_{\partial\sigma_j} \bar{g}_j \omega,$$

donde g_j y σ_j son los mismos que en (8.3). El mismo razonamiento que hemos aplicado a Σ nos da ahora que

$$\Sigma' = \sum_{k=1}^{g} (\bar{A}_k B_k - \bar{B}_k A_k),$$

luego basta probar que, para cada j,

$$-i \int_{\partial\sigma_j} \bar{g}_j \omega > 0.$$

Recordemos que, salvo un sumando constante, la función g_j se obtiene integrando ω desde un punto fijo de σ_j, por lo que $\omega|_{\sigma_j[\Delta_2]} = dg_j$. Sin embargo, ahora no podemos decir que la integral sobre $\partial\sigma_j$ es nula porque la forma $\bar{g}_j\omega$ no es holomorfa. Vamos a calcularla explícitamente.

Sea $g_j = u + iv$, de modo que $\omega = dg_j = du + idv$. Aplicamos el teorema de Stokes:

$$-i\int_{\partial\sigma_j} \bar{g}_j\omega = -i\int_{\partial\sigma_j}((u\,du + v\,dv) + i(u\,dv - v\,du)) = \int_{\sigma_j} du \wedge dv.$$

Podemos suponer que $\sigma_j[\Delta_2]$ está contenido en el dominio de una carta z, con lo que

$$\begin{aligned} du \wedge dv &= \left(\frac{\partial\operatorname{Re} g_j}{\partial x}\,dx + \frac{\partial\operatorname{Re} g_j}{\partial y}\,dy\right) \wedge \left(\frac{\partial\operatorname{Im} g_j}{\partial x}\,dx + \frac{\partial\operatorname{Im} g_j}{\partial y}\,dy\right) \\ &= \left(\frac{\partial\operatorname{Re} g_j}{\partial x}\frac{\partial\operatorname{Im} g_j}{\partial y} - \frac{\partial\operatorname{Re} g_j}{\partial y}\frac{\partial\operatorname{Im} g_j}{\partial x}\right) dx \wedge dy \\ &= \left(\left(\frac{\partial\operatorname{Re} g_j}{\partial x}\right)^2 + \left(\frac{\partial\operatorname{Re} g_j}{\partial y}\right)^2\right) dx \wedge dy. \end{aligned}$$

Así pues, al transportar la integral mediante la carta, obtenemos

$$\int_{\sigma_j} du \wedge dv = \int_{z_\sharp(\sigma_j)} \left(\left(z^{-1} \circ \frac{\partial\operatorname{Re} g_j}{\partial x}\right)^2 + \left(z^{-1} \circ \frac{\partial\operatorname{Re} g_j}{\partial y}\right)^2\right) dxdy,$$

que es un número real estrictamente positivo, ya que si fuera cero entonces $\operatorname{Re} g_j$ sería constante en un abierto de S, al igual que $\operatorname{Im} g_j$ por las ecuaciones de Cauchy-Riemann, pero entonces g_j sería constante y ω sería nula. ■

Como ya hemos dicho, este teorema implica que si una diferencial de primera clase ω tiene todos sus A-periodos (o todos sus B-periodos) nulos, entonces es la forma nula. Más aún, comparando los dos teoremas anteriores vemos que si ω tiene todos sus periodos reales entonces ha de ser la forma nula.

Las relaciones de Riemann pueden expresarse matricialmente:

Teorema 8.4 (Relaciones de Riemann) *Sea $\Omega = (\omega_1, \ldots, \omega_g)$ una base del espacio de diferenciales de primera clase en una superficie de Riemann de género $g \geq 1$ y sean A_{jk}, B_{jk} los periodos de ω_j, que forman sendas matrices cuadradas A y B. Entonces $AB^t = BA^t$ y la matriz $i(A\bar{B}^t - B\bar{A}^t)$ es definida positiva.*

DEMOSTRACIÓN: No sólo vamos a probar lo que afirma el teorema, sino, de hecho, que este enunciado es equivalente a los enunciados de los dos teoremas precedentes.

Si $\omega = \alpha\Omega$ y $\eta = \beta\Omega$ son dos diferenciales de primera clase arbitrarias (donde α, $\beta \in \mathbb{C}^g$), los vectores de periodos de ω son αA, αB, y los de η son βA, βB. Las primeras relaciones de Riemann afirman que $\alpha AB^t\beta^t - \alpha BA^t\beta^t = 0$ o, equivalentemente, que $\alpha(AB^t - BA^t)\beta^t = 0$ para todos los α, $\beta \in \mathbb{C}^g$. Esto se reduce a la igualdad $AB^t = BA^t$.

Las segundas relaciones de Riemann afirman que si $\alpha \neq 0$ entonces

$$i(\alpha A\bar{B}^t\bar{\alpha}^t - \alpha B\bar{A}^t\bar{\alpha}^t) > 0$$

o, lo que es lo mismo, que $\alpha(i(A\bar{B}^t - B\bar{A}^t))\bar{\alpha}^t > 0$ para todo $\alpha \in \mathbb{C}^g$ no nulo. Esto es, por definición, que la matriz $i(A\bar{B}^t - B\bar{A}^t)$ es definida positiva. ■

Como consecuencia, la matriz A ha de ser regular, pues en caso contrario existiría un $\alpha \in \mathbb{C}^g$ no nulo tal que $\alpha A = 0$, lo que a su vez implicaría que $\alpha(i(A\bar{B}^t - B\bar{A}^t))\bar{\alpha}^t = 0$, en contradicción con el teorema anterior.

Observemos ahora que si M es una matriz regular y consideramos la base $\Omega' = \Omega M$, entonces $\omega'_i = \sum\limits_k m_{ki}\omega_k$, y el periodo A'_j de ω'_i es $A'_j = \sum\limits_k m_{ki}A_{kj}$, luego la matriz de A-periodos de Ω' es M^tA. En particular, tomando la matriz $M = (A^{-1})^t$, obtenemos una base cuya matriz de A-periodos es la identidad.

Definición 8.5 Sea S una superficie de Riemann de género $g \geq 1$. Una *base canónica* del espacio de diferenciales de primera clase de S (respecto de una base prefijada de $H_1(S)$) es una base tal que su matriz de A-periodos es la identidad.

Acabamos de demostrar que existen bases canónicas. Respecto a tales bases, las relaciones de Riemann se expresan de forma especialmente simple: las primeras relaciones afirman que la matriz B es simétrica, mientras que las segundas se reducen a que la matriz $i(\bar{B} - B) = 2\,\mathrm{Im}\,B$ es definida positiva. Puesto que se trata de una matriz real, esto implica que es definida positiva como matriz real, es decir, que $\alpha(\mathrm{Im}\,B)\alpha^t > 0$ para todo $\alpha \in \mathbb{R}^g$ no nulo.

A partir de una base canónica podemos formar diferenciales de primera clase con cualquier vector de A-periodos prefijado. Como consecuencia podemos dar una condición de unicidad en la descomposición de una forma diferencial:

Teorema 8.6 *Si ω es una forma diferencial en una superficie de Riemann de género $g \geq 1$, entonces ω se descompone de forma única como $\omega = \omega_1 + \omega_2 + \omega_3$, donde los sumandos son, respectivamente, una diferencial de primera clase, una diferencial de segunda clase con A-periodos nulos y una diferencial de tercera clase con A-periodos nulos (respecto de una base de homología prefijada cuyos ciclos no pasen por los polos de ω).*

Demostración: El teorema 7.26 nos da una diferencial de tercera clase ω'_3 con los mismos polos de orden 1 que ω y con los mismos residuos, luego $\omega'_2 = \omega - \omega_3$ es una diferencial de segunda clase. Sean ω'_1 y ω''_1 diferenciales de primera clase con los mismos A-periodos que ω'_2 y ω'_3 respectivamente. Entonces $\omega_2 = \omega'_2 - \omega'_1$ y $\omega_3 = \omega'_3 - \omega''_1$ son diferenciales de segunda y tercera clase con A-periodos nulos y, llamando $\omega_1 = \omega'_1 + \omega''_1$ tenemos $\omega = \omega_1 + \omega_2 + \omega_3$.

La descomposición es única, pues si $\omega = \omega'_1 + \omega'_2 + \omega'_3$ es otra descomposición en las mismas condiciones, entonces ω_1 y ω'_1 son diferenciales de primera clase con los mismos A-periodos (los de ω), luego $\omega_1 - \omega'_1$ tiene A-periodos nulos y es, por consiguiente, la forma nula.

Similarmente, ω_3 y ω'_3 tienen los mismos polos simples que ω con los mismos residuos, luego su diferencia no tiene polos, luego se trata también de una diferencial de primera clase con A-periodos nulos y por lo tanto $\omega_3 = \omega'_3$. Necesariamente entonces $\omega_2 = \omega'_2$. ■

El grupo de periodos de una forma diferencial es en general denso en $\mathbb{C}$, por lo que calcular una integral salvo periodos es hacer poco. La situación es distinta si trabajamos vectorialmente, como vamos a ver a continuación:

Sea $\Omega = (\omega_1, \ldots, \omega_g)$ una base del espacio de diferenciales de primera clase en una superficie de Riemann S. Definimos

$$A_k = \int_{a_k} \Omega = \left(\int_{a_k} \omega_1, \ldots, \int_{a_k} \omega_g \right) \in \mathbb{C}^g,$$

$$B_k = \int_{b_k} \Omega = \left(\int_{b_k} \omega_1, \ldots, \int_{b_k} \omega_g \right) \in \mathbb{C}^g.$$

A estos vectores los llamaremos *periodos* de Ω. Si z es un ciclo en S, la relación (8.2) implica que

$$\int_z \Omega = \left(\int_z \omega_1, \ldots, \int_z \omega_g \right)$$

es una combinación lineal entera de los periodos de Ω, por lo que si P, $Q \in S$, la integral

$$\int_P^Q \Omega = \left(\int_P^Q \omega_1, \ldots, \int_P^Q \omega_g \right),$$

(donde todas las integrales se calculan sobre un mismo arco que una P con Q) está definida salvo combinaciones enteras de los periodos de Ω. La diferencia es que, según se deduce del teorema siguiente, el grupo generado por los periodos es ahora un subespacio discreto de $\mathbb{C}^g$.

Teorema 8.7 *Sea S una superficie de Riemann de género $g \geq 1$ y sea Ω una base de las diferenciales de primera clase. Entonces, los periodos A_k, B_k de Ω (respecto a una base de $H_1(S)$) son linealmente independientes sobre $\mathbb{R}$.*

DEMOSTRACIÓN: Al construir las bases canónicas hemos visto que los periodos de dos bases distintas se corresponden por un automorfismo de $\mathbb{C}^g$, luego podemos suponer que la base Ω es canónica. Si vemos la matriz de periodos (A, B) como una matriz real de dimensión $2g \times 2g$, es decir, si desdoblamos cada fila en dos filas correspondientes a la parte real y la parte imaginaria, obtenemos una matriz de la forma

$$\left(\begin{array}{c|c} I & \operatorname{Re} B \\ \hline 0 & \operatorname{Im} B \end{array} \right)$$

Sabemos que $\operatorname{Im} B$ es definida positiva, luego en particular es regular, luego la matriz tiene determinante no nulo y sus columnas son linealmente independientes. ■

Por consiguiente, el grupo generado por los periodos de una base Ω es un retículo R_Ω en $\mathbb{C}^g$. Observemos que no depende de la elección de la base de homología, ya que

$$R_\Omega = \left\{ \int_\gamma \Omega \;\Big|\; \gamma \in Z_1(S) \right\}.$$

Por otra parte, los retículos asociados a dos bases del espacio de diferenciales de primera clase se corresponden a través de un automorfismo de $\mathbb{C}^g$, lo que implica que el toro complejo $\mathbb{C}^g/J_\Omega$ está determinado por S salvo un isomorfismo inducido por un automorfismo de $\mathbb{C}^g$, que es claramente una aplicación biholomorfa.

Definición 8.8 Si S es una superficie de Riemann de género $g \geq 1$, definimos la *variedad jacobiana* de S como el toro complejo $J(S) = \mathbb{C}^g/J_\Omega$, donde Ω es una base del espacio de diferenciales de primera clase de S y J_Ω es el retículo generado por sus periodos.

En las próximas secciones estudiaremos la relación entre una superficie S y su variedad jacobiana. Ahora vamos a probar que las variedades jacobianas cumplen la hipótesis del teorema de Lefschetz 4.41, por lo que son proyectivas:

Teorema 8.9 *Sea S una superficie de Riemann de género $g \geq 1$, sea Ω una base de las diferenciales de primera clase y sea $R_\Omega \subset \mathbb{C}^g$ el retículo generado por los periodos A_k, B_k de Ω respecto a una base de $H_1(S)$. Entonces existe una forma de Riemann en $\mathbb{C}^g$ respecto de R_Ω. Por consiguiente, la variedad jacobiana $J(S)$ es proyectiva.*

DEMOSTRACIÓN: Como ya hemos observado, no perdemos generalidad si tomamos como Ω una base canónica. Consideremos los periodos A_k, B_k como una $\mathbb{R}$-base de $V = \mathbb{C}^g = \mathbb{R}^{2g}$ y sea x_k, y_k su base dual. Definimos la forma bilineal alternada $E : V \times V \longrightarrow \mathbb{R}$ mediante

$$E(u, v) = \sum_{j=1}^{g} (y_j(u)x_j(v) - x_j(u)y_j(v)).$$

Es obvio que E toma valores enteros sobre R_Ω. Para probar que E es una forma de Riemann sólo falta ver que la forma $S(u, v) = E(iu, v)$ es simétrica y definida positiva.

Dado $u \in V$, sean (α, β) sus coordenadas en la base de periodos, es decir, $u = \alpha + \beta B$. Por otra parte, descompongamos $u = a + ib$, donde a, $b \in \mathbb{R}^g$ y, del mismo modo, $B = P + iQ$, donde las matrices reales P y Q son simétricas y Q es definida positiva. En estos términos, $a + ib = u = \alpha + \beta P + i\beta Q$, luego $a = \alpha + \beta P$, $b = \beta Q$, luego

$$y_j(u) = \beta_j = (bQ^{-1})_j, \qquad x_j(u) = \alpha_j = (a - bQ^{-1}P)_j.$$

Por consiguiente, $y_j(iu) = (aQ^{-1})_j$, $x_j(iu) = -(b + aQ^{-1}P)_j$. Ahora tomamos dos vectores $u = a + ib$, $v = a' + ib'$ y calculamos:

$$S(u, v) = E(iu, v) = \sum_{j=1}^{g} (y_j(iu)x_j(v) - x_j(iu)y_j(v))$$

$$= \sum_{j=1}^{g} ((aQ^{-1})_j(a' - b'Q^{-1}P)_j + (b + aQ^{-1}P)_j(b'Q^{-1})_j)$$

$$= (aQ^{-1})(a' - b'Q^{-1}P) + (b + aQ^{-1}P)(b'Q^{-1}) = aQ^{-1}a'^t + bQ^{-1}b'^t,$$

donde hemos usado que todas las matrices son simétricas. Ahora es inmediato que la forma S es simétrica. Además,

$$S(u,u) = aQ^{-1}a^t + bQ^{-1}b^t.$$

Ahora basta tener en cuenta que si Q es definida positiva Q^{-1} también lo es.[1]

■

8.3 El teorema de Abel

El teorema de Abel nos da una caracterización en términos de integrales de los divisores principales de una superficie de Riemann S. Equivalentemente, nos da una condición necesaria y suficiente para que exista una función meromorfa en S con una distribución dada de ceros y polos. Si Ω es una base del espacio de las diferenciales de primera clase de S, en la sección anterior hemos visto que la integral

$$\int_P^Q \Omega$$

está bien definida módulo los periodos de Ω, es decir, como elemento de la variedad jacobiana $J(S)$, con independencia del arco de extremos P y Q con que la calculemos.

Si identificamos los puntos de S con los divisores primos del cuerpo $\mathcal{M}(S)$ de las funciones meromorfas en S, entonces la integral (con un origen fijo $O \in S$) se extiende por linealidad a un homomorfismo sobre todo el grupo de divisores de S, de modo que

$$\int_O^{\mathfrak{a}} \Omega = \sum_Q v_Q(\mathfrak{a}) \int_O^Q \Omega \in J.$$

La restricción de este homomorfismo al grupo de los divisores de grado 0 es independiente de la elección de O, pues

$$\int_O^{\mathfrak{a}} \Omega - \int_{O'}^{\mathfrak{a}} \Omega = \sum_Q v_Q(\mathfrak{a}) \int_O^{O'} \Omega = 0.$$

Tenemos así un homomorfismo natural del grupo de divisores de grado 0 en la variedad jacobiana J. El teorema de Abel dice esencialmente que el núcleo de este homomorfismo es el subgrupo de los divisores principales. Para probarlo usaremos la versión vectorial de la relación (8.4), que se prueba sin más que aplicar dicha relación componente a componente:

Teorema 8.10 *Sea S una superficie de Riemann de género $g \geq 1$, sea Ω una base del espacio de diferenciales de primera clase en S y η una diferencial de*

---

[1] Existe una matriz regular H tal que $Q' = HQH^t$ es diagonal [TAl 6.3]. Entonces Q' es definida positiva, lo que equivale a que todos los coeficientes de su diagonal sean positivos. Lo mismo le sucede a $Q'^{-1} = H^{-1t}Q^{-1}H^{-1}$, luego Q^{-1} es definida positiva.

Historia de las fórmulas y algoritmos para π

por

Jesús Guillera Goyanes

A lo largo de más de dos milenios se han obtenido muchas fórmulas, algunas de gran belleza, para el número π. Entre ellas: series, productos infinitos, desarrollos en fracciones continuas y desarrollos con radicales. También se han conseguido evaluar algunas expresiones que, ¡oh maravilla!, estaban relacionadas con π. Además ha habido una continua batalla por conseguir records de cálculo de las cifras de este número, que se han ido estableciendo con series de convergencia rápida, algoritmos ultrarápidos y otros de cálculo aislado de cifras realmente sorprendentes. En estos logros de cálculo el desarrollo de ordenadores cada vez más potentes ha jugado un papel esencial.

1 . La primera fórmula: El algoritmo de Arquímedes

El algoritmo para el cálculo de π que Arquímedes demostró unos 250 años A.C. constituyó durante un periodo de aproximadamente 1800 años la forma más eficiente para el cálculo de π. La idea consistía en considerar un círculo de diámetro unidad y polígonos circunscritos e inscritos de $3 \cdot 2^n$ lados. Denotando sus perímetros con a_n y b_n respectivamente, Arquímedes, con razonamientos puramente geométricos, demostró las relaciones

$$a_1 = 2\sqrt{3}, \quad b_1 = 3, \qquad a_{n+1} = \frac{2a_n b_n}{a_n + b_n}, \qquad b_{n+1} = \sqrt{a_{n+1} b_n}. \qquad (1)$$

Obviamente $b_n < \pi < a_n$ y las sucesiones a_n y b_n convergen hacia el número π. Se trata de un algoritmo que hoy en día podemos demostrar fácilmente usando trigonometría elemental. En efecto, llamando $k_n = 3 \cdot 2^n$ se tienen las relaciones

$$a_n = k_n \tan \frac{\pi}{k_n}, \qquad b_n = k_n \mathrm{sen} \frac{\pi}{k_n}.$$

Por lo tanto

$$\frac{2a_n b_n}{a_n + b_n} = 2k_n \frac{\tan \frac{\pi}{k_n} \mathrm{sen} \frac{\pi}{k_n}}{\tan \frac{\pi}{k_n} + \mathrm{sen} \frac{\pi}{k_n}} = 2k_n \tan \frac{\pi}{2k_n} = a_{n+1}.$$

Por otra parte

$$\sqrt{a_{n+1} b_n} = \sqrt{2k_n \tan \frac{\pi}{2k_n} \cdot k_n \mathrm{sen} \frac{\pi}{k_n}} = 2k_n \sqrt{\tan \frac{\pi}{2k_n} \mathrm{sen} \frac{\pi}{2k_n} \cos \frac{\pi}{2k_n}} = b_{n+1}.$$

La convergencia del algoritmo es lineal, cada 5 iteraciones se obtienen 3 cifras de π. Para verlo utilizamos las desigualdades $\tan x < x$ y $1 - \cos x < \frac{x^2}{2}$. Se tiene entonces

$$a_n - b_n = k_n \tan \frac{\pi}{k_n} \left(1 - \cos \frac{\pi}{k_n}\right) < \frac{\pi^3}{2k_n^2} = \frac{\pi^3}{18 \cdot 2^{2n}} < \frac{\pi^3}{18 \cdot 1000^{n/5}}.$$

Para $n = 7$ este algoritmo proporciona para π la acotación $3{,}1415 < \pi < 3{,}1417$.

Es instructivo señalar que en la época de Arquímedes no se conocía la notación decimal de los números ni ninguna otra notación posicional, por lo que el resultado que obtuvo con polígonos de 96 lados ($n = 5$) lo expreso con fracciones:

$$3 + \frac{10}{71} < \pi < 3 + \frac{1}{7}.$$

Esta acotación determina dos cifras decimales de π.

2 . SIN GRANDES NOVEDADES HASTA 1800 AÑOS DESPUÉS

Durante un periodo de aproximadamente 1800 años todas las fórmulas que se obtuvieron para π se basaron en la idea de aproximar el círculo mediante polígonos regulares y tienen la forma de algoritmos iterativos. En el año 1593 Viète obtiene una expresión diferente mediante un bonito desarrollo con infinitos radicales anidados:

$$\frac{2}{\pi} = \sqrt{\frac{1}{2}} \cdot \sqrt{\frac{1}{2} + \frac{1}{2}\sqrt{\frac{1}{2}}} \cdot \sqrt{\frac{1}{2} + \frac{1}{2}\sqrt{\frac{1}{2} + \frac{1}{2}\sqrt{\frac{1}{2}}}} \cdots . \tag{2}$$

El método usado por Viète se basa, como todos los anteriores, en la geometría y consiste en considerar un círculo de diámetro 2 e ir aproximando su área, es decir π, sucesivamente por las áreas de un cuadrado inscrito, de un octógono inscrito, de un polígono inscrito de 16 lados, etc. De esta manera Viète obtiene π con 9 cifras decimales: 3,141592653.

Hacia el año 1650 los métodos analíticos de Descartes y Fermat, precursores del cálculo infinitesimal que pronto sería desarrollado, comenzaron a sustituir a los métodos geométricos. Uno de los resultados para π correspondiente a esta etapa es el famoso producto infinito de Wallis (1655):

$$\frac{2}{\pi} = \frac{1\cdot 3}{2\cdot 2}\cdot\frac{3\cdot 5}{4\cdot 4}\cdot\frac{5\cdot 7}{6\cdot 6}\cdot\frac{7\cdot 9}{8\cdot 8}\cdots \tag{3}$$

En 1999 Osler demostró una fórmula que incluye como casos particulares tanto la fórmula de Viète como el producto infinito de Wallis. La veremos en la sección 10.

3 . COMIENZOS DEL CÁLCULO INFINITESIMAL: NUEVAS FÓRMULAS PARA π

Entre 1665 y 1680 Newton y Leibniz desarrollaron de forma independiente los principios básicos del cálculo infinitesimal que proporcionaron una poderosa herramienta de cálculo no sólo para las matemáticas sino también para la física y otras ciencias. Estos métodos, como no podía ser de otra manera, tienen también su repercusión en la obtención de nuevas fórmulas para π como por ejemplo la obtenida por Newton

$$\pi = \frac{3\sqrt{3}}{4} + 2 - \frac{3}{4}\sum_{n=0}^{\infty}\frac{\binom{2n}{n}}{(n+1)(2n+5)16^n}, \tag{4}$$

con la cual calculó 15 decimales de π en el año 1665. Newton llega a esta fórmula observando que el área limitada entre la circunferencia de ecuación

$$\left(x-\frac{1}{2}\right)^2 + y^2 = \frac{1}{4}$$

y las rectas $x = \frac{1}{4}$ e $y = 0$ es igual a la diferencia entre el área de un sector circular que abarca un ángulo de 60^o y su triángulo correspondiente y que por lo tanto

$$\int_0^{1/4} y\,dx = \int_0^{1/4}\sqrt{x-x^2}dx = \int_0^{1/4} x^{1/2}(1-x)^{1/2}dx = \frac{\pi}{24} - \frac{\sqrt{3}}{32}.$$

La fórmula de Newton se obtiene a partir de aquí desarrollando $(1-x)^{1/2}$ por medio de la fórmula del binomio, que él mismo había demostrado, e integrando a continuación término a término. Fórmulas como la (4) se conocen actualmente como sumas binomiales. Una serie similar a la de Newton pero más sencilla es

$$\frac{\pi}{3} = \sum_{n=1}^{\infty} \frac{\binom{2n}{n}}{(2n+1)16^n}, \tag{5}$$

que se obtiene sustituyendo $x = \frac{1}{4}$ en el desarrollo en serie (ver [3], pág. 386)

$$\frac{\operatorname{arc\,sen} 2x}{2x} = \sum_{n=1}^{\infty} \frac{\binom{2n}{n}}{2n+1} x^{2n}.$$

Otro ejemplo interesante de suma binomial es la obtenida por Comtet en 1974

$$\pi^4 = \frac{3240}{17} \sum_{n=1}^{\infty} \frac{1}{n^4 \binom{2n}{n}} \tag{6}$$

que se demuestra a partir de la identidad [5]

$$\sum_{n=1}^{\infty} \frac{1}{n^4 \binom{2n}{n}} = 2 \int_0^{\pi/3} \theta \log^2 \left(2\text{sen} \frac{\theta}{2} \right) d\theta.$$

Gregory en 1671 integra término a término la serie geométrica

$$1 - x^2 + x^4 - x^6 + \cdots = \frac{1}{1+x^2}, \qquad |x| < 1$$

y obtiene la fórmula (que lleva su nombre)

$$\arctan x = x - \frac{x^3}{3} + \frac{x^5}{5} - \frac{x^7}{7} + \cdots, \qquad |x| \leq 1,$$

que es lo que luego se conocería como desarrollo en serie de potencias de x de la función $\arctan x$. Sustituyendo $x = 1$, Leibniz obtiene en 1674 la serie para π

$$\frac{\pi}{4} = 1 - \frac{1}{3} + \frac{1}{5} - \frac{1}{7} + \cdots. \tag{7}$$

Es extraño que Gregory no diera él mismo este paso, seguramente no lo hizo porque no estaba interesado en series de convergencia lenta. Sharp sustituye $x = \sqrt{3}/3$ en la fórmula de Gregory y obtiene la serie

$$\frac{\pi}{6} = \frac{\sqrt{3}}{3} \left(1 - \frac{1}{3 \cdot 3} + \frac{1}{5 \cdot 3^2} - \frac{1}{7 \cdot 3^3} + \cdots \right) \tag{8}$$

que le sirve para conseguir en 1699 un record de 71 cifras decimales de π.

En 1665 Brounker halla el bonito desarrollo en fracción continua

$$\frac{4}{\pi} = 1 + \cfrac{1^2}{2 + \cfrac{3^2}{2 + \cfrac{5^2}{2 + \cfrac{7^2}{2 + \cfrac{9^2}{2 + \ddots}}}}}. \tag{9}$$

Unos 100 años más tarde Euler la demuestra de forma ingeniosa: Comienza con la siguiente igualdad

$$a_1 + a_1a_2 + a_1a_2a_3 + a_1a_2a_3a_4 \cdots = \cfrac{a_1}{1 - \cfrac{a_2}{1 + a_2 - \cfrac{a_3}{1 + a_3 - \cfrac{a_4}{1 + a_4 - \ddots}}}},$$

lo que permite representar la serie de Gregory escrita en la forma

$$\arctan x = x + x\left(\frac{-x^2}{3}\right) + x\left(\frac{-x^2}{3}\right)\left(\frac{-3x^2}{5}\right) + x\left(\frac{-x^2}{3}\right)\left(\frac{-3x^2}{5}\right)\left(\frac{-5x^2}{7}\right) + \cdots$$

mediante una fracción continua de la que obtiene la fórmula de Brounker sustituyendo $x = 1$.

Un ejemplo reciente de desarrollo de π en fracción continua es [16]

$$\pi = 3 + \cfrac{1^2}{6 + \cfrac{3^2}{6 + \cfrac{5^2}{6 + \cfrac{7^2}{6 + \cfrac{9^2}{6 + \ddots}}}}}, \tag{10}$$

obtenido en 1999 por Lange.

4 . SERIES RÁPIDAS DE TIPO MACHIN

En 1706 John Machin demostró la fórmula que lleva su nombre

$$\frac{\pi}{4} = 4 \arctan \frac{1}{5} - \arctan \frac{1}{239} \tag{11}$$

y utilizando la fórmula de Gregory la escribió en forma de serie y consiguió con ella calcular los 100 primeros decimales de π. Las siguientes identidades son del mismo tipo pero conducen a series de convergencia más lenta:

$$\frac{\pi}{4} = \arctan\frac{1}{2} + \arctan\frac{1}{3}, \qquad \frac{\pi}{4} = 2\arctan\frac{1}{3} + \arctan\frac{1}{7}. \tag{12}$$

Demostrar una fórmula de tipo Machin, una vez conocida, se reduce a la comprobación rutinaria de una identidad entre operaciones elementales con números complejos. Así, la identidad

$$\frac{(5+i)^4}{239+i} = 2+2i$$

encapsula la demostración de la fórmula de Machin –basta con igualar los argumentos. Gauss también participó en la búsqueda de series para π de convergencia rápida y en 1863 demostró la siguiente identidad

$$\frac{\pi}{4} = 12\arctan\frac{1}{18} + 8\arctan\frac{1}{57} - 5\arctan\frac{1}{239}, \tag{13}$$

que es como las anteriores pero que involucra un término más. En el año 2002 Kanada y su equipo, empleando ciertos trucos para hacer más eficaces los cálculos por ordenador, consiguieron un record de cálculo de π por medio de las series:

$$\frac{\pi}{4} = 12\arctan\frac{1}{49} + 32\arctan\frac{1}{57} - 5\arctan\frac{1}{239} + 12\arctan\frac{1}{110443}, \tag{14}$$

$$\frac{\pi}{4} = 44\arctan\frac{1}{57} + 7\arctan\frac{1}{239} - 12\arctan\frac{1}{682} + 24\arctan\frac{1}{12943}, \tag{15}$$

la primera obtenida en 1982 por Takano (profesor de secundaria y compositor de canciones) y la segunda en 1896 por Störmer. El record consistió en más de un billón de cifras decimales de π.

5 . LAS FÓRMULAS DEL GENIAL MATEMÁTICO SUIZO L. EULER

Grandes matemáticos, entre ellos Leibniz y los hermanos Jacob (1654-1705) and Johann Bernoulli (1667-1748) habían intentado sin lograrlo evaluar la suma infinita

$$\frac{1}{1^2} + \frac{1}{2^2} + \frac{1}{3^2} + \frac{1}{4^2} + \frac{1}{5^2} + \cdots . \tag{16}$$

Finalmente Euler, en 1736, demostró que su valor era $\frac{\pi^2}{6}$. Para ello, partió del desarrollo en serie de la función $\frac{\operatorname{sen} x}{x}$

$$\frac{\operatorname{sen} x}{x} = 1 - \frac{x^2}{3!} + \frac{x^4}{5!} - \frac{x^6}{7!} + \cdots$$

y consideró la ecuación

$$1-\frac{x^2}{3!}+\frac{x^4}{5!}-\frac{x^6}{7!}+\cdots=0.$$

Las soluciones de esta ecuación tenían que ser las soluciones de sen$x = 0$, excepto lógicamente $x = 0$, es decir: $\pm\pi$, $\pm 2\pi$, $\pm 3\pi$, $\cdots$. Imaginó la serie infinita como si se tratase de un polinomio y procedió a descomponerlo en factores

$$1-\frac{x^2}{3!}+\frac{x^4}{5!}-\frac{x^6}{7!}+\cdots=\left(1-\frac{x^2}{\pi^2}\right)\left(1-\frac{x^2}{4\pi^2}\right)\left(1-\frac{x^2}{9\pi^2}\right)\cdots.$$

Igualando los coeficientes de x^2 obtuvo finalmente la demostración. Además, demostró muchas fórmulas parecidas, entre ellas

$$\sum_{n=1}^{\infty}\frac{1}{(2n+1)^2}=\frac{\pi^2}{8},\qquad \sum_{n=1}^{\infty}\frac{1}{n^4}=\frac{\pi^4}{90},\qquad \sum_{n=0}^{\infty}\frac{(-1)^n}{(2n+1)^3}=\frac{\pi^3}{32} \tag{17}$$

y la no tan parecida

$$\sum_{n=1}^{\infty}\frac{1+\frac{1}{2}+\frac{1}{3}+\cdots\frac{1}{n}}{n^3}=\frac{\pi^4}{72}. \tag{18}$$

Fórmulas similares a esta última se conocen hoy en día como sumas de Euler [10]. Algunas de ellas sólo se han conseguido sumar muy recientemente, como por ejemplo

$$\sum_{n=1}^{\infty}\frac{\left(1+\frac{1}{2}+\frac{1}{3}+\cdots\frac{1}{n}\right)^2}{n^2}=\frac{17\pi^4}{360} \tag{19}$$

cuya demostración se obtuvo en 1991.

Euler, en su estudio de la divergencia de los inversos de los números primos, consideró progresiones geométricas de la forma:

$$1+\frac{1}{p^2}+\frac{1}{p^4}+\frac{1}{p^6}+\frac{1}{p^8}+\cdots=\frac{1}{1-\frac{1}{p^2}},$$

y observó que multiplicando estos desarrollos para todos los primos p se obtiene

$$\sum_{n=1}^{\infty}\frac{1}{n^2}=\frac{\pi^2}{6}=\prod_{p}\left(1-\frac{1}{p^2}\right)^{-1}, \tag{20}$$

que relaciona el número π con los números primos.

6 . UN EXTRAORDINARIO ALGORITMO OLVIDADO: FÓRMULA DE C. F. GAUSS

Con tan sólo 14 años de edad, Gauss (uno de los más grandes matemáticos de todos los tiempos) considera el siguiente proceso iterativo

$$a_0 = a, \quad b_0 = b, \quad a_{n+1} = \frac{a_n + b_n}{2}, \qquad b_{n+1} = \sqrt{a_n b_n}$$

y define la media aritmético-geométrica de a y b como el límite común

$$M(a, b) = \lim a_n = \lim b_n.$$

En el año 1800 sus investigaciones sobre la media aritmético geométrica le conducen a la siguiente maravillosa fórmula (ver [1], pág. 94-102) en la cual los valores iniciales son $a_0 = 1$ y $b_0 = 1/\sqrt{2}$:

$$\sum_{k=1}^{\infty} 2^k (a_k^2 - b_k^2) = \frac{1}{2} - \frac{2}{\pi} \left[M \left(1, \frac{\sqrt{2}}{2} \right) \right]^2. \tag{21}$$

Por razones no muy claras Gauss no utilizó su fórmula para calcular π y la fórmula se olvidó hasta que en 1970 fue redescubierta de forma independiente por Eugene Salamin y Richard Brent [20] que la expresan en forma apropiada para el cálculo iterativo:

$$\lim \frac{2a_n^2}{\frac{1}{2} - \sum_{k=1}^{n} 2^k (a_k^2 - b_k^2)} = \pi.$$

Se puede demostrar que la convergencia hacia π es cuadrática, es decir al pasar de n a $n+1$ se dobla el número de decimales correctos. Brent y Salamin programan el algoritmo en un ordenador, lo que les permite conseguir en 1976 un record al calcular π con 3 millones de cifras decimales, cuando el record hasta entonces era de 1 millón de cifras decimales y se había logrado con fórmulas de tipo Machin.

7 . SERIES PARA $1/\pi$ DE UN GENIO MATEMÁTICO INCREÍBLE: S. RAMANUJAN

Gran parte de la obra del genio matemático hindú Ramanujan se relaciona con la teoría de las funciones modulares, que tiene su origen en el estudio de las integrales elípticas de primera y segunda especie

$$K(k) = \int_0^{\pi/2} \frac{1}{\sqrt{1 - k^2 \mathrm{sen}^2 t}}\, dt, \qquad E(k) = \int_0^{\pi/2} \sqrt{1 - k^2 \mathrm{sen}^2 t}\, dt.$$

En 1914 estas investigaciones le llevan a la obtención de extraordinarias series para $1/\pi$ totalmente diferentes de todas las conocidas hasta entonces y que son del tipo siguiente

$$\sum_{n=0}^{\infty} B_n z^n (bn+a) = \frac{1}{\pi},$$

siendo $b, a > 0$ y $-1 < z < 1$ números algebraicos, y que quedan clasificadas en 4 familias de acuerdo a las siguientes posibilidades de B_n

$$\frac{(2n)!^3}{n!^6}, \qquad \frac{(4n)!}{n!^4}, \qquad \frac{(2n)!(3n)!}{n!^5}, \qquad \frac{(6n)!}{(3n)!n!^3}.$$

Demuestra parcialmente fórmulas que permiten obtener las series de la primera familia [19] y da 3 ejemplos, uno de los cuales es

$$\sum_{n=0}^{\infty} \frac{(2n)!^3}{n!^6} \frac{1}{2^{12n}} (42n+5) = \frac{16}{\pi}. \tag{22}$$

Continúa diciendo que existen teorías alternativas (pero casi no da ningún detalle de ellas) con las que pueden obtenerse series pertenecientes a las otras tres familias y da 14 ejemplos [19] entre los cuales están los siguientes

$$\sum_{n=0}^{\infty} \frac{(4n)!}{n!^4} \frac{1}{396^{4n}} (26390n+1103) = \frac{9801\sqrt{2}}{4\pi}, \tag{23}$$

$$\sum_{n=0}^{\infty} \frac{(2n)!(3n)!}{n!^5} \frac{1}{1458^n} (15n+2) = \frac{27}{4\pi}, \tag{24}$$

$$\sum_{n=0}^{\infty} \frac{(6n)!}{(3n)!n!^3} \frac{1}{54000^n} (11n+1) = \frac{5\sqrt{15}}{6\pi}. \tag{25}$$

La serie (23) es increíblemente rápida ya que con ella se obtienen unos 8 decimales de π por término. En 1985 B. Gosper programa la fórmula en un ordenador, antes de que se conociera la demostración, y consigue con ella un record de 17 millones de cifras de π.

Los hermanos Jonathan and Peter Borwein son los primeros en demostrar (1985) fórmulas que permiten obtener las dos primeras familias de fórmulas de Ramanujan [3] y consiguen demostrar la identidad (23). Los hermanos David y Gregory Chudnovsky contribuyen hallando la cuarta familia [9] y como caso particular consiguen la impresionante serie, no descubierta por Ramanujan:

$$\sum_{n=0}^{\infty} \frac{(6n)!}{(3n)!n!^3} \frac{(-1)^n}{640320^{3n}} (545140134n+13591409) = \frac{\sqrt{640320^3}}{12\pi} \tag{26}$$

que aporta 15 decimales de π por término y con la cual baten records de cálculo de π en los años 1989, 1991 y 1994, este último de 4044 millones de cifras de π. Finalmente, H.H. Chan, W. C. Liaw y V. Tan hallan las fórmulas necesarias que determinan la tercera familia [7] y a partir de ellas demuestran la fórmula, tampoco descubierta por Ramanujan:

$$\sum_{n=0}^{\infty} \frac{(3n)!(2n)!}{n!^5} \frac{(-1)^n}{300^{3n}} (14151n + 827) = \frac{1500\sqrt{3}}{\pi}. \tag{27}$$

La demostración de las fórmulas correspondientes a familias de series para $1/\pi$ consiste en hallar ciertas funciones $z(q)$, $b(q)$ y $a(q)$, relacionadas con las funciones modulares elípticas, tales que

$$\sum_{n=0}^{\infty} B_n \left\{ b(q)n + a(q) \right\} z(q)^n = \frac{1}{\pi}.$$

Recientemente el autor ha conjeturado (ver [14] y [15]) que si definimos las funciones

$$S(z) = \sum_{n=0}^{\infty} B_n z^n, \qquad W(z) = \sum_{n=0}^{\infty} B_n^{'} z^n,$$

donde $B_n^{'}$ se obtiene derivando B_n respecto de n como si se tratase de una variable continua, entonces $z(q)$ es la solución de la ecuación funcional

$$q = z \exp \frac{W(z)}{S(z)}$$

y que las funciones $b(q)$ y $a(q)$ vienen dadas por

$$b = \sqrt{N} \frac{q}{zS} \frac{dz}{dq}, \qquad a = \frac{1}{S} \left[\frac{1}{\pi} - \frac{q\sqrt{N}}{S} \frac{dS}{dq} \right].$$

Esta conjetura parece estar en perfecta armonía con los resultados ya establecidos y permitiría obtener los desarrollos en series de potencias de q para $z(q)$, $S(q)$ que a su vez determinan $b(q)$ y $a(q)$. Para N racional y $q = \pm e^{-\pi\sqrt{N}}$ los valores que se obtienen para $z(q)$, $b(q)$, $a(q)$ son números algebraicos que coinciden con los ya conocidos. Por ejemplo, para

$$S(q) = \sum_{n=0}^{\infty} \frac{(6n)!}{(3n)!n!^3} z(q)^n$$

se obtienen los desarrollos

$$z = q - 744q^2 + 356652q^3 - 140361152q^4 + 49336682190q^5 - 16114625669088q^6 + \cdots$$

$$S = 1 + 120q - 6120q^2 + 737760q^3 - 107249640q^4 + 17385063120q^5 - 3014720249760q^6 + \cdots$$

que son precisamente los desarrollos de las funciones

$$z(q) = J(q)^{-1}, \qquad S(q) = \theta_3^4(q)\sqrt{1 + \mu(-q)},$$

donde

$$J(q) = \frac{16}{\mu(q)}\left\{1 + 16\mu(q)\right\}^3, \quad \mu(q) = \frac{\theta_2^4(q)\theta_3^4(q)}{\theta_4^8(q)}$$

siendo θ_2, θ_3, θ_4, las funciones elípticas θ de Jacobi, definidas mediante

$$\theta_2(q) = \sum_{n=-\infty}^{n=\infty} q^{(n+1/2)^2}, \quad \theta_3(q) = \sum_{n=-\infty}^{n=\infty} q^{n^2}, \quad \theta_4(q) = \sum_{n=-\infty}^{n=\infty} (-1)^n q^{n^2}.$$

Estas fórmulas son equivalentes a las ya obtenidas por los hermanos David and Gregory Chudnovsky que, tomando $q = -e^{-\pi\sqrt{163}}$, obtienen la serie (26) y demuestran que es la serie de tipo Ramanujan con parámetro z racional cuya velocidad de convergencia es la más rápida posible.

8 . El algoritmo cuártico de los hermanos Borwein

Las funciones

$$s(q) = \frac{\theta_2(q)}{\theta_3(q)}, \quad t(q) = \frac{1}{\pi} \cdot \frac{1}{\theta_3^4(q)}\left[1 + (4q\ln q)\frac{\theta_4'(q)}{\theta_4(q)}\right].$$

verifican las siguientes magníficas propiedades difíciles de demostrar:

$$s(q^4) = \frac{1 - [1 - s^4(q)]^{1/4}}{1 + [1 - s^4(q)]^{1/4}},$$

$$t(q^4) = [1 + s(q^4)]^4 t(q) - \frac{4\ln q}{\pi} s(q^4)[1 + s(q^4) + s(q^4)^2],$$

que relacionan valores de las funciones en q con valores en q^4, lo que nos va a permitir obtener un algoritmo cuártico [4]. En efecto, llamando

$$q = e^{-2\pi\cdot 4^n}, \quad s_n = s(q), \quad t_n = t(q)$$

y teniendo en cuenta que los valores de s_0 y t_0 son conocidos, obtenemos el siguiente algoritmo cuártico

$$s_0 = \sqrt{2} - 1, \quad t_0 = 6 - 4\sqrt{2},$$

$$s_{n+1} = \frac{1-(1-s_n^4)^{1/4}}{1+(1-s_n^4)^{1/4}}, \tag{28}$$

$$t_{n+1} = t_n(1+s_{n+1})^4 - 2^{2n+3}s_{n+1}(1+s_{n+1}+s_{n+1}^2)$$

en el cual t_n tiende a $1/\pi$, cuadruplicándose en cada iteración el número de cifras exactas. Este asombroso algoritmo fue descubierto y demostrado por los hermanos Borwein en 1987.

Podría pensarse que con los algoritmos cuadráticos, cuárticos, etc. se tendrían que lograr siempre los records de cálculo de π. Sin embargo no es así pues estos algoritmos no auto-corrigen los errores y obligan a realizar todas las operaciones con la precisión final deseada. En cambio para las series se ha encontrado la forma de ir aumentando la precisión de cálculo sin afectar el resultado final, lo que les permite batir records aún teniendo la desventaja de ser lineales.

9 . EL CÁLCULO DESORDENADO DE LAS CIFRAS DE π

En 1995 Peter Borwein y Simon Plouffe se dieron cuenta de que la serie

$$\ln 2 = \frac{1}{1\cdot 2} + \frac{1}{2\cdot 2^2} + \frac{1}{3\cdot 2^3} + \frac{1}{4\cdot 2^4} + \cdots = \sum_{n=1}^{\infty} \frac{1}{n2^n}$$

podía ser utilizada para hallar el valor de una de las cifras en binario de $\ln 2$ sin necesidad de hallar las cifras que le preceden, mediante el siguiente ingenioso esquema en el cual $\{x\}$ significa la parte fraccionaria de x:

$$\left\{2^k \ln 2\right\} = \left\{\left\{\sum_{n=0}^{k} \frac{2^{k-n}}{n}\right\} + \sum_{n=k+1}^{\infty} \frac{1}{n2^{n-k}}\right\} = \left\{\left\{\sum_{n=0}^{k} \frac{2^{k-n} \bmod n}{n}\right\} + \sum_{n=k+1}^{\infty} \frac{1}{n2^{n-k}}\right\},$$

que permite obtener de forma eficiente las cifras binarias de $\ln 2$ a partir de la posición $k+1$. La principal observación para efectuar los cálculos implicados es que el numerador de la primera suma, es decir $2^{k-n} \bmod n$, se puede evaluar con extraordinaria rapidez. Por ejemplo, el cálculo 2^{65} no requiere 65 multiplicaciones sino sólo 7 si lo realizamos en la forma $((((((2^2)^2)^2)^2)^2)^2)\cdot 2$. Teniendo en cuenta la explicación anterior podemos evaluar las operaciones de aritmética modular aplicando un algoritmo muy eficiente que para el caso particular $2^{65} \bmod 9$ consiste en hacer una reducción módulo 9 después de cada multiplicación de las 7 que se requieren en lugar de hacer todas las multiplicaciones seguidas.

En 1989 los hermanos Borwein afirmaron que obtener una cifra binaria de π no podía ser más sencillo que calcular todas las cifras que le preceden. Sin embargo, después de este descubrimiento para $\ln 2$, ya no lo tenían tan claro y el equipo formado por D. Bailey, P. Borwein y S. Plouffe se puso a buscar, con la ayuda del algoritmo PSLQ, una serie para π que permitiera el cálculo aislado de sus cifras en base 2 (ver [6], capítulo 8).

El algoritmo PSLQ es un algoritmo numérico que opera con una precisión prefijada asociando a una entrada de n elementos $x_1, x_2, \cdots, x_n$ una salida de n números enteros $a_1, a_2, \cdots, a_n$, no todos nulos, de forma que, para la precisión prefijada, se verifica

$$a_1x_1 + a_2x_2 + \cdots + a_nx_n = 0.$$

El éxito llegó al considerar los valores

$$x_j = \sum_{n=0}^{\infty} \frac{1}{(8n+j)16^n}, \qquad j = 1, 2, \cdots, 7$$

y buscar con PSLQ una relación lineal con coeficientes enteros entre las entradas π, x_1, x_2, x_3, x_4, x_5, x_6, x_7. La salida obtenida fue la sucesión de enteros: -1, 4, 0, 0, -2, -1, -1, 0. Es decir habían encontrado una serie [2] que llamaron de tipo BBP (iniciales de los nombres del equipo)

$$\pi = \sum_{n=0}^{\infty} \frac{1}{16^n}\left(\frac{4}{8n+1} - \frac{2}{8n+4} - \frac{1}{8n+5} - \frac{1}{8n+6}\right), \tag{29}$$

que permitía el cálculo desordenado de las cifras de π en hexadecimal y por lo tanto también en binario. La demostración de la fórmula se consiguió poco después a partir del sencillo resultado

$$\int_0^{1/\sqrt{2}} \frac{x^{k-1}}{1-x^8}dx = \int_0^{1/\sqrt{2}} \sum_{n=0}^{\infty} x^{k-1+8n}dx = \frac{1}{2^{k/2}} \sum_{n=0}^{\infty} \frac{1}{16^n(8n+k)}$$

que permite escribir

$$\frac{1}{16^n}\left(\frac{4}{8n+1} - \frac{2}{8n+4} - \frac{1}{8n+5} - \frac{1}{8n+6}\right) = \int_0^{1/\sqrt{2}} \frac{4\sqrt{2} - 8x^3 - 4\sqrt{2}x^4 - 8x^5}{1-x^8}dx,$$

integral que se puede evaluar fácilmente con el cambio de variable $y = x\sqrt{2}$ de la manera siguiente

$$16\int_0^1 \frac{4-2y^3-y^4-y^5}{16-y^8}dy = \int_0^1 \frac{16y-16}{(y^2-2)(y^2-2y+2)}dy = \pi.$$

Nada más anunciar la sorprendente fórmula (29) otros investigadores se lanzaron también a la caza de otras bellas fórmulas de tipo BBP. La más sencilla para π fue encontrada y demostrada por Viktor Adamchik y Stan Wagon (ver [23] pág. 66 y 67)

$$\pi = \sum_{n=0}^{\infty} \frac{(-1)^n}{4^n} \left(\frac{2}{4n+1} + \frac{2}{4n+2} + \frac{1}{4n+3} \right), \tag{30}$$

que se puede demostrar de forma similar a la anterior partiendo de la identidad

$$\int_0^{1/\sqrt{2}} \frac{x^{k-1}}{1+x^4} dx = \int_0^{1/\sqrt{2}} \sum_{n=0}^{\infty} (-1)^n x^{k-1+4n} dx = \frac{1}{2^{k/2}} \sum_{n=0}^{\infty} \frac{(-1)^n}{4^n(4n+k)}.$$

En 1997 Fabrice Bellard consigue un record de cálculo con su fórmula

$$\pi = 4 \sum_{n=0}^{\infty} \frac{(-1)^n}{4^n(2n+1)} - \frac{1}{64} \sum_{n=0}^{\infty} \frac{(-1)^n}{1024^n} \left(\frac{32}{4n+1} + \frac{8}{4n+2} + \frac{1}{4n+3} \right). \tag{31}$$

El último record es de C. Percival que ha obtenido que la cifra binaria de π que ocupa la posición 10000 billones es 0.

También se conocen fórmulas BBP para otros valores relacionados con π, por ejemplo para $\pi\sqrt{3}$

$$\pi\sqrt{3} = \frac{9}{32} \sum_{n=0}^{\infty} \frac{1}{64^n} \left(\frac{16}{6n+1} + \frac{8}{6n+2} - \frac{2}{6n+4} - \frac{1}{6n+5} \right) \tag{32}$$

y para π^2

$$\pi^2 = \frac{9}{8} \sum_{n=0}^{\infty} \frac{1}{64^n} \left(\frac{16}{(6n+1)^2} - \frac{24}{(6n+2)^2} - \frac{8}{(6n+3)^2} - \frac{6}{(6n+4)^2} + \frac{1}{(6n+5)^2} \right). \tag{33}$$

10 . BONITOS DESARROLLOS INFINITOS PARA π CON PRODUCTOS Y RADICALES

Osler, en 1999, demuestra la siguiente fórmula [17]:

$$\frac{2}{\pi} = \prod_{n=1}^{p} \sqrt{\frac{1}{2} + \frac{1}{2}\sqrt{\frac{1}{2} + \frac{1}{2}\sqrt{\frac{1}{2} + \overset{n}{\cdots} + \frac{1}{2}\sqrt{\frac{1}{2}}}}} \cdot \prod_{n=1}^{\infty} \frac{2^{p+1}n-1}{2^{p+1}n} \cdot \frac{2^{p+1}n+1}{2^{p+1}n}, \tag{34}$$

donde la n en el interior de las raíces denota el número de sumandos. Esta fórmula engloba la fórmula de Viète (2) ($p = \infty$); el producto de Wallis (3) ($p = 0$) y también fórmulas nuevas. Por ejemplo tomando $p = 2$ se tiene

$$\frac{2}{\pi} = \sqrt{\frac{1}{2}}\sqrt{\frac{1}{2}+\frac{1}{2}\sqrt{\frac{1}{2}}} \cdot \frac{7\cdot 9}{8\cdot 8} \cdot \frac{15\cdot 17}{16\cdot 16} \cdot \frac{23\cdot 25}{24\cdot 24} \cdot \frac{31\cdot 33}{32\cdot 32} \cdots . \tag{35}$$

Para llegar a su expresión para π, Osler, partiendo del seno de x, aplica p veces, de forma reiterada, la fórmula del seno del ángulo doble:

$$\operatorname{sen} x = 2\cos\frac{x}{2}\operatorname{sen}\frac{x}{2} = 2^2\cos\frac{x}{2}\cos\frac{x}{2^2}\operatorname{sen}\frac{x}{2^2} = 2^p\cos\frac{x}{2}\cos\frac{x}{2^2}\cdots\cos\frac{x}{2^p}\operatorname{sen}\frac{x}{2^p}$$

y sustituye $t = \frac{x}{2^p}$ en la fórmula de Euler

$$\frac{\operatorname{sen} t}{t} = \prod_{n=1}^{\infty}\left(1-\frac{t^2}{\pi^2 n^2}\right) = \prod_{n=1}^{\infty}\left(\frac{n\pi - t}{n\pi}\cdot\frac{n\pi + t}{n\pi}\right)$$

lo que le permite combinar las dos fórmulas anteriores para llegar a

$$\frac{\operatorname{sen} x}{x} = \cos\frac{x}{2}\cos\frac{x}{2^2}\cdots\cos\frac{x}{2^p}\cdot\prod_{n=1}^{\infty}\left(\frac{2^p n\pi - x}{2^p n\pi}\cdot\frac{2^p n\pi + x}{2^p n\pi}\right).$$

Para terminar utiliza las siguientes relaciones de trigonometría elemental

$$\cos\frac{x}{2} = \sqrt{\frac{1}{2}+\frac{1}{2}\cos x}, \qquad \cos\frac{x}{2^2} = \sqrt{\frac{1}{2}+\frac{1}{2}\sqrt{\frac{1}{2}+\frac{1}{2}\cos x}}, \qquad \cdots$$

y sustituye $x = \frac{\pi}{2}$.

J. Sondow obtiene en 2002 otra bonita expresión con productos y radicales [21]:

$$\frac{\pi}{2} = \prod_{n=0}^{\infty}\left[1^{(-1)^1\binom{n}{0}}\cdot 2^{(-1)^2\binom{n}{1}}\cdots(n+1)^{(-1)^{n+1}\binom{n}{n}}\right]^{\frac{1}{2^n}} \tag{36}$$

Para ello comienza tomando logaritmos en el producto de Wallis:

$$\ln\frac{\pi}{2} = \sum_{k=1}^{\infty}(-1)^{k-1}\ln\frac{k+1}{k}.$$

Teniendo en cuenta que $\sum_{n\geq k}\frac{\binom{n}{k}}{2^{n+1}} = 1$, podemos continuar de la siguiente manera

$$\ln\frac{\pi}{2} = \sum_{k\geq 1}(-1)^{k-1}\ln\frac{k+1}{k}\sum_{n\geq k}\frac{\binom{n}{k}}{2^{n+1}} = \sum_{n=0}^{\infty}\frac{1}{2^{n+1}}\sum_{k=0}^{n}(-1)^k\binom{n}{k}\ln\frac{k+2}{k+1}.$$

En la última expresión reemplaza n con $n-1$, escribe el logaritmo como $\ln(k+2)-\ln(k+1)$ y la suma sobre k como la diferencia de dos sumas, en la primera de las cuales reemplaza k con $k-1$. Aplicando la relación binomial $\binom{n-1}{k-1}+\binom{n-1}{k}=\binom{n}{k}$ llega al resultado mediante exponenciación.

11 . RESULTADOS MUY RECIENTES: SERIES PARA $1/\pi$, $1/\pi^2$ Y $1/\pi^3$

T. Sato, en una conferencia en Japón en 2002, presenta la serie

$$\sum_{n=0}^{\infty} u_n \left(\frac{\sqrt{5}-1}{2}\right)^{12n} (20n+10-3\sqrt{5}) = \frac{20\sqrt{3}+9\sqrt{15}}{6\pi}, \tag{37}$$

siendo u_n los números de Apéry, definidos mediante

$$u_n = \sum_{k=0}^{n} \binom{n}{k}^2 \binom{n+k}{k}^2.$$

Poco después se encuentran series de este estilo con otros tipos de números [8], [22], por ejemplo con los números de Domb; H. H. Chan y Y. Yang desarrollan independientemente una teoría explicativa de este tipo de fórmulas que incluye también como caso particular a las de tipo Ramanujan y les dan el nombre de fórmulas de tipo Ramanujan-Sato.

Una explicación radicalmente diferente para algunas fórmulas de tipo Ramanujan, que no hace uso de la teoría de funciones modulares, se basa en el método WZ de Herb Wilf y Doron Zeilberger [18] que permite demostrar automáticamente identidades de la forma

$$\sum_{n=0}^{\infty} G(n,k) = \text{Constante}$$

en el caso en que la función $G(n,k)$ sea hipergeométrica en sus dos variables, es decir si los cocientes $G(n+1,k)/G(n,k)$ y $G(n,k+1)/G(n,k)$ son funciones racionales. El programa EKHAD escrito por D. Zeilberger realiza el trabajo duro encontrando a la función $G(n,k)$ una compañera $F(n,k)$ tal que $F(0,k)=0$ y con la cual forma un par de Wilf y Zeilberger (WZ), es decir, un par que se caracteriza por la propiedad

$$F(n+1,k)-F(n,k)=G(n,k+1)-G(n,k).$$

Además Zeilberger ha demostrado que si definimos $H(n,k)=F(n+1,n+k)+G(n,n+k)$, entonces obtenemos una identidad asociada a la de partida

$$\sum_{n=0}^{\infty} H(n,k) = \sum_{n=0}^{\infty} G(n,k) = \text{Constante}.$$

Es importante señalar que el método WZ es un método simbólico y no numérico como el algoritmo PSLQ (ver sección 9), por lo que las demostraciones que se obtienen son completamente rigurosas. El precio a pagar es la dificultad de encontrar funciones interesantes que sean una componente de un par.

Un tipo de identidades descubiertas por el autor [13], entre las que se encuentran

$$\sum_{n=0}^{\infty} \frac{1}{2^{8n}2^{4k}} \frac{\binom{2n}{n}^3 \binom{2k}{k}^2}{\binom{n+k}{k}^2} (6n+4k+1) = \frac{4}{\pi}, \tag{38}$$

$$\sum_{n=0}^{\infty} \frac{(-1)^n}{2^{12n}2^{8k}} \frac{\binom{2n}{n}^5 \binom{2k}{k}^4}{\binom{n+k}{k}^4} (20n^2+8n+1+24kn+8k^2+4k) = \frac{8}{\pi^2} \tag{39}$$

son aptas para la demostración automática con EKHAD. Para ver en que consiste el método WZ, explicamos a continuación con detalle la demostración de la identidad (38) basada en dicho método: A la función

$$G(n,k) = \frac{1}{2^{8n}2^{4k}} \frac{\binom{2n}{n}^3 \binom{2k}{k}^2}{\binom{n+k}{k}^2} (6n+4k+1),$$

EKHAD le encuentra una compañera

$$F(n,k) = \frac{1}{2^{8n}2^{4k}} \frac{\binom{2n}{n}^3 \binom{2k}{k}^2}{\binom{n+k}{k}^2} 8n$$

con la que forma un par WZ, es decir que verifica

$$F(n+1,k) - F(n,k) = G(n,k+1) - G(n,k),$$

propiedad qué tiene la siguiente consecuencia

$$\sum_{n=0}^{\infty} [G(n,k+1) - G(n,k)] = \sum_{n=0}^{\infty} [F(n+1,k) - F(n,k)] = -F(0,k) = 0.$$

Por lo tanto

$$\sum_{n=0}^{\infty} G(n,0) = \sum_{n=0}^{\infty} G(n,1) = \sum_{n=0}^{\infty} G(n,2) = \cdots .$$

Pero

$$\mathop{\mathrm{lím}}_{k\to\infty} \sum_{n=0}^{\infty} G(n,k) = \mathop{\mathrm{lím}}_{k\to\infty} G(0,k) + \mathop{\mathrm{lím}}_{k\to\infty} \sum_{n=1}^{\infty} G(n,k) = \mathop{\mathrm{lím}}_{k\to\infty} \frac{\binom{2k}{k}^2}{2^{4k}} (4k+1) = \frac{4}{\pi}.$$

Así que

$$\sum_{n=0}^{\infty} G(n,0) = \sum_{n=0}^{\infty} G(n,1) = \sum_{n=0}^{\infty} G(n,2) = \cdots = \frac{4}{\pi}.$$

Más aún, aplicando un teorema de Carlson se deduce que

$$\sum_{n=0}^{\infty} G(n,k) = \frac{4}{\pi}$$

incluso para valores no enteros de k. Sustituyendo $k=0$ en la identidad (38) y en su asociada, obtenemos las series de Ramanujan

$$\sum_{n=0}^{\infty} \frac{(2n)!^3}{n!^6} \frac{1}{2^{8n}} (6n+1) = \frac{1}{4} \sum_{n=0}^{\infty} \frac{(2n)!^3}{n!^6} \frac{1}{2^{12n}} (42n+5) = \frac{4}{\pi}. \tag{40}$$

Para la función $G(n,k)$ en la serie (39), EKHAD encuentra su compañera

$$F(n,k) = \frac{(-1)^n}{2^{12n} 2^{8k}} \frac{\binom{2n}{n}^5 \binom{2k}{k}^4}{\binom{n+k}{k}^4} \cdot 8n(2n+4k+1),$$

y podemos decir que la demostración de (39) está encapsulada en dicho par $F(n,k)$, $G(n,k)$. Sustituyendo $k=0$ en la identidad (39) y en su asociada, obtenemos las nuevas fórmulas [11], [13]:

$$\sum_{n=0}^{\infty} \frac{(2n)!^5}{n!^{10}} \frac{(-1)^n}{2^{12n}} (20n^2+8n+1) = \frac{1}{16} \sum_{n=0}^{\infty} \frac{(2n)!^5}{n!^{10}} \frac{(-1)^n}{2^{20n}} (820n^2+180n+13) = \frac{8}{\pi^2}. \tag{41}$$

Con el algoritmo PSLQ el autor consigue encontrar más series de este estilo para $1/\pi^2$ [12], por ejemplo

$$\sum_{n=0}^{\infty} \frac{(6n)!}{n!^6} \frac{(-1)^n}{2880^{3n}} (5418n^2 + 693n + 29) = \frac{128\sqrt{5}}{\pi^2}, \tag{42}$$

para las que todavía no se conoce la demostración. En [14] se encuentran de nuevo las mismas series a partir de una conjetura.

B. Gourevitch, haciendo uso del algoritmo PSLQ, encuentra una serie para $1/\pi^3$ [12]

$$\sum_{n=0}^{\infty} \frac{(2n)!^7}{n!^{14}} \frac{1}{2^{20n}} (168n^3 + 76n^2 + 14n + 1) = \frac{32}{\pi^3} \tag{43}$$

que tampoco ha podido ser demostrada todavía.

W. Zudilin, mediante transformaciones cuadráticas de las identidades (41) demuestra las nuevas identidades [24]

$$\sum_{n=0}^{\infty} w_n \frac{(4n)!}{n!^2(2n)!}(18n^2-10n-3)\frac{1}{(2^8 5^2)^n} = \frac{10\sqrt{5}}{\pi^2}, \tag{44}$$

$$\sum_{n=0}^{\infty} w_n \frac{(4n)!}{n!^2(2n)!}(1046529n^2+227104n+16032)\frac{1}{(5^4 41^2)^n} = \frac{5^4 41\sqrt{41}}{\pi^2}, \tag{45}$$

siendo w_n los números definidos por

$$w_n = \sum_{k=0}^{n} \binom{2k}{k}^3 \binom{2n-2k}{n-k} 2^{4(n-k)}$$

y con estas fórmulas damos por concluido nuestro recorrido histórico.

AGRADECIMIENTO al profesor D. Javier Cilleruelo por sus valiosas sugerencias y comentarios.

24.3 Aplicación de la ley de Gauss a varias distribuciones de carga

Como se mencionó, la ley de Gauss es útil para determinar campos eléctricos cuando la distribución de carga está caracterizada por un alto grado de simetría. Los ejemplos siguientes muestran cómo escoger la superficie gaussiana que permita simplificar la integral de superficie dad por en la ecuación 24.6 y determinar el campo eléctrico. Al seleccionar la superficie, siempre debe aprovechar la simetría de la distribución de la carga de manera que retire a E de la integral y la resuelva. El objetivo en este tipo de cálculo es encontrar una superficie para la que cada parte de la superficie satisfaga una o más de las condiciones siguientes:

1. Demostrar por simetría que el valor del campo eléctrico es constante sobre la porción de superficie.
2. Que el producto punto de la ecuación 24.6 se expresa como un producto algebraico simple $\vec{\mathbf{E}}$, ya que $d\vec{\mathbf{A}}$ son paralelos entre sí.
3. Que el producto punto de la ecuación 24.6 sea cero, ya que $\vec{\mathbf{E}}$ y $d\vec{\mathbf{A}}$ son perpendiculares entre sí.
4. Que el campo eléctrico es igual a cero sobre la porción de superficie.

Diferentes porciones de la superficie gaussiana puedan satisfacer varias condiciones en tanto que cada porción satisfaga al menos una condición. Estas cuatro condiciones son utilizadas en los ejemplos del resto de este capítulo y serán identificadas por su número. Si la distribución de carga no tiene simetría suficiente para que una superficie gaussiana que satisfaga estas condiciones se pueda encontrar, la ley de Gauss sigue siendo cierta, pero no es útil para determinar el campo eléctrico para esta distribución de carga.

Prevención de riesgos ocultos 24.2

Las superficies gaussianas no son reales La superficie gaussiana es una superficie imaginaria que se elige para satisfacer las condiciones mencionadas en este caso. No tiene que coincidir con una superficie física en una situación determinada.

Ejemplo 24.3 Distribución de carga para una simetría esférica

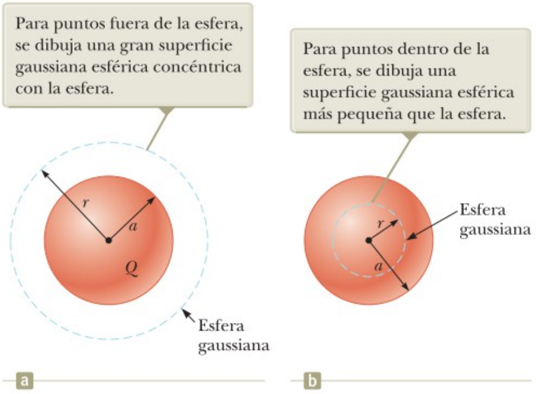
Una esfera sólida aislante con radio a tiene una densidad de carga volumétrica uniforme ρ y una carga positiva total Q (figura 24.10).

(A) Calcule la magnitud del campo eléctrico en un punto fuera de la esfera.

SOLUCIÓN

Conceptualizar Observe cómo difiere este problema de la explicación anterior de la ley de Gauss. El campo eléctrico debido a cargas puntuales se explicó en la sección 24.2. Ahora se considera el campo eléctrico debido a una distribución de carga. En el capítulo 23 encontró el campo para varias distribuciones de carga, al integrar sobre la distribución. Este ejemplo muestra una diferencia con nuestra discusión en el capítulo 23. En este capítulo debe encontrar el campo eléctrico mediante la ley de Gauss.

Categorizar Puesto que la distribución de la carga es uniforme en toda la esfera, la distribución de carga tiene simetría esférica y se puede aplicar la ley de Gauss para hallar el campo eléctrico.



Para puntos fuera de la esfera, se dibuja una gran superficie gaussiana esférica concéntrica con la esfera.
r
a
Q
Esfera gaussiana
a
Para puntos dentro de la esfera, se dibuja una superficie gaussiana esférica más pequeña que la esfera.
r
a
Esfera gaussiana
b

Figura 24.10 (Ejemplo 24.3) Esfera aislante con carga uniforme de radio a y carga total Q. En diagramas como éste, la línea discontinua representa la intersección de la superficie gaussiana con el plano de la página.

Analizar Para reflejar la simetría esférica, elija una superficie gaussiana esférica de radio r, concéntrica con la esfera, como se muestra en la figura 24.10a. Para esta elección, la condición (2) se satisface en cualquier parte sobre la superficie y $\vec{\mathbf{E}} \cdot d\vec{\mathbf{A}} = E\,dA$.

continúa

24.3 continuación

Sustituya $\vec{\mathbf{E}} \cdot d\vec{\mathbf{A}}$ en la ley de Gauss con $E\,dA$:

$$\Phi_E = \oint \vec{\mathbf{E}} \cdot d\vec{\mathbf{A}} = \oint E\,dA = \frac{Q}{\epsilon_0}$$

Por simetría, E es constante en todas partes sobre la superficie, lo que satisface la condición (1), de modo que se puede retirar E de la integral:

$$\oint E\,dA = E\oint dA = E(4\pi r^2) = \frac{Q}{\epsilon_0}$$

Al resolver para E:

$$(1)\quad E = \frac{Q}{4\pi\epsilon_0 r^2} = \boxed{k_e\frac{Q}{r^2}\quad (\text{para } r > a)}$$

Finalizar Este campo es idéntico al de una carga puntual. Por lo tanto, **el campo eléctrico debido a una esfera con carga uniforme en la región externa a la esfera es *equivalente* a una carga puntual ubicada en el centro de la esfera.**

(B) Encuentre la magnitud del campo eléctrico en un punto dentro de la esfera.

SOLUCIÓN

Analizar En este caso, elija una superficie gaussiana esférica que tenga radio $r < a$, concéntrica con la esfera aislante (figura 24.10b). Sea V' el volumen de esta esfera más pequeña. Para aplicar la ley de Gauss en esta situación, considere que la carga q_{int} dentro de la superficie gaussiana de volumen V' es menor que Q.

Calcule q_{int} usando $q_{\text{int}} = \rho V'$:

$$q_{\text{int}} = \rho V' = \rho\left(\tfrac{4}{3}\pi r^3\right)$$

Observe que las condiciones (1) y (2) se satisfacen en todas partes sobre la superficie gaussiana en la figura 24.10b. Aplique la ley de Gauss en la región $r < a$:

$$\oint E\,dA = E\oint dA = E(4\pi r^2) = \frac{q_{\text{in}}}{\epsilon_0}$$

Resuelva para E y sustituya para q_{int}:

$$E = \frac{q_{\text{int}}}{4\pi\epsilon_0 r^2} = \frac{\rho\left(\frac{4}{3}\pi r^3\right)}{4\pi\epsilon_0 r^2} = \frac{\rho}{3\epsilon_0}r$$

Sustituya $\rho = Q/\frac{4}{3}\pi a^3$ y $\epsilon_0 = 1/4\pi k_e$:

$$(2)\quad E = \frac{Q/\frac{4}{3}\pi a^3}{3(1/4\pi k_e)}r = \boxed{k_e\frac{Q}{a^3}r\quad (\text{para } r < a)}$$

Finalizar Este resultado para E difiere del obtenido en el inciso (A). Muestra que $E \to 0$ cuando $r \to 0$. Por lo tanto, el resultado elimina el problema que existiría en $r = 0$ si E variara como $1/r^2$ dentro de la esfera como lo hace afuera de la esfera. Es decir: si $E \propto 1/r^2$ para $r < a$, el campo sería infinito en $r = 0$, lo que es físicamente imposible.

¿QUÉ PASARÍA SI? Suponga que la posición radial $r = a$ se alcanza desde adentro de la esfera y desde el exterior. ¿Se obtiene el mismo valor del campo eléctrico desde ambas direcciones?

Respuesta La ecuación (1) muestra que el campo eléctrico se aproxima a un valor desde el exterior dado por

$$E = \lim_{r \to a}\left(k_e\frac{Q}{r^2}\right) = k_e\frac{Q}{a^2}$$

Desde el interior, la ecuación (2) da

$$E = \lim_{r \to a}\left(k_e\frac{Q}{a^3}r\right) = k_e\frac{Q}{a^3}a = k_e\frac{Q}{a^2}$$

Por lo tanto, el valor del campo es el mismo, aunque se llegue a la superficie desde ambas direcciones. En la figura 24.11 se muestra una gráfica de E en función de r. Observe que la magnitud del campo es continua.

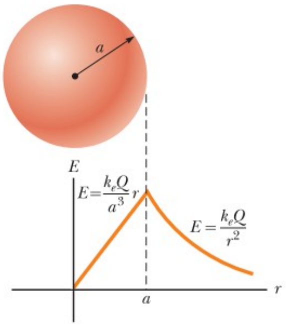


Figura 24.11 (Ejemplo 24.3) Gráfica de E en función de r para una esfera aislante con carga uniforme. El campo eléctrico dentro de la esfera ($r < a$) varía linealmente con r. El campo afuera de la esfera ($r > a$) es el mismo que el de una carga puntual Q ubicada en $r = 0$.

Ejemplo 24.4 Distribución de carga con simetría cilíndrica

Encuentre el campo eléctrico a una distancia r de una línea de carga positiva de longitud infinita y carga constante por unidad de longitud λ (figura 24.12a).

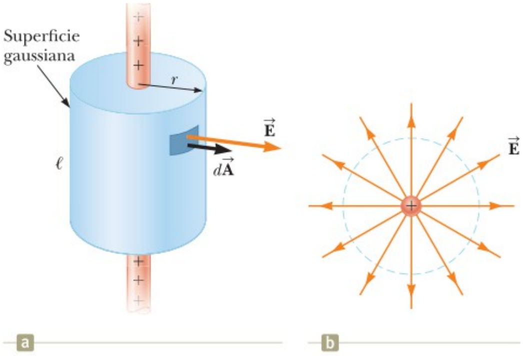

Figura 24.12 (Ejemplo 24.4) (a) Línea infinita de carga rodeada por una superficie gaussiana cilíndrica concéntrica con la línea. (b) Una vista lateral muestra que el campo eléctrico en la superficie cilíndrica es constante en magnitud y perpendicular a la superficie.

SOLUCIÓN

Conceptualizar La línea de carga es *infinitamente* larga. Por consiguiente, el campo es el mismo en todos los puntos equidistantes de la línea, sin importar la posición vertical del punto en la figura 24.12a. Esperamos que el campo sea más débil a medida que nos alejamos de la línea de carga.

Categorizar Ya que la carga está distribuida uniformemente a lo largo de la línea, la distribución de carga tiene simetría cilíndrica y se puede aplicar la ley de Gauss para encontrar el campo eléctrico.

Analizar La simetría de la distribución de carga requiere que $\vec{\mathbf{E}}$ sea perpendicular a la línea de carga y dirigida hacia fuera, como se muestra en las figuras 24.12b. Para reflejar la simetría de la distribución de carga, elija una superficie gaussiana cilíndrica de radio r y longitud ℓ que sea coaxial con la línea de carga. Para la parte curva de esta superficie, $\vec{\mathbf{E}}$ es constante en magnitud y perpendicular a la superficie en cada punto, lo que satisface las condiciones (1) y (2). Además, el flujo a través de los extremos del cilindro gaussiano es cero porque $\vec{\mathbf{E}}$ es paralelo a estas superficies. Ésta es la primera aplicación de la condición (3).

Debe tomar la integral de superficie en la ley de Gauss sobre toda la superficie gaussiana. Sin embargo, ya que $\vec{\mathbf{E}} \cdot d\vec{\mathbf{A}}$ es cero para los extremos planos del cilindro, restrinja la atención sólo a la superficie curva del cilindro.

Aplique la ley de Gauss y las condiciones (1) y (2) para la superficie curva, y note que la carga total dentro de la superficie gaussiana es $\lambda\ell$:

$$\Phi_E = \oint \vec{\mathbf{E}} \cdot d\vec{\mathbf{A}} = E \oint dA = EA = \frac{q_{\text{int}}}{\epsilon_0} = \frac{\lambda \ell}{\epsilon_0}$$

Sustituya el área $A = 2\pi r\ell$ de la superficie curva:

$$E(2\pi r \ell) = \frac{\lambda \ell}{\epsilon_0}$$

Resuelva para la magnitud del campo eléctrico:

$$E = \frac{\lambda}{2\pi\epsilon_0 r} = \boxed{2k_e \frac{\lambda}{r}} \qquad \textbf{(24.7)}$$

Finalizar Este resultado muestra que el campo eléctrico debido a una distribución de carga con simetría cilíndrica varía como $1/r$, mientras que el campo externo a una distribución de carga con simetría esférica varía como $1/r^2$. La ecuación 24.7 también se puede deducir mediante integración directa sobre la distribución de carga. (Véase el problema 44 del capítulo 23.)

¿QUÉ PASARÍA SI? ¿Y si el segmento de línea en este ejemplo no fuese infinitamente largo?

Respuesta Si la línea de carga de este ejemplo tuviese longitud finita, el campo eléctrico no se conocería por la ecuación 24.7. Una línea de carga finita no tiene suficiente simetría para utilizar la ley de Gauss, porque la magnitud del campo eléctrico ya no es constante sobre la superficie del cilindro gaussiano: el campo cerca de los extremos de la línea sería diferente de los que se encuentren lejos de los extremos. Por lo tanto, la condición (1) no se satisfaría en esta situación. Además, $\vec{\mathbf{E}}$ no es perpendicular a la superficie cilíndrica en todos los puntos: los vectores de campo cerca de los extremos tendrían una componente paralela a la línea. Por consiguiente, la condición (2) no se satisfaría. Para puntos cerca de una línea de carga finita y lejos de los extremos, la ecuación 24.7 da una buena aproximación del valor del campo.

Se le deja demostrar (véase el problema 33) que el campo eléctrico dentro de una barra de radio finito y longitud infinita, con carga uniforme, es proporcional a r.

Ejemplo 24.5 Un plano de carga

Encuentre el campo eléctrico debido a un plano infinito de carga positiva con densidad de carga superficial uniforme σ.

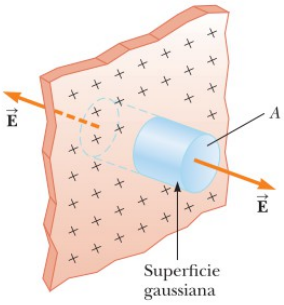

Figura 24.13 (Ejemplo 24.5) Superficie gaussiana cilíndrica que penetra un plano infinito de carga. El flujo es EA a través de cada extremo de la superficie gaussiana y cero a través de su superficie curva.

SOLUCIÓN

Conceptualizar Observe que el plano de carga es *infinitamente* largo. Por lo tanto, el campo eléctrico debe ser el mismo en todos los puntos equidistantes al plano. ¿Cómo esperaría que el campo eléctrico dependa de la distancia al plano?

Categorizar Ya que la carga se distribuye de manera uniforme sobre el plano, la distribución de carga es simétrica; en consecuencia, se puede usar la ley de Gauss para encontrar el campo eléctrico.

Analizar Por simetría, $\vec{\mathbf{E}}$ debe ser perpendicular al plano en todos los puntos. La dirección de $\vec{\mathbf{E}}$ se aleja de las cargas positivas, lo que indica que la dirección de $\vec{\mathbf{E}}$ en un lado del plano debe ser opuesta a su dirección sobre el otro lado, como se muestra en la figura 24.13. Una superficie gaussiana que refleja la simetría es un pequeño cilindro cuyo eje es perpendicular al plano y cada uno de sus extremos tiene un área A y son equidistantes del plano. Ya que $\vec{\mathbf{E}}$ es paralelo a la superficie curva, y debido a eso perpendicular a $d\vec{\mathbf{A}}$ en todos los puntos sobre la superficie, la condición (3) se satisface y no hay aportación a la integral de superficie por parte de esta superficie. Para los extremos planos del cilindro, se satisfacen las condiciones (1) y (2). El flujo a través de cada extremo del cilindro es EA; por esto, el flujo total a través de toda la superficie gaussiana es justo el que atraviesa los extremos, $\Phi_E = 2EA$.

Escriba la ley de Gauss para esta superficie y observe que la carga encerrada es $q_{\text{int}} = \sigma A$:

$$\Phi_E = 2EA = \frac{q_{\text{int}}}{\epsilon_0} = \frac{\sigma A}{\epsilon_0}$$

Resuelva para E:

$$E = \boxed{\frac{\sigma}{2\epsilon_0}} \qquad \textbf{(24.8)}$$

Finalizar Ya que la distancia desde cada extremo plano del cilindro al plano no aparece en la ecuación 24.8, se concluye que $E = \sigma/2\epsilon_0$ en *cualquier* distancia desde el plano. Es decir: el campo es uniforme en todas partes. La figura 24.14 muestra este campo eléctrico uniforme debido a un plano infinito de carga, visto de perfil.

¿QUÉ PASARÍA SI? Suponga que dos planos infinitos de carga son mutuamente paralelos, uno con carga positiva y el otro con carga negativa. Ambos planos tienen la misma densidad de carga superficial. ¿En esta situación a qué se parece el campo eléctrico?

Respuesta En primer lugar, abordamos esta configuración en la sección **¿Qué pasaría si?** del ejemplo 23.9. Los campos eléctricos debidos a los dos planos se suman en la región entre los planos, lo que resulta en un campo uniforme de magnitud σ/ϵ_0, y se cancela en otra parte para dar un campo de cero. La figura 24.15 muestra las líneas de campo para tal configuración. Este método es una forma práctica de lograr campos eléctricos uniformes con planos de tamaño finito colocados uno cerca del otro.

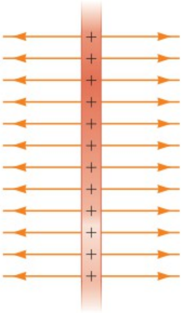

Figura 24.14 (Ejemplo 24.5) Líneas de campo eléctrico debidas a un plano infinito de carga positiva.

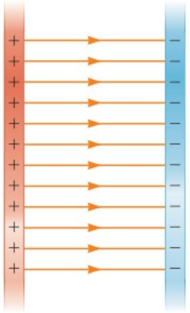

Figura 24.15 (Ejemplo 24.5) Líneas de campo eléctrico entre dos planos infinitos de carga, uno positivo y otro negativo. En la práctica, las líneas de campo cerca de los bordes de las hojas de tamaño finito de carga se curvan hacia fuera.

Ejemplo conceptual 24.6 ¡En este caso no utilice la ley de Gauss!

Explique por qué no es posible utilizar la ley de Gauss para calcular el campo eléctrico cercano a un dipolo eléctrico, a un disco con carga o a un triángulo con una carga puntual en cada vértice.

24.6 continuación

SOLUCIÓN

Las distribuciones de carga de todas estas configuraciones no tienen una simetría suficiente que haga práctico el uso de la ley gaussiana. En este caso no es posible encontrar una superficie cerrada que rodee a cualquiera de las distribuciones y satisfaga una o más de las cuatro condiciones mencionadas al principio de esta sección.

24.4 Conductores en equilibrio electrostático

Como aprendió en la sección 23.2, un buen conductor eléctrico contiene cargas (electrones) que no se encuentran unidas a ningún átomo y debido a eso tienen la libertad de moverse en el interior del material. Cuando dentro de un conductor no existe ningún movimiento neto de carga, el conductor está en **equilibrio electrostático.** Un conductor en equilibrio electrostático tiene las siguientes propiedades:

Propiedades de un conductor en equilibrio electrostático.

1. En el interior del conductor el campo eléctrico es cero, si el conductor es sólido o hueco.
2. Si un conductor aislado tiene carga, ésta reside en su superficie.
3. El campo eléctrico justo fuera de un conductor con carga es perpendicular a la superficie del conductor y tiene una magnitud σ/ϵ_0, donde σ es la densidad de carga superficial en ese punto.
4. En un conductor de forma irregular, la densidad de carga superficial es máxima en aquellos puntos donde el radio de curvatura de la superficie es menor.

En el análisis siguiente se comprueban las primeras tres propiedades. Se presenta la cuarta propiedad para tener una lista completa de las mismas para conductores en equilibrio electrostático (pero esta última no podrá ser comprobada sino hasta el capítulo 25.)

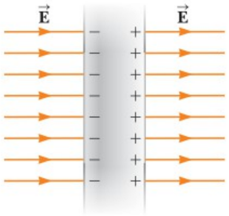

Figura 24.16 Placa conductora en un campo eléctrico externo $\vec{\mathbf{E}}$. Las cargas inducidas sobre las dos superficies de la placa producen un campo eléctrico que se opone al campo externo, lo que produce en el interior de la placa un campo eléctrico resultante igual a cero.

Es posible comprender la primera propiedad considerando una placa conductora colocada en un campo eléctrico externo $\vec{\mathbf{E}}$ (figura 24.16). El campo eléctrico en el interior del conductor *debe ser* igual a cero bajo la hipótesis de que existe equilibrio electrostático. En caso de que el campo no sea cero, los electrones libres en el interior del conductor experimentarían una fuerza eléctrica ($\vec{\mathbf{F}} = q\vec{\mathbf{E}}$) y, debido a ella, se acelerarían. Sin embargo, este movimiento de electrones significaría que el conductor no está en equilibrio electrostático. Por lo tanto, la existencia de un equilibrio electrostático es consistente solamente cuando se tiene un campo cero dentro del conductor.

Vea cómo se da este campo cero. Antes de aplicar el campo externo, en todo el volumen del conductor están distribuidos electrones libres de manera uniforme. Al aplicar el campo externo, los electrones libres se aceleran hacia la izquierda, como se ve en la figura 24.16, lo que genera un plano con carga negativa que se acumula en la superficie izquierda. El movimiento de los electrones hacia la izquierda causa un plano de carga positiva en la superficie derecha. Estos planos de carga crean un campo eléctrico adicional en el interior del conductor que se opone al campo externo. Conforme se mueven los electrones, las densidades de carga superficial de las superficies izquierda y derecha se incrementan hasta que la magnitud del campo interno es igual a la magnitud del externo, lo que resulta en un campo eléctrico cero en el interior del conductor. El tiempo que necesita un buen conductor para alcanzar el equilibrio es del orden de 10^{-16} s, lo que para la mayor parte de los efectos se considera instantáneo.

Si el conductor es hueco, el campo eléctrico dentro del conductor también es cero, ya sea que considere puntos en el conductor o en la cavidad dentro del conductor. El valor cero del campo eléctrico en la cavidad es más fácil de argumentar con el concepto de potencial eléctrico, así que este tema se abordará en la sección 25.6.

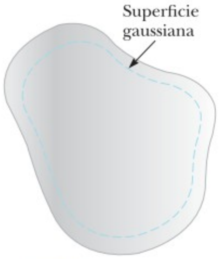

Figura 24.17 Conductor con forma arbitraria. La línea discontinua representa una superficie gaussiana que puede estar justo adentro de la superficie del conductor.

Es posible utilizar la ley de Gauss para verificar la segunda propiedad de un conductor en equilibrio electrostático. La figura 24.17 muestra un conductor de forma arbitraria. Se ha dibujado una superficie gaussiana en el interior del conductor, que quede

Parallel Projection

In the course of this chapter, we will need to use a few properties of parallelograms. It is rather common to confuse the properties of a parallelogram with its definition, so first, recall the definition of a parallelogram.

Definition 12.1 A *parallelogram* is a simple quadrilateral whose opposite sides are parallel.

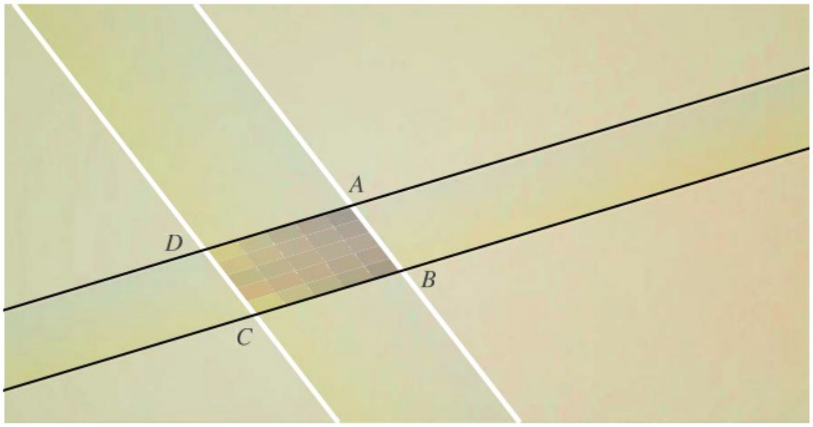

Figure 1. A parallelogram.

Now on to the properties of parallelograms that we will need for this chapter.

Exercise 12.1 Prove that in a parallelogram, the two pairs of opposite sides are congruent and the two pairs of opposite angles are congruent.

Exercise 12.2 Prove that if a convex quadrilateral has one pair of opposite sides that are both parallel and congruent, then it is a parallelogram.

Exercise 12.3 Let $\square ABB'A'$ be a simple quadrilateral. Verify that if AA' and BB' are parallel, but AB and $A'B'$ are not, then AA' and BB' cannot be congruent.

12.1 Parallel projection

The purpose of this chapter is to introduce a mechanism called *parallel projection*, a particular kind of mapping from the points on one line to the points on another. Parallel projection is the piece of machinery that you have to have in place to understand similarity, which is in turn essential for much of what we will be doing in the next chapters. The primary goal at this point is to understand how distances between points may be distorted by the parallel projection mapping. Once that is figured out, we will be able to turn our attention to the geometry of similarity.

Definition 12.2 A *parallel projection* from one line ℓ to another ℓ' is a map $\Phi : \ell \to \ell'$ that assigns to each point P on ℓ a point $\Phi(P)$ on ℓ' so that all the lines connecting a point and its image are parallel to one another.

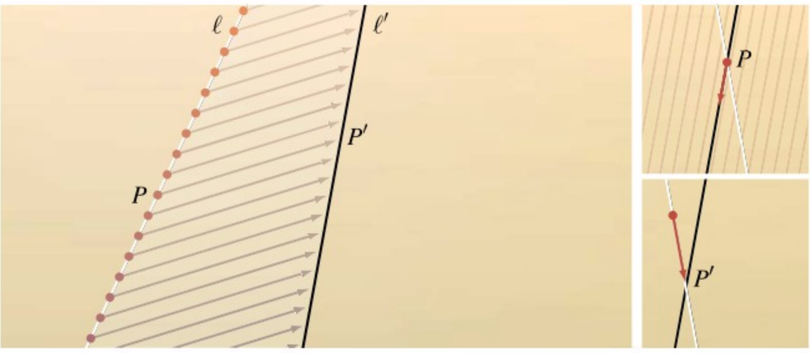

Figure 2. The path from a point P on ℓ to a point P' on ℓ' defines a parallel projection as long as neither P nor P' is the intersection of ℓ and ℓ' (as shown at right).

It is easy to construct parallel projections. Any point P on ℓ and its image $\Phi(P)$ on ℓ' completely determines the projection: for any other point Q on ℓ there is a unique line that passes through Q and is parallel to $\overline{P\,\Phi(P)}$. Wherever the line intersects ℓ' will have to be $\Phi(Q)$. There are only two cases where this construction will not work: if P is the intersection of ℓ and ℓ', then the lines of projection run parallel to ℓ' and so fail to provide a point of intersection; and if $\Phi(P)$ is the intersection of ℓ and ℓ', then the lines of projection actually coincide rather than being parallel.

Theorem 12.3 *A parallel projection is both one-to-one and onto.*

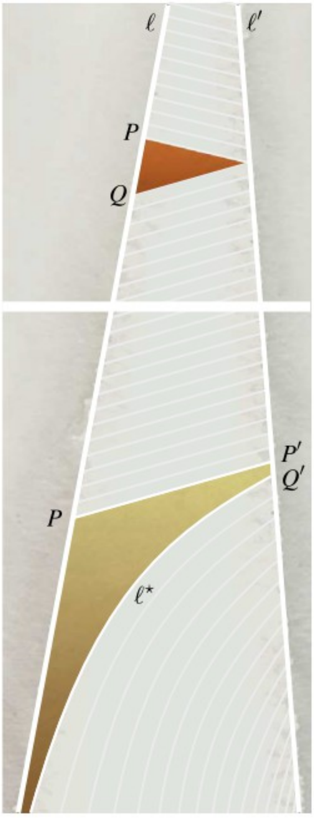

Figure 3. Using proofs by contradiction, we can show that parallel projection is both one-to-one (top) and onto (bottom).

Proof Let $\Phi : \ell \to \ell'$ be a parallel projection. First let's see why Φ is one-to-one. Suppose that it is not. That is, suppose that P and Q are two distinct points on ℓ but that $\Phi(P) = \Phi(Q)$. Then the two projecting lines $\overline{P\,\Phi(P)}$ and $\overline{Q\,\Phi(Q)}$, which ought to be parallel, actually share a point. This can't happen.

Now let's see why Φ is onto. Suppose that Q' is a point on ℓ' that is not in the image of Φ. To get a sense of how Φ is casting points from ℓ to ℓ', consider a point P on ℓ and its image $P' = \Phi(P)$ on ℓ'. By Playfair's axiom, there is a unique line $\ell^\star$ that passes through Q' and is parallel to $\overline{PP'}$. If $\ell^\star$ intersects ℓ at a point Q, then $\Phi(Q) = Q'$, contradicting the initial supposition that Q' is not in the image of Φ. If $\ell^\star$ does not intersect ℓ, then both ℓ and $\overline{PP'}$ are lines that pass through P and are parallel to $\ell^\star$, in violation of Playfair's axiom. In either case, we arrive at a contradiction. Therefore, an arbitrary point Q' of ℓ must be in the image of Φ, and so Φ is onto. $\square$

Now that we have established that parallel projection is a bijection, it helps to use a naming convention to makes things more readable. I will use a prime mark $'$ to indicate the parallel projection of a point, so $\Phi(P) = P'$, $\Phi(Q) = Q'$, and so on.

12.2 Parallel projection, order, and congruence

So far we have seen that parallel projection establishes a correspondence between the points of one line and the points of another. What about the order of the points? Can points get shuffled up in the process of a parallel projection? No.

Theorem 12.4 *Let $\Phi : \ell \to \ell'$ be a parallel projection. If A, B, and C are points on ℓ and $A * B * C$, then $A' * B' * C'$.*

Proof Because B is between A and C, A and C must be on opposite sides of $\overline{BB'}$. But, $\overline{AA'}$ does not intersect $\overline{BB'}$, so A' has to be on the same side of $\overline{BB'}$ as A; and $\overline{CC'}$ does not

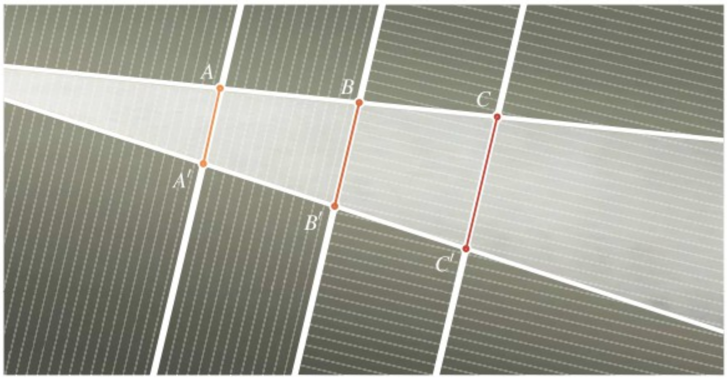

Figure 4. Parallel projection keeps points in order.

intersect $\overline{BB'}$, so C' has to be on the same side of $\overline{BB'}$ as C. Therefore A' and C' have to be on opposite sides of $\overline{BB'}$, and so the intersection of $\overline{BB'}$ and $A'C'$, which is B', must be between A' and C'. □

Now what about congruence?

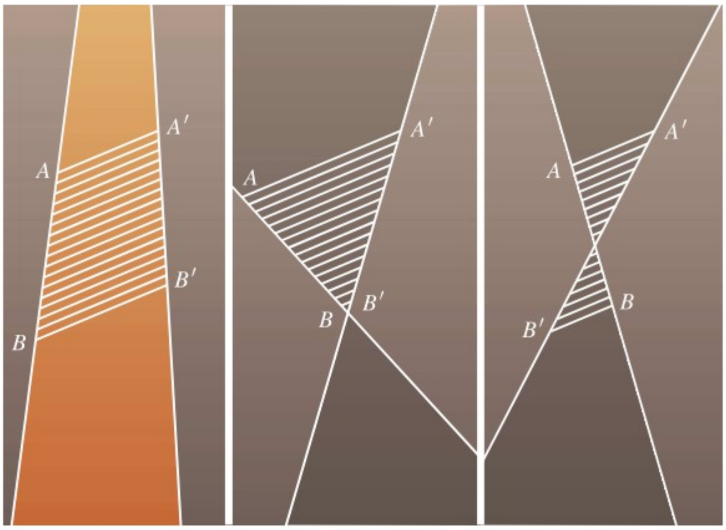

Figure 5. There are three positions for A and B relative to the image line: both on the same side, one on the image line, or one on each side. Likewise, there are three positions for a and b. There are nine cases in all.

Theorem 12.5 *Let $\Phi : \ell \to \ell'$ be a parallel projection. If a, b, A, and B are points on ℓ and if $ab \simeq AB$, then $a'b' \simeq A'B'$.*

Proof There are several cases, depending on the positions of ab and AB relative to ℓ'. They could lie on the same side of ℓ', they could lie on opposite sides of ℓ', one or both could straddle

ℓ', or one or both could have an endpoint on ℓ'. Each case must be handled differently. We will look at the case where both segments are on the same side of ℓ'. The others are left as exercises. There are still two cases to consider, depending on whether or not ℓ and ℓ' are parallel.

Case 1: when ℓ and ℓ' are parallel (see figure 6). This is the simpler case, but it helps illuminate the more general case. Because aa' is parallel to bb' and ab is parallel to $a'b'$, $\square aa'b'b$ is a parallelogram; AA' is parallel to BB' and AB is parallel to $A'B'$ so $\square AA'B'B$ is also a parallelogram. Because the opposite sides of a parallelogram are congruent (exercise 12.1), $a'b' \simeq ab$ and $AB \simeq A'B'$. Since $ab \simeq AB$, $a'b' \simeq A'B'$.

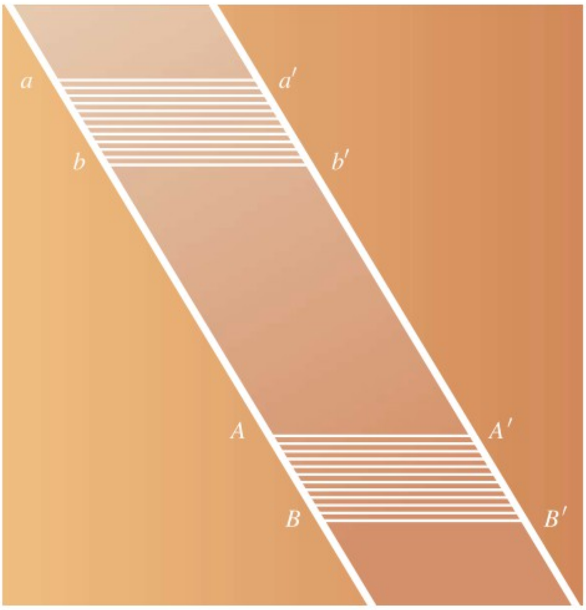

Figure 6. Case 1, when the two lines are parallel.

Case 2: when ℓ and ℓ' are not parallel (see figure 7). This is the more likely case, in which $\square aa'b'b$ and $\square AA'B'B$ will not be parallelograms. We can takes a similar approach to case 1, though, by building some parallelograms into the problem. Because ℓ and ℓ' are not parallel, the segments aa' and bb' cannot have the same length (exercise 12.3), and the segments AA' and BB' cannot have the same length. Let's assume that aa' is shorter than bb' and that AA' is shorter than BB'. If this is not the case, then it is just a matter of switching some labels to make it so. Then

- there is a point c between b and b' so that $bc \simeq aa'$, and
- there is a point C between B and B' so that $BC \simeq AA'$.

This creates four shapes of interest: the quadrilaterals $\square a'abc$ and $\square A'ABC$ that are parallelograms (exercise 12.2), and the triangles $\triangle a'b'c$ and $\triangle A'B'C$. The key here is to prove that $\triangle a'b'c \simeq \triangle A'B'C$.

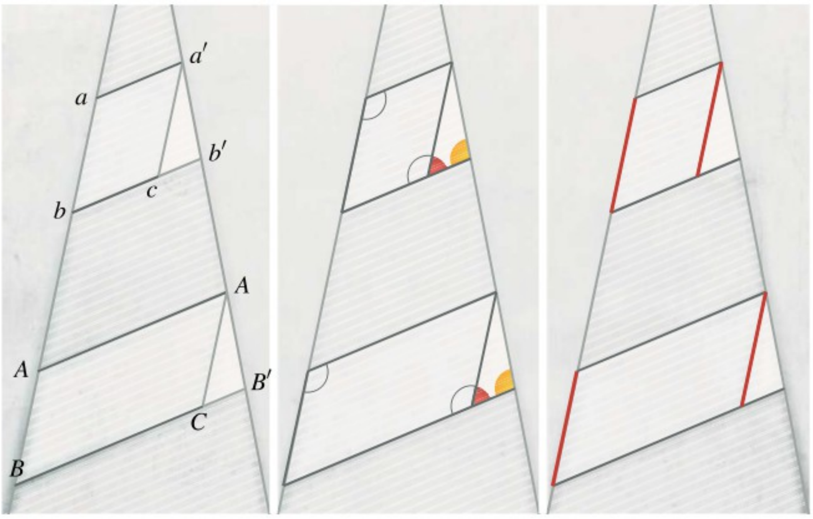

Figure 7. The non-parallel case. (l) First construct parallelograms. (c) The two angles and (r) the sides needed for AAS to show that $\triangle a'b'c' \simeq \triangle A'B'C'$.

- **A:** $\angle b' \simeq \angle B'$. The lines $\overline{cb'}$ and $\overline{CB'}$ are parallel (they are two of the projecting lines) and they are crossed by the transversal ℓ'. By the converse of the alternate interior angle theorem, $\angle a'b'c$ and $\angle A'B'C$ are congruent.
- **A:** $\angle c \simeq \angle C$. The opposite angles of the two parallelograms are congruent. Therefore $\angle a'cb \simeq \angle a'ab$ and $\angle A'AB \simeq \angle A'CB$. But $\overline{aa'}$ and $\overline{AA'}$ are parallel lines cut by the transversal ℓ, so $\angle a'ab \simeq \angle A'AB$, so $\angle a'cb \simeq \angle A'CB$, and so their supplements $\angle a'cb'$ and $\angle A'CB'$ are also congruent.
- **S:** $a'c \simeq A'C$. The opposite sides of the two parallelograms are congruent too. Therefore $a'c \simeq ab$ and $AB \simeq A'C$, and since $ab \simeq AB$, we get $a'c \simeq A'C$.

By AAS, then, $\triangle a'b'c \simeq \triangle A'B'C$. The corresponding sides $a'b'$ and $A'B'$ have to be congruent. □

Exercise 12.4 Fill in some gaps:

(1) Prove the theorem in the case when both a and A lie on ℓ' (at the intersection of ℓ and ℓ').
(2) Prove the theorem in the case when a and A lie on opposite sides of ℓ' from b and B.

12.3 Parallel projection and distance

That brings us to the question at the very heart of parallel projection. If Φ is a parallel projection and A and B are two points on ℓ, how do the lengths $|AB|$ and $|A'B'|$ compare? In case 1 of the last proof, AB and $A'B'$ ended up being congruent, but that was because ℓ and ℓ' were parallel. In general, AB and $A'B'$ do not have to be congruent. But it turns out that in the process of parallel projecting from one line to another, all distances are scaled by a constant multiple.

Theorem 12.6 *If $\Phi : \ell \to \ell'$ is a parallel projection, then there is a constant k such that*

$$|A'B'| = k|AB|$$

for all points A and B on ℓ.

It is helpful to get a little perspective on this before the proof. First note that the previous theorem gives us a way to narrow the scope of the problem. Fix a point O on ℓ and let r be one of the two rays along ℓ with O as its endpoint. The segment construction axiom says that every segment AB on ℓ is congruent to a segment OP where P is some point on r. We have just seen that parallel projection maps congruent segments to congruent segments. So if Φ scales all segments of the form OP by a factor of k, then it must scale all the segments of ℓ by the same factor.

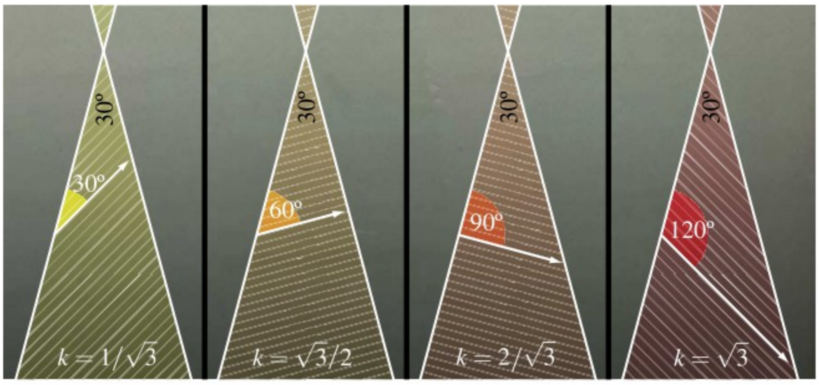

Figure 8. Some parallel projections and their scaling constants.

Second, we can extend that by considering what happens when we parallel project end-to-end congruent copies of a segment. For this, let me introduce another convenient notation convention: for the rest of this argument, let P_d denote the point on r that is a distance d from O. Now, pick a positive real value x, and let

$$k = |O'P_x'|/|OP_x|,$$

so that Φ scales the segment OP_x by a factor of k. Eventually we will have to show that Φ scales all segments by that factor, but for now let's restrict our attention to the segments OP_{nx}, where n is a positive integer. Between O and P_{nx} are P_x, P_{2x}, $\ldots$ $P_{(n-1)x}$ in order:

$$O * P_x * P_{2x} * \cdots * P_{(n-1)x} * P_{nx}.$$

We have seen that parallel projection preserves the order of points, so

$$O' * P_x' * P_{2x}' * \cdots * P_{(n-1)x}' * P_{nx}'.$$

Each segment $P_{ix}P_{(i+1)x}$ is congruent to OP_x and consequently each parallel projection $P'_{ix}P'_{(i+1)x}$ is congruent to $O'P'_x$. Add their lengths:

$$\begin{aligned}|O'P'_{nx}| &= |O'P'_x| + |P'_xP'_{2x}| + |P'_{2x}P'_{3x}| + \cdots + |P'_{(n-1)x}P'_{nx}| \\ &= kx + kx + kx + \cdots + kx \quad (n \text{ times}) \\ &= k \cdot nx\end{aligned}$$

and so Φ scales OP_{nx} by a factor of k.

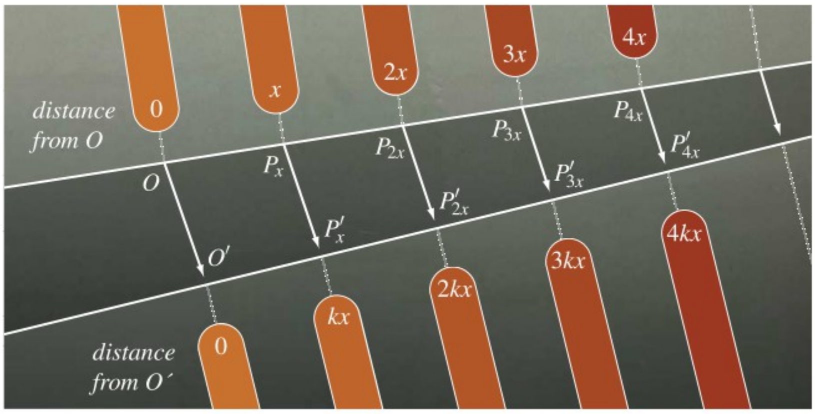

Figure 9. Scaling of segments of length kx, where k is an integer.

Sadly, no matter what x is, the points P_{nx} account for an inconsequential portion of the set of all points of r. However, if OP_x and OP_y were to have two different scaling factors we could use this end-to-end copying to magnify the difference between them. Third, then, consider an example that demonstrates how this works, and which shows how this ultimately prevents there being two different scaling factors. In this example, let's suppose that $|O'P'_1| = 2$, so all integer length segments on ℓ are scaled by a factor of 2. Let's take a look at what this means for $P_{3.45}$. Let k be the scaling factor for $OP_{3.45}$. Figure 10 shows how the first few end-to-end copies of $OP_{3.45}$ begin to limit the possible values of k.

Fourth, note that the floor function, $f(x) = \lfloor x \rfloor$, assigns to each real number x the largest integer that is less than or equal to it. The ceiling function, $f(x) = \lceil x \rceil$, assigns to each real number x the smallest integer that is greater than or equal to it.

It is finally time to prove that parallel projection scales distance.

Proof Let $k = |O'P'_1|$ so that k is the scaling factor for the segment of length 1 (and consequently for all integer length segments). Now take a point P_x on ℓ and let k' be the scaling factor for the segment OP_x. We want to show that $k' = k$ and we can do that by following the same strategy as in the example above, by capturing k' in an increasingly narrow band around k by looking at the parallel projection of P_{nx} as n increases. Start by working back and forth between

Figure 10. An example. Projecting end-to-end congruent copies of a segment of length 3.45 by a parallel projection that scales all integer length segments by a factor of two.

inequalities of real numbers and orders of points:

$$
\begin{gathered}
\lfloor nx \rfloor \le nx \le \lceil nx \rceil \\
O * P_{\lfloor nx \rfloor} * P_{nx} * P_{\lceil nx \rceil} \\
O' * P'_{\lfloor nx \rfloor} * P'_{nx} * P'_{\lceil nx \rceil} \\
k\lfloor nx \rfloor \le k'nx \le k\lceil nx \rceil .
\end{gathered}
$$

(The notation here is a bit casual—if nx is an integer, then $\lfloor nx \rfloor = nx$, so $P_{\lfloor nx \rfloor}$ is not actually between O and P_{nx}. This does not cause any problems for the proof.) Because $(nx - 1) \le \lfloor nx \rfloor$

and $\lceil nx \rceil \leq (nx + 1)$ we can move to a less precise but more manageable set of inequalities:

$$k(nx - 1) \leq k'nx \leq k(nx + 1).$$

Divide by nx to get

$$k\left(\frac{nx - 1}{nx}\right) \leq k' \leq k\left(\frac{nx + 1}{nx}\right).$$

As n increases, the ratios $(nx - 1)/(nx)$ and $(nx + 1)/(nx)$ both approach 1. In the limit as n goes to infinity, they are 1. Since the inequalities have to be true for all n, the only possible value for k' , then, is k. □

12.4 Exercises

12.5. Suppose that Φ is a parallel projection from ℓ to ℓ'. If ℓ and ℓ' intersect at P, prove that $\Phi(P) = P$.

12.6. Prove that if ℓ and ℓ' are parallel, then the scaling factor of a parallel projection between them must be one, but that if ℓ and ℓ' are not parallel, then there is a parallel projection with every possible scaling factor k where $0 < k < \infty$.

12.7. Let $\Phi : \ell \to \ell'$ be a parallel projection. Show that the inverse map $\Phi^{-1} : \ell' \to \ell$ is also a parallel projection.

12.8. Let $\Phi_1 : \ell \to \ell'$ and $\Phi_2 : \ell' \to \ell''$ be parallel projections. Is the composition $\Phi_2 \circ \Phi_1 : \ell \to \ell''$ necessarily a parallel projection?

12.9. In chapter 6, we constructed a distance function, and one of the keys to the construction was locating the points on a ray that were a distance of $m/2^n$ from its endpoint. In Euclidean geometry, there is a construction that locates all the points on a ray that are any rational distance m/n from its endpoint. Take two non-opposite rays r and r' with a common endpoint O. Along r, lay out m congruent copies of a segment of length 1, ending at the point P_m. Along r', lay out n congruent copies of a segment of length 1, ending at the point Q_n. Mark the point Q_1 on r' that is a distance 1 from O. Verify that the line that passes through Q_1 and is parallel to $P_m Q_n$ intersects r a distance of m/n from O.

15

Circumference

15.1 A theorem on perimeters

In chapter 9 on polygons, we defined the perimeter of a polygon $\mathcal{P} = P_1 \cdots P_n$ as

$$|\mathcal{P}| = \sum_{i=1}^{n} |P_i P_{i+1}|,$$

but then left it at that. In this lesson we are going to use perimeters of cyclic polygons to find the circumference of the circle. Along the way, we will need to use the following result that compares the perimeters of two convex polygons when one is contained in the other. We will prove the theorem by a process of "shaving down" the sides of the larger polygon until we reach the smaller one.

Theorem 15.1 *If $\mathcal{P}$ and $\mathcal{Q}$ are convex polygons and all the points of $\mathcal{P}$ are on or inside $\mathcal{Q}$, then $|\mathcal{P}| \leq |\mathcal{Q}|$.*

Proof Some of the edges of $\mathcal{P}$ may run along the edges of $\mathcal{Q}$, but unless $\mathcal{P} = \mathcal{Q}$, at least one edge of $\mathcal{P}$ must pass through the interior of $\mathcal{Q}$. Let s be one of those interior edges. The line containing s intersects $\mathcal{Q}$ twice—call the intersections a and b—dividing $\mathcal{Q}$ into two smaller polygons that share the side ab, one on the same side of s as $\mathcal{P}$, the other on the opposite side. Define a new polygon $\mathcal{Q}_1$ that consists of

- points of $\mathcal{Q}$ on the same side of s as $\mathcal{P}$, and
- points on the segment ab.

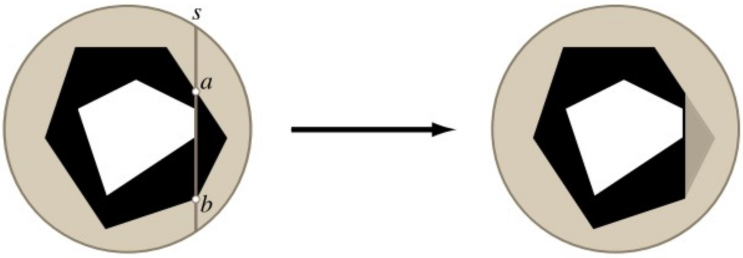

Figure 1. Shaving a corner off of a polygon.

There are two things to notice about $\mathcal{Q}_1$. First, $\mathcal{Q}_1$ and $\mathcal{P}$ have one more coincident side (the side s) than $\mathcal{Q}$ and $\mathcal{P}$ had. Second, the portions of $\mathcal{Q}$ and $\mathcal{Q}_1$ on the side of s with $\mathcal{P}$ are identical, so the segments making up that part contribute the same amount to their perimeters. On the other side, though, the path that $\mathcal{Q}$ takes from a to b is longer than the direct route along the segment ab of $\mathcal{Q}_1$ (because of the triangle inequality). Combining the two parts, we get $|\mathcal{Q}_1| \leq |\mathcal{Q}|$.

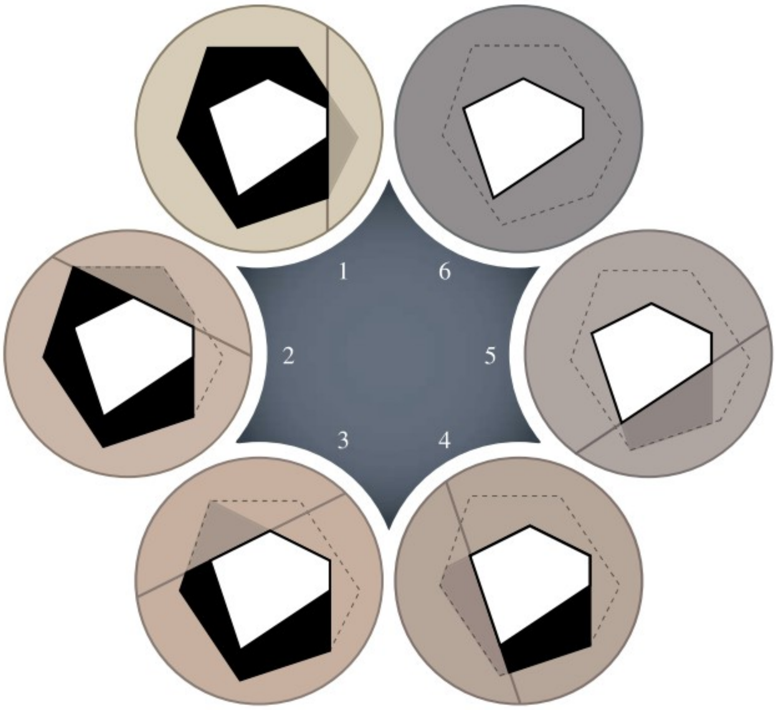

Figure 2. One at a time, shave the edges of the outer polygon down to the inner one.

Now we can repeat this process with $\mathcal{P}$ and $\mathcal{Q}_1$, generating $\mathcal{Q}_2$ with even smaller perimeter than $\mathcal{Q}_1$ and another coincident side with $\mathcal{P}$. And again, to get $\mathcal{Q}_3$. Eventually, though, after say m steps, we run out of sides that pass through the interior, at which point $\mathcal{P} = \mathcal{Q}_m$. Then

$$|\mathcal{P}| = |\mathcal{Q}_m| \leq |\mathcal{Q}_{m-1}| \leq \cdots \leq |\mathcal{Q}_2| \leq |\mathcal{Q}_1| \leq |\mathcal{Q}|. \qquad \square$$

15.2 Circumference

The purpose of this chapter is to understand the connection between the radius of a circle, and the distance around it, its circumference. The final result, the formula $C = 2\pi r$, ranks with the Pythagorean theorem in celebrity, although I think it is an often misunderstood celebrity. Let's be clear about what this equation is not. It is not an equation comparing two known quantities C and $2\pi r$. Instead, it is saying that the ratio $C/(2r)$ is a constant. The constant is what we have come to call π.

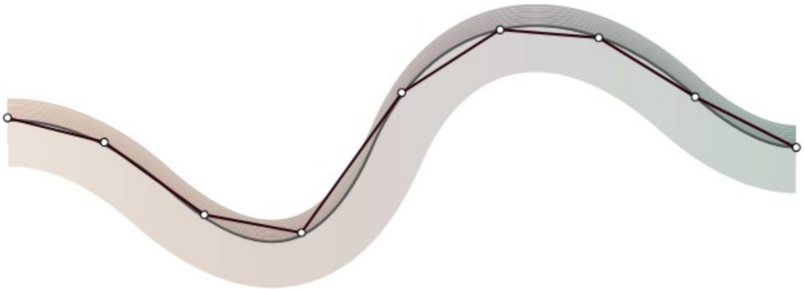

Figure 3. An approximation of an arc by segments.

To define the circumference of a circle, let's borrow an idea from calculus, the idea of approximating a curve by straight line segments, and then refining the approximation by increasing the number of segments. For a circle $\mathcal{C}$, the approximating line segments will be the edges of a simple cyclic polygon $\mathcal{P}$ inscribed in the circle. We will want the circumference of $\mathcal{C}$ to be bigger than the perimeter of $\mathcal{P}$. We should also expect that by adding in additional vertices to $\mathcal{P}$, we should be able to get the perimeter of $\mathcal{P}$ as close as we want to the circumference of $\mathcal{C}$. All this suggests that to get the circumference of $\mathcal{C}$, we need to find out how large the perimeters of inscribed polygons can be.

Definition 15.2 The circumference of a circle $\mathcal{C}$, written $|\mathcal{C}|$, is

$$|\mathcal{C}| = \sup \left\{ |\mathcal{P}| \middle| \mathcal{P} \text{ is a simple cyclic polygon inscribed in } \mathcal{C} \right\}.$$

There is nothing in the definition to guarantee that the supremum exists. It is conceivable that the lengths of the approximating perimeters might grow with bound. An example is the *Koch snowflake*. It is constructed as follows. Take an equilateral triangle with sides of length 1. The perimeter of this triangle is 3. Divide each side into thirds. On each middle third, build an equilateral triangle by adding two more sides then remove the original side. You have made a shape with $3 \cdot 4$ sides, each with length 1/3, for a perimeter of 4. Now iterate: divide the sides into thirds; build equilateral triangles on each middle third, and remove the base. That will make $3 \cdot 16$ sides of length 1/9, for a perimeter of 16/3. After the next step, there are $3 \cdot 64$ sides of length 1/27 for a perimeter of $64/9$. Generally, after n iterations, there are $3 \cdot 4^n$ sides of length $1/3^n$ for a total perimeter of $4^n/3^{n-1}$, and

$$\lim_{n\to\infty} \frac{4^n}{3^{n-1}} = \lim_{n\to\infty} 3\left(\frac{4}{3}\right)^n = \infty.$$

The Koch snowflake, which is the limiting shape in this process, has infinite perimeter! The first thing we need to do, then, is to make sure that circles are better behaved than this.

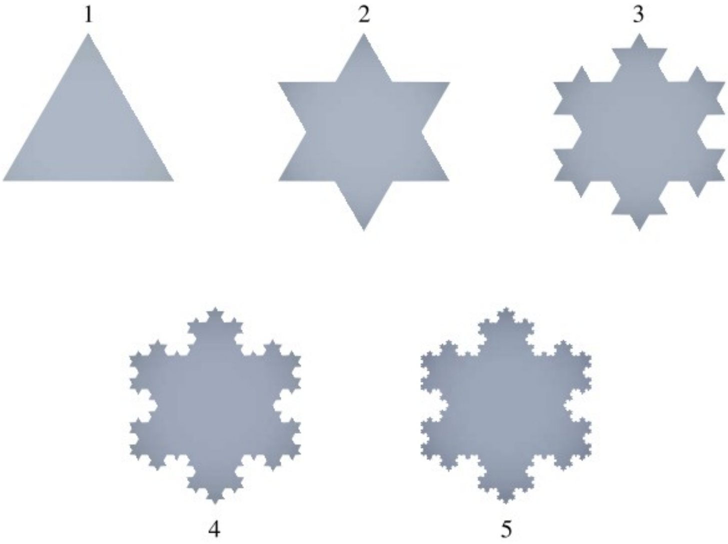

Figure 4. The first few steps in the construction of the Koch snowflake.

Theorem 15.3 *If* $\mathcal{C}$ *is a circle of radius* r*, then* $|\mathcal{C}| \leq 8r$.

Proof The first step is to build a circumscribing square around $\mathcal{C}$, the smallest square that still contains $\mathcal{C}$. Begin by choosing two perpendicular diameters d_1 and d_2. Each will intersect $\mathcal{C}$ twice, for a total of four intersections, P_1, P_2, P_3, and P_4. For each i between 1 and 4, let t_i be the tangent line to $\mathcal{C}$ at P_i. The tangents intersect to form the circumscribing square. The length of each side of the square is equal to the diameter of $\mathcal{C}$, so the perimeter of the square is $4 \cdot 2r = 8r$.

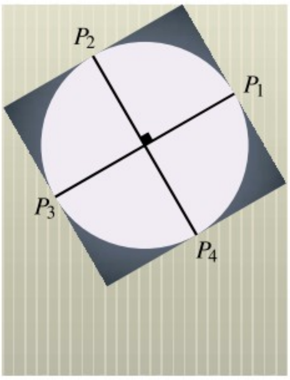

Figure 5. The circumscribing square.

Now we turn to the theorem we proved to start this chapter. Each simple cyclic polygon inscribed in $\mathcal{C}$ is a convex polygon contained in the circumscribing square. Therefore the perimeter of any such approximating polygon is bounded above by $8r$. Remember that we have defined $|\mathcal{C}|$ to be the supremum of all the approximating perimeters, so it cannot exceed $8r$ either. □

Now that we know that a circle has a circumference, the next step is to find a way to calculate it. The key to that is the next theorem.

Theorem 15.4 *The ratio of the circumference of a circle to its radius is a constant.*

Proof Let's suppose that the ratio is not a constant, so that there are two circles $\mathcal{C}_1$ and $\mathcal{C}_2$ with centers O_1 and O_2 and radii r_1 and r_2, but with unequal ratios

$$|\mathcal{C}_1|/r_1 > |\mathcal{C}_2|/r_2.$$

As we have defined circumference, there are approximating cyclic polygons to $\mathcal{C}_1$ whose perimeters are arbitrarily close to its circumference. In particular, there is an approximating cyclic polygon $\mathcal{P} = P_1 P_2 \dots P_n$ for $\mathcal{C}_1$ so that

$$|\mathcal{P}|/r_1 > |\mathcal{C}_2|/r_2.$$

We can construct a cyclic polygon $\mathcal{Q}$ on $\mathcal{C}_2$ that is similar to $\mathcal{P}$. Intuitively, we just need to scale $\mathcal{P}$ so that it fits in the circle $\mathcal{C}_2$. The formal construction is:

- Begin by placing a point Q_1 on circle $\mathcal{C}_2$.
- Locate Q_2 on $\mathcal{C}_2$ so that $\angle P_1 O_1 P_2$ is congruent to $\angle Q_1 O_2 Q_2$ (there are two choices for Q_2).
- Locate Q_3 on $\mathcal{C}_2$ and on the opposite side of $O_2 Q_2$ from Q_1 so that $\angle P_2 O_1 P_3$ is congruent to $\angle Q_2 O_2 Q_3$.
- Continue placing points on $\mathcal{C}_2$ in this fashion until Q_n has been placed to form the polygon $\mathcal{Q} = Q_1 Q_2 \dots Q_n$. At the end of the process $\angle P_n O_1 P_1$ is congruent to $\angle Q_n O_2 Q_1$ by angle subtraction.

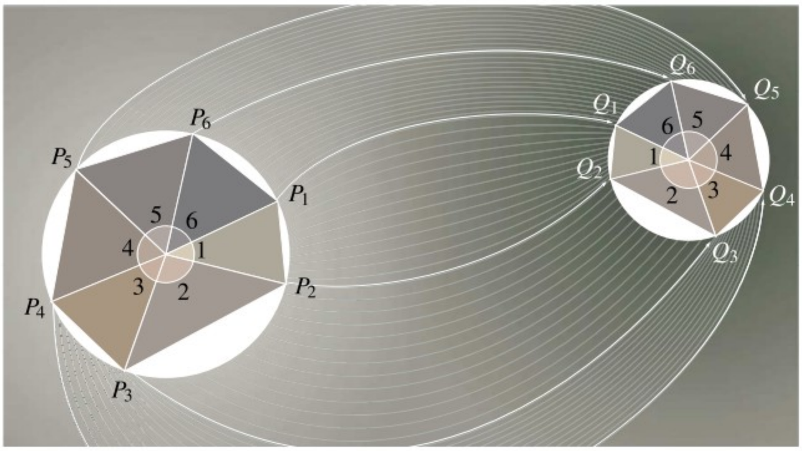

Figure 6. The ratio $|Q_i Q_{i+1}|/|P_i P_{i+1}|$ is a constant.

Then

$$\frac{|O_2Q_i|}{|O_1P_i|} = \frac{r_2}{r_1} = \frac{|O_2Q_{i+1}|}{|O_1P_{i+1}|} \text{ and } \angle Q_iO_2Q_{i+1} \simeq \angle P_iO_1P_{i+1},$$

so by SAS similarity, $\triangle Q_iO_2Q_{i+1}$ is similar to $\triangle P_iO_1P_{i+1}$. That gives us the ratio of the third sides of the triangle as

$$\frac{|Q_iQ_{i+1}|}{|P_iP_{i+1}|} = \frac{r_2}{r_1}.$$

Thus we can describe the perimeter of $\mathcal{Q}$ as

$$|\mathcal{Q}| = \sum_{i=1}^{n} |Q_iQ_{i+1}| = \sum_{i=1}^{n} \frac{r_2}{r_1}|P_iP_{i+1}| = \frac{r_2}{r_1}\sum_{i=1}^{n} |P_iP_{i+1}| = \frac{r_2}{r_1}|\mathcal{P}|.$$

That would mean that

$$\frac{|\mathcal{Q}|}{r_2} = \frac{|\mathcal{P}|}{r_1} > \frac{|\mathcal{C}_2|}{r_2}.$$

That is, $|\mathcal{Q}| > |\mathcal{C}_2|$, when in fact the circumference of $\mathcal{C}_2$ is supposed to be greater than the perimeter of any of its approximating cyclic polygons. □

Definition 15.5 The constant π is the ratio of the circumference of a circle to its diameter: $\pi = |\mathcal{C}|/(2r)$.

It is more convenient to express this definition in terms of a limit rather than a supremum. Fortunately, the supremum can be reached as a limit of perimeters of a sequence of regular polygons as follows. Arrange n angles each measuring $360^\circ/n$ around the center of a circle $\mathcal{C}$. The rays of the angles intersect $\mathcal{C}$ n times, and the points P_i are the vertices of a regular n-gon, $\mathcal{P}_n = P_1P_2\ldots P_n$. The tangent lines to $\mathcal{C}$ at the neighboring points P_i and P_{i+1} intersect at a point Q_i. Taken together, the n points are the vertices of another regular n-gon $\mathcal{Q}_n = Q_1Q_2\ldots Q_n$. The polygon $\mathcal{P}_n$ is just one of the many cyclic polygons inscribed in $\mathcal{C}$ so $|\mathcal{P}_n| \le |\mathcal{C}|$. The polygon $\mathcal{Q}_n$ circumscribes $\mathcal{C}$, and every cyclic polygon inscribed on $\mathcal{C}$ lies inside $\mathcal{Q}_n$, so $|\mathcal{Q}_n| \ge |\mathcal{C}|$.

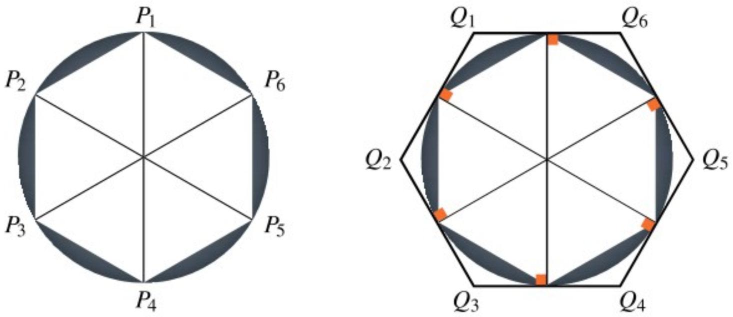

Figure 7. Regular inscribed (l) and circumscribed (r) hexagons.

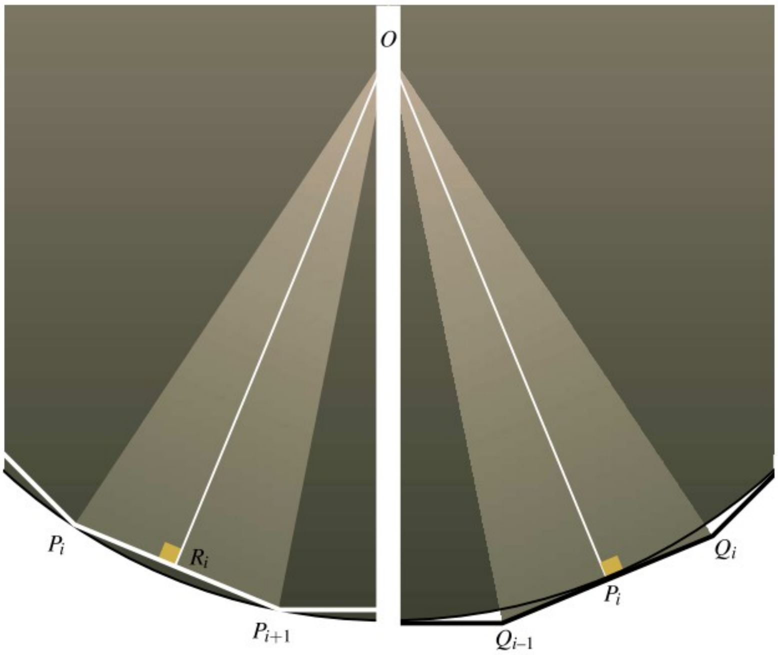

Figure 8. Approximation by inscribed and circumscribed polgons.

The lower bound prescribed by $\mathcal{P}_n$. $\overrightarrow{OQ_i}$ is a perpendicular bisector of P_iP_{i+1}, intersecting it at a point R_i and dividing $\triangle OP_iP_{i+1}$ in two. By the HL congruence theorem for right triangles, the two parts, $\triangle OR_iP_i$ and $\triangle OR_iP_{i+1}$, are congruent. Then $\mathcal{P}_n$ is built from $2n$ segments of length $|P_iR_i|$. Now for a little trigonometry:

$$\sin(360^\circ/2n) = \frac{|P_iR_i|}{r} \implies |P_iR_i| = r\sin(360^\circ/2n)$$

so $|\mathcal{P}_n| = 2nr\sin(360^\circ/2n)$.

The upper bound prescribed by $\mathcal{Q}_n$. $\overrightarrow{OP_i}$ is a perpendicular bisector of $Q_{i-1}Q_i$, intersecting it at P_i and dividing $\triangle OQ_{i-1}Q_i$ in two. By SAS, the two parts, $\triangle OP_iQ_{i-1}$ and $\triangle OP_iQ_i$, are congruent. Then $\mathcal{Q}_n$ is built from $2n$ segments of length $|P_iQ_i|$. Because

$$\tan(360^\circ/2n) = |P_iQ_i|/r \implies |P_iQ_i| = r\tan(360^\circ/2n),$$

$|\mathcal{Q}_n| = 2nr\tan(360^\circ/2n)$.

Let's compare $|\mathcal{P}_n|$ and $|\mathcal{Q}_n|$ as n increases (the key to the calculation is that as x approaches 0, $\cos(x)$ approaches 1):

$$\begin{aligned}\lim_{n\to\infty}\frac{|\mathcal{P}_n|}{|\mathcal{Q}_n|} &= \lim_{n\to\infty}\frac{2nr\tan(360^\circ/2n)}{2nr\sin(360^\circ/2n)}\\ &= \lim_{n\to\infty}\frac{\sin(360^\circ/2n)}{\cos(360^\circ/2n)}\cdot\frac{1}{\sin(360^\circ/2n)}\\ &= \lim_{n\to\infty}\frac{1}{\cos(360^\circ/2n)}\\ &= 1.\end{aligned}$$

Therefore $\lim_{n\to\infty} |\mathcal{P}_n| = \lim_{n\to\infty} |\mathcal{Q}_n|$. Since $|\mathcal{C}|$ is trapped between $|\mathcal{P}_n|$ and $|\mathcal{Q}_n|$ for all n, and since they approach the same number as n goes to infinity, $|\mathcal{C}|$ also approaches this number. That gives a more comfortable equation for circumference as

$$|\mathcal{C}| = \lim_{n\to\infty} 2nr \sin(360^\circ/2n),$$

and since $|\mathcal{C}| = 2\pi r$, we can make a definition of π as

$$\pi = \lim_{n\to\infty} n \sin(360^\circ/2n).$$

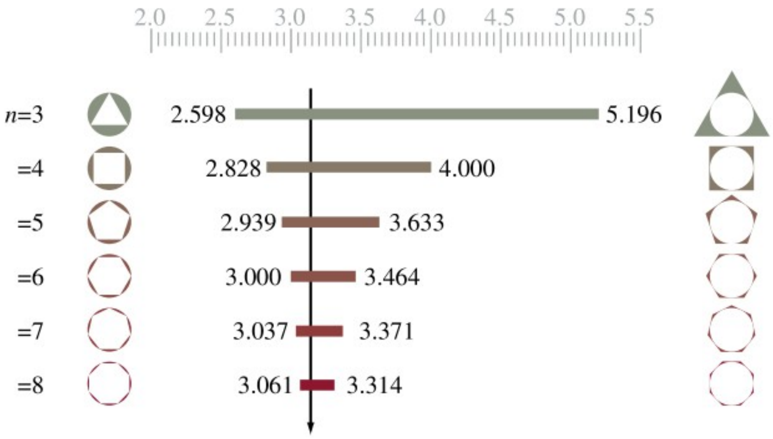

Figure 9. Using perimeters of regular inscribed and circumscribed polygons to determine upper and lower bounds for π.

15.3 Lengths of arcs and radians

It doesn't take much modification to get a formula for the length of an arc. The 360° in the formula for $|\mathcal{C}|$ is the measure of the central angle corresponding to an arc that goes completely around the circle. To get the measure of any other arc, we can replace the 360° with the measure of the corresponding central angle.

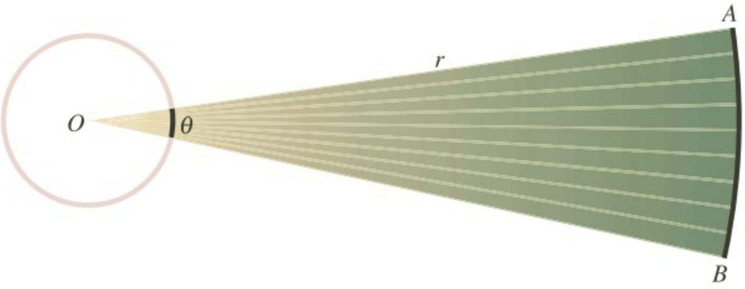

Figure 10. An arc.

Theorem 15.6 *If $\widehat{AB}$ is the arc of a circle with radius r, and if θ is the measure of the central angle $\angle AOB$, then*

$$|\widehat{AB}| = \frac{\pi}{180^\circ}\theta \cdot r.$$

Proof To start, replace the 360° in the circumference formula with θ:

$$|\widehat{AB}| = \lim_{n\to\infty} 2nr \sin(\theta/2n) = 2r \cdot \lim_{n\to\infty} n \sin(\theta/2n).$$

This limit is clearly related to the one that defines π. We can absorb the difference between the two into the variable with the substitution $n = m \cdot \theta/360^\circ$. As n approaches infinity, m will as well, so

$$\begin{aligned} |\widehat{AB}| &= 2r \cdot \lim_{m\to\infty} \frac{m \cdot \theta}{360^\circ} \sin\left(\frac{\theta}{2m \cdot \theta/360^\circ}\right) \\ &= \frac{2r\theta}{360^\circ} \cdot \lim_{m\to\infty} m \sin(360^\circ/2m) \\ &= \frac{\theta}{180^\circ} r\pi. \end{aligned}$$

□

There is one more thing to notice before the end of this chapter. The arc length formula provides a direct connection between angle measure (of the central angle) and distance (along the arc). And yet, the $\frac{\pi}{180^\circ}$ factor in that formula suggests that distance and the degree measurement system are a little out of sync with one another. This can be fixed by modernizing our method of angle measurement. The preferred angle measurement system, and the one that we will use, is *radian* measurement.

Definition 15.7 One radian is $180^\circ/\pi$.

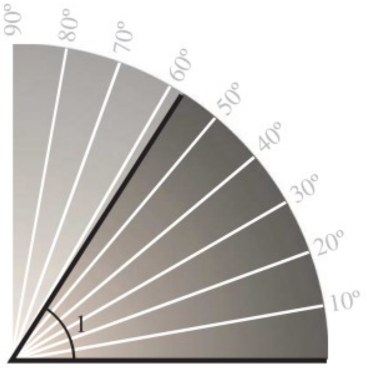

Figure 11. One radian is approximately 57.296°.

Then the measure of a straight angle is π radians. The measure of a right angle is $\pi/2$ radians. One complete turn of the circle is 2π radians. If $\theta = (\angle AOB)$ is measured in radians, then $|\widehat{AB}| = r \cdot \theta$.

15.4 Exercises

15.1. Let A and B be points on a circle $\mathcal{C}$ with radius r. Let θ be the measure of the central angle corresponding to the minor arc (or semicircle) $\widehat{AB}$. What is the relationship (in the form of an equation) between θ, r, and $|AB|$?

15.2. Let A and B be points on a circle $\mathcal{C}$ with center O and radius r. If $(\angle BAO) = \theta$, what is $|\widehat{AB}|$ (in terms of r and θ)?

15.3. Let AB be a diameter of a circle $\mathcal{C}$, and let P be a point on AB. Let $\mathcal{C}_1$ be the circle with diameter AP and let $\mathcal{C}_2$ be the circle with diameter BP. Show that the sum of the circumferences of $\mathcal{C}_1$ and $\mathcal{C}_2$ is equal to the circumference of $\mathcal{C}$ (the shape formed by the three semicircles on one side of AB is called an *arbelos*).

15.4. What is the radius of the circle that passes through the three vertices of a equilateral triangle with sides of length 1?

15.5. Let $\mathcal{C}_1$ be the circle inscribed in an equilateral triangle $\triangle ABC$ with sides of length 1. There is a line that is parallel to AB and tangent to $\mathcal{C}_1$ that divides $\triangle ABC$ into a trapezoid and a smaller equilateral triangle. Let $\mathcal{C}_2$ be the circle inscribed in the smaller equilateral triangle. Continuing in this way, we can form a stack of smaller and smaller circles. Is the sum of their circumferences finite, and if so, what is it?

15.6. In the construction of the Koch snowflake, the middle third of each segment is replaced with two-thirds of an equilateral triangle. Suppose, instead, that middle third was replaced with three of the four sides of a square. What is the perimeter of the n-th stage of this operation? Would the limiting perimeter still be infinite?

15.7. This problem deals with the possibility of angle measurement systems other than degrees or radians. Let $\mathscr{A}$ be the set of angles in the plane. Consider a function

$$\star : \mathscr{A} \to (0, \infty) : \angle A \to (\angle A)^\star$$

that satisfies

- if $\angle A \simeq \angle B$, then $(\angle A)^\star = (\angle B)^\star$
- if D is in the interior of $\angle ABC$, then

$$(\angle ABC)^\star = (\angle ABD)^\star + (\angle DBC)^\star.$$

Prove that the $\star$ measurement system is a constant multiple of the degree measurement system (or, for that matter, the radian measurement system). That is, prove that there is a $k > 0$ such that for all $\angle A \in \mathscr{A}$,

$$(\angle A)^\star = k \cdot (\angle A).$$

15.5 References

The Koch snowflake is an example of a fractal. Gerald Edgar's book *Measure, Topology, and Fractal Geometry* [Edg90], deals with these objects and their measures.

THE TRISECTION AND QUADRATURE AGAIN.

A method to trisect a series of angles having relation to each other; also another to trisect any given angle. By James Sabben. 1848 (two quarto pages).

"The consequence of years of intense thought": very likely, and very sad.

1848. The following was sent to me in manuscript. I give the whole of it:

"*Quadrature of the Circle.*—A quadrant is a curvilinear angle traversing round and at an equal distance from a given point, called a center, no two points in the curve being at the same angle, but irreptitiously graduating from 90 to 60. It is therefore a mean angle of 90 and 60, which is 75, because it is more than 60, and less than 90, approximately from 60 to 90, and from 90 to 60, with equal generation in each irreptitious approximation, therefore meeting in 75, and which is the mean angle of the quadrant.

"Or suppose a line drawn from a given point at 90, and from the same point at 60. Let each of these lines revolve on this point toward each other at an equal ratio. They will become one line at 75, and bisect the curve, which is one-sixth of the entire circle. The result, taking 16 as a diameter, gives an area of 201.072400, and a circumference of 50.2681.

"The original conception, its natural harmony, and the result, to my own mind is a demonstrative truth, which I presume it right to make known, though perhaps at the hazard of unpleasant if not uncourteous remarks."

I have added punctuation: the handwriting and spelling are those of an educated person; the word *irreptitious* is indubitable. The whole is a natural curiosity.

The quadrature and exact area of the circle demonstrated. By Wm. Peters. 8vo. *n. d.* (circa 1848).[1]

Suggestions as to the necessity for a revolution in philosophy; and prospectus for the establishment of a new quarterly, to be called the *Physical Philosopher and Heterodox Review.* By Q. E. D. 8vo. 1848.

These works are by one author, who also published, as appears by advertisement,

"Newton rescued from the precipitancy of his followers through a century and a half,"[2] and "Dangers along a coast by correcting (as it is called) a ship's reckoning by bearings of the land at night fall, or in a fog, nearly out of print. Subscriptions are requested for a new edition."

The area of a circle is made four-fifths of the circumscribed square: proved on an assumption which it is purposed to explain in a longer essay.[3] The author, as Q. E. D., was in controversy with the *Athenæum* journal, and criticised a correspondent, D., who wrote against a certain class of discoverers. He believed the common theories of hydrostatics to be wrong, and one of his questions was:

"Have you ever taken into account anent gravity and gravitation the fact that a five grain cube of cork will of itself half sink in the water, whilst it will take 20 grains of brass, which will sink of itself, to pull under the other half? Fit this if you can, friend D., to your notions of gravity and specific gravity, as applied to the construction of a universal law of gravitation."

This the *Athenæum* published—but without some Italics, for which the editor was sharply reproved, as a sufficient specimen of the *quod erat* D. *monstrandum*: on which the author remarks—"D,—Wherefore the e caret? is it D apostrophe? D', D'M, D'Mo, D'Monstrandum; we cannot find the *wit* of it." This I conjecture to contain an illusion to the name of the supposed author; but whether De Mocritus, De Mosthenes, or De Moivre was intended, I am not willing to decide.

---

[1] This was published in London in 1851 instead of 1848.

[2] This appeared in 1846.

[3] This was done in *The Circle Squared*, published at Brighton in 1865.

The Scriptural Calendar and Chronological Reformer, for the statute year 1849. Including a review of recent publications on the Sabbath question. London, 1849, 12mo.[4]

This is the almanac of a sect of Christians who keep the Jewish Sabbath, having a chapel at Mill Yard, Goodman's Fields. They wrote controversial works, and perhaps do so still; but I never chanced to see one.

Geometry *versus* Algebra; or the trisection of an angle geometrically solved. By W. Upton, B. A.[5] Bath (circa 1849). 8vo.

The author published two tracts under this title, containing different alleged proofs: but neither gives any notice of the change. Both contain the same preface, complaining of the British Association for refusing to examine the production. I suppose that the author, finding his first proof wrong, invented the second, of which the Association never had the offer; and, feeling sure that they would have equally refused to examine the second, thought it justifiable to present that second as the one which they had refused. Mr. Upton has discovered that the common way of finding the circumference is wrong, would set it right if he had leisure, and, in the mean time, has solved the problem of the duplication of the cube.

---

[4] It first appeared in 1847, under the title, *The Scriptural Calendar and Chronological Reformer, 1848. Including a review of tracts by Dr. Wardlaw and others on the Sabbath question. By W. H. Black.* The one above mentioned, for 1849, was printed in 1848, and was also by Black (1808-1872). He was pastor of the Seventh Day Baptists and was interested in archeology and in books. He catalogued the manuscripts of the Ashmolean Museum at Oxford.

[5] William Upton, a Trinity College man, Dublin. He also wrote *Upton's Physioglyphics,* London, 1844; *Pars prima. Geometria vindicata; antiquorumque Problematum, ad hoc tempus desperatorum, Trisectionis Anguli, Circulique Quadraturae, Solutio, per Eucliden effecta, London* (printed at Southampton), 1847; *The Uptonian Trisection,* London, 1866; and *The Circle Squared,* London, 1872.

The trisector of an angle, if he demand attention from any mathematician, is bound to produce, from his construction, an expression for the sine or cosine of the third part of any angle, in terms of the sine or cosine of the angle itself, obtained by help of no higher than the square root. The mathematician knows that such a thing cannot be; but the trisector virtually says it can be, and is bound to produce it, to save time. This is the misfortune of most of the solvers of the celebrated problems, that they have not knowledge enough to present those consequences of their results by which they can be easily judged. Sometimes they have the knowledge and quibble out of the use of it. In many cases a person makes an honest beginning and presents what he is sure is a solution. By conference with others he at last feels uneasy, fears the light, and puts self-love in the way of it. Dishonesty sometimes follows. The speculators are, as a class, very apt to imagine that the mathematicians are in fraudulent confederacy against them: I ought rather to say that each one of them consents to the mode in which the rest are treated, and fancies conspiracy against himself. The mania of conspiracy is a very curious subject. I do not mean these remarks to apply to the author before me.

One of Mr. Upton's trisections, if true, would prove the truth of the following equation:

$$3\cos(\theta/3) = 1 + \surd(4 - \sin^2\theta)$$

which is certainly false.[6]

---

[6] For example, if $\theta = 90°$ we should have $3\cos 30° = 1 + \sqrt{4 - \sin^2 90°}$, or $3 . \frac{1}{2}\sqrt{3} = 1 + \sqrt{3}$, or $\frac{1}{2}\sqrt{3} = 1$.

In 1852 I examined a terrific construction, at the request of the late Dr. Wallich,[7] who was anxious to persuade a poor countryman of his, that trisection of the angle was waste of time. One of the principles was, that "magnitude and direction determine each other." The construction was equivalent to the assertion that, θ being any angle, the cosine of its third part is

$$\sin 3\theta . \cos(5\theta/2) + \sin^2\theta \sin(5\theta/2)$$

divided by the square root of

$$\sin^2 3\theta . \cos^2(5\theta/2) + \sin^4\theta + \sin 3\theta . \sin 5\theta . \sin^2\theta .$$

This is from my rough notes, and I believe it is correct.[8] It is so nearly true, unless the angle be very obtuse, that common drawing, applied to the construction, will not detect the error. There are many formulae of this kind: and I have several times found a speculator who has discovered the corresponding construction, has seen the approximate success of his drawing—often as great as absolute truth could give in graphical practice,—and has then set about his demonstration, in which he always succeeds to his own content.

There is a trisection of which I have lost both cutting and reference: I think it is in the *United Service Journal.* I could not detect any error in it, though certain there must

---

[7] Nathaniel Wallich (1786-1854) was surgeon at the Danish settlement at Serampore when the East India Company took over the control in 1807. He entered the British medical service and was invalided to England in 1828. His *Plantae Asiaticae Rariores* (3 vols., London, 1830-1832) was recognized as a standard. He became vice-president of the Linnean Society, F. R. S., and fellow of the Royal Asiatic Society.

[8] But if $\theta = 90°$ this asserts that

$$\cos 30° = \frac{\sin 270° . \cos 225° + \sin^2 90° . \sin 225°}{\sqrt{\sin^2 270° . \cos^2 225° + \sin^4 90° + \sin 270° . \sin 450° . \sin^2 90°}},$$

or that

$$\tfrac{1}{2}\sqrt{3} = \frac{-1 . (-1/\sqrt{2}) + 1 . (-1/\sqrt{2})}{\sqrt{1 . \tfrac{1}{2} + 1 - 1 . 1 . 1}} = 0/\sqrt{\tfrac{1}{2}},$$

so that De Morgan must have made some error in copying.

be one. At least I discovered that two parts of the diagram were incompatible unless a certain point lay in line with two others, by which the angle to be trisected—and which was trisected—was bound to be either 0° or 180°.

Aug. 22, 1866. Mr. Upton sticks to his subject. He has just published "The Uptonian Trisection. Respectfully dedicated to the schoolmasters of the United Kingdom." It seems to be a new attempt. He takes no notice of the sentence I have put in italics: nor does he mention my notice of him, unless he means to include me among those by whom he has been "ridiculed and sneered at" or "branded as a brainless heretic." I did neither one nor the other: I thought Mr. Upton a paradoxer to whom it was likely to be worth while to propound the definite assertion now in italics; and Mr. Upton does not find it convenient to take issue on the point. He prefers general assertions about algebra. So long as he cannot meet algebra on the above question, he may issue as many "respectful challenges" to the mathematicians as he can find paper to write: he will meet with no attention.

There is one trisection which is of more importance than that of the angle. It is easy to get half the paper on which you write for margin; or a quarter; but very troublesome to get a third. Show us how, easily and certainly, to fold the paper into three, and you will be a real benefactor to society.

Early in the century there was a Turkish trisector of the angle, Hussein Effendi, who published two methods. He was the father of Ameen Bey, who was well known in England thirty years ago as a most amiable and cultivated gentleman and an excellent mathematician. He was then a student at Cambridge; and he died, years ago, in command of the army in Syria. Hussein Effendi was instructed in mathematics by Ingliz Selim Effendi, who translated a work of Bonnycastle[9] into Turkish.[10] This Englishman was Richard Baily, brother of Francis Baily[11] the astronomer, who emigrated to Turkey in his youth, and adopted the manners of the Turks, but whether their religion also I never heard, though I should suppose he did.

I now give the letters from the agricultural laborer and his friend, described on page 12, Vol. I. They are curiosities; and the history of the quadrature can never be well written without some specimens of this kind:

"Doctor Morgan, Sir. Permit me to address you

"Brute Creation may perhaps enjoy the faculty of beholding visible things with a more penitrating eye than ourselves. But Spiritual objects are as far out of their reach as though they had no being

"Nearest therefore to the brute Creation are those men who Suppose themselves to be so far governed by external objects as to believe nothing but what they See and feel And Can accomedate to their Shallow understanding and Imaginations

"My Dear Sir Let us all Consult ourselves by the wise proverb.

"I believe that evry man[s] merit & ability aught to be appreciated and valued In proportion to its worth & utility

"In whatever State or Circumstances they may fortunately or unfortunately be placed

"And happy it is for evry man to know his worth and place

"When a Gentleman of your Standing in Society Clad with those honors Can not understand or Solve a problem That is explicitly explained by words and Letters and mathematically operated by figuers He had best consult the wise proverd

---

[9] John Bonnycastle (died in 1821) was professor of mathematics at Woolwich. His edition of Bossut's *History of Mathematics* (1803), and his works on elementary mathematics were well known.

[10] The bibliographies give Husain Rifki as the translator, a practical geometry as the work, and 1802 as the date.

[11] See Vol. I, page 309, note 2.

"Do that which thou Canst understand and Comprehend for thy good.

"I would recommend that Such Gentleman Change his business

"And appropriate his time and attention to a Sunday School to Learn what he Could and keep the Litle Children form durting their Close

"With Sincere feelings of Gratitude for your weakness and Inability I am

"Sir your Superior in Mathematics ——"

"1849 June th29."

"Dor Morgin Sir

"I wrote and Sent my work to Professor —— of —— State of —— United States

"I am now in the possession of the facts that he highly approves of my work. And Says he will Insure me Reward in the States

"I write this that you may understand that I have knowledge of the unfair way that I am treated In my own nati County

"I am told and have reasons to believe that it is the Clergy that treat me so unjust.

"I am not Desirous of heaping Disonors upon my own nation. But if I have to Leave this kingdom without my Just dues. The world Shall know how I am and have been treated.

"I am Sir Desirous of my

"Just dues ——"

"1849 July 3."

"July 7th, 1849.

"Sir, I have been given to understand that a friend of mine one whom I shall never be ashamed to acknowledge as such tho' lowly his origine; nay not only not ashamed but proud of doing so for I am one of those who esteem and respect a man according to his ability and probity, deeming with Dr. Watts 'that the mind is the standard of the man,'[12] has laid before you and asked your opinion of his extraordinary performance, viz. the quadrature of the circle, he did this with the firmest belief that you would not only treat the matter in a straightforward manner but with the conviction that from your known or supposed knowledge of mathematicks would have given an upright and honorable decision upon the subject; but the question is have you done so? Could I say yes I would with the greatest of pleasure and have congratulated you upon your decision whatever it might have been but I am sorry to say that I cannot your letter is a paltry evasion, you say 'that it is a great pity that you (Mr. ——) should have attempted this (the quadrature of the circle) for your mathematical knowledge is not sufficient to make you know in what the problem consists,' you don't say in what it does consist *according to your ideas,* oh! no nothing of the sort, you enter into no disquisition upon the subject in order to show where you think Mr.—— is wrong and why you have not is simply—*because you cannot*—you know that he has done it and what is if I am not wrongly informed *you have been heard to say so.* He has done what you nor any other mathematician as those who call themselves such have done. And what is the reason that you will not candidly acknowledge to him as you have to others that he has squared the circle shall I tell you? it is because he has performed the feat to obtain the glory of which mathematicians have battled from time immemorial that they might encircle their brows with a wreath of laurels far more glorious than ever conqueror won it is simply this that it is a poor man a humble artisan who has gained that victory that you don't like to acknowledge it you don't like to be beaten and worse to acknowledge that you have miscalculated, you have in short too small a soul to acknowledge that he is right.

---

[12] Probably in *The Improvement of the Mind* which Isaac Watts (1674-1748) published in 1741. His *Horae Lyricae* appeared in 1706, and the *Hymns,* by which he is still well known, in 1707.

"I was asked my opinion and *I* gave it unhesitatingly in the affirmative and I am backed in my opinion not only by Mr. —— a mathematician and watchmaker residing in the boro of Southwark but by no less an authority than the Professor of mathematics of —— College —— —— United States Mr.—— and I presume that he at least is your equal as an authority and Mr. —— says that the government of the U. S. will recompense M. D. for the discovery he has made if so what a reflection upon Old england the boasted land of freedom the nursery of arts and sciences that her sons are obliged to go to a foreign country to obtain that recompense to which they are justly entitled

"In conclusion I had to contradict an assertion you made to the effect that 'there is not nor ever was any reward offered by the government of this country for the discovery of the quadrature of the circle.' I beg to inform you that there *was* but that it having been deemed an impossibility the government has withdrawn it. I do this upon no less an authority than the Marquis of Northampton.[13]

"I am, sir, yours ——"

"Dr. Morgan."

THE MOON'S ROTATION.

Notes on the Kinematic Effects of Revolution and Rotation, with reference to the Motions of the Moon and of the earth. By Henry Perigal, Jun. Esq. London, 1846-1849, 8vo.

On the misuse of technical terms. Ambiguity of the terms *Rotation* and *Revolution,* owing to the double meaning improperly

---

[13] Spencer Joshua Alwyne Compton, second Marquis of Northampton (1790-1851), was a poet, a scientist, and a statesman. He was president of the Royal Society from 1838 to 1849.

It follows that finite group transformations compose as

$$\phi \xrightarrow{\theta_2} \phi' = U(\Theta_2)\phi \xrightarrow{\theta_1} \phi'' = U(\Theta_2)U(\Theta_1)\phi. \tag{1.23}$$

We show in Sec. 1.5 that this agrees with the composition of the unitary transformations which implement the symmetry in the quantum theory.

1.2.3 Spacetime symmetries – the Lorentz and Poincaré groups

The Lorentz group is defined as the group of homogeneous linear transformations of coordinates in D-dimensional Minkowski spacetime that preserve the Minkowski norm of any vector. We write

$$x^\mu = \Lambda^\mu{}_\nu x'^\nu \qquad \text{or} \qquad x'^\mu = \Lambda^{-1\mu}{}_\nu x^\nu\,, \tag{1.24}$$

and require that

$$x^\mu \eta_{\mu\nu} x^\nu = x'^\mu \eta_{\mu\nu} x'^\nu. \tag{1.25}$$

The Poincaré group is defined by adjoining global translations and considering

$$x'^\mu = \Lambda^{-1\mu}{}_\nu \left(x^\nu - a^\nu\right). \tag{1.26}$$

In this section we review the properties of these groups, their Lie algebras and the group action on fields such as $\phi^i(x)$.

If (1.25) holds for any vector x^μ, it follows that

$$\Lambda^\mu{}_\rho \eta_{\mu\nu} \Lambda^\nu{}_\sigma = \eta_{\rho\sigma}\,. \tag{1.27}$$

This is the defining property of the Λ matrices. If the Minkowski metric were replaced by the Kronecker delta, $\delta_{\mu\nu}$, these conditions would define the orthogonal group $\mathrm{O}(D)$, but here we have the pseudo-orthogonal group $\mathrm{O}(D-1,1)$. For most purposes we need only the connected component of this group, which we call the proper Lorentz group.

The metric tensor (and its inverse) are used to lower (or raise) vector indices. Thus one has, for example, $x_\mu = \eta_{\mu\rho} x^\rho$ and $\Lambda_{\mu\nu} = \eta_{\mu\rho}\Lambda^\rho{}_\nu$. Upper or lower indices are called contravariant or covariant, respectively.

Exercise 1.3 *Show that (1.24) and (1.27) imply*

$$\begin{aligned} \Lambda_{\mu\nu} &= (\Lambda^{-1})_{\nu\mu}\,, \qquad \Lambda^\mu{}_\nu = (\Lambda^{-1})_\nu{}^\mu\,, \\ x'_\mu &= (\Lambda^{-1})_\mu{}^\nu x_\nu = x_\nu \Lambda^\nu{}_\mu. \end{aligned} \tag{1.28}$$

The first relation of the exercise resembles the standard matrix orthogonality property, but it holds for Lorentz when both indices are down (or both up), which is not the correct position for their action as linear transformations. Indeed, Lorentz matrices must be multiplied with indices in up–down position, viz. $\Lambda^\mu{}_\rho \Lambda'^\rho{}_\nu$.

We now introduce the Lie algebra of the Lorentz group, proceeding in parallel[7] to the discussion of the group SO(n) in Sec. 1.2.1. For a small parameter ϵ, we write the infinitesimal transformation

$$\Lambda^{\mu}{}_{\nu} = \delta^{\mu}_{\nu} + \epsilon m^{\mu}{}_{\nu} + \cdots . \tag{1.29}$$

It is straightforward to see that (1.29) satisfies (1.27) to first order in ϵ as long as the generator (m with two lower indices) is antisymmetric, viz.

$$m_{\mu\nu} \equiv \eta_{\mu\rho} m^{\rho}{}_{\nu} = -m_{\nu\mu} . \tag{1.30}$$

The *Lie algebra* is the real linear space spanned by the $\frac{1}{2}D(D-1)$ independent generators, with the commutator product $[m, m'] = m\,m' - m'm$. These matrices must also be multiplied as $m^{\mu}{}_{\rho} m'^{\rho}{}_{\nu}$, but the forms with both indices down, as in (1.30), (or both up) are often convenient.

A useful basis for the Lie algebra is to choose generators that act in each of the $\frac{1}{2}D(D-1)$ coordinate 2-planes. For the 2-plane in the directions ρ, σ this generator is given by

$$m_{[\rho\sigma]}{}^{\mu}{}_{\nu} \equiv \delta^{\mu}_{\rho}\eta_{\nu\sigma} - \delta^{\mu}_{\sigma}\eta_{\rho\nu} \;= -m_{[\sigma\rho]}{}^{\mu}{}_{\nu} . \tag{1.31}$$

Note the distinction between the coordinate plane labels in brackets and the row and column indices. In this basis, a finite proper Lorentz transformation is specified by a set of $\frac{1}{2}D(D-1)$ real parameters $\lambda^{\rho\sigma} = -\lambda^{\sigma\rho}$ and takes exponential form

$$\Lambda = \mathrm{e}^{\frac{1}{2}\lambda^{\rho\sigma} m_{[\rho\sigma]}} . \tag{1.32}$$

When matrix indices are restored, we have, with the representation (1.31), the series[8]

$$\Lambda^{\mu}{}_{\nu} = \delta^{\mu}{}_{\nu} + \lambda^{\mu}{}_{\nu} + \tfrac{1}{2}\lambda^{\mu}{}_{\rho}\lambda^{\rho}{}_{\nu} + \ldots . \tag{1.33}$$

The commutators of the generators defined in (1.31) are

$$[m_{[\mu\nu]}, m_{[\rho\sigma]}] = \eta_{\nu\rho} m_{[\mu\sigma]} - \eta_{\mu\rho} m_{[\nu\sigma]} - \eta_{\nu\sigma} m_{[\mu\rho]} + \eta_{\mu\sigma} m_{[\nu\rho]} . \tag{1.34}$$

These equations specify the structure constants of the Lie algebra, which may be written as

$$f_{[\mu\nu][\rho\sigma]}{}^{[\kappa\tau]} = 8\eta_{[\rho[\nu}\delta^{[\kappa}_{\mu]}\delta^{\tau]}_{\sigma]} . \tag{1.35}$$

Note that antisymmetrization is always done with 'weight 1', see (A.8), such that the right-hand side can be written as eight terms with coefficients ±1.

Exercise 1.4 *Check that (1.34) leads to (1.35). To compare with (1.13), you have to replace each of the indices A, B, C by antisymmetric combinations, e.g. $A \to [\mu\nu]$. Moreover, you have to insert a factor $\frac{1}{2}$ each time that you sum over such a combined index to avoid double counting, as e.g. the factor $\frac{1}{2}$ in (1.32). Therefore we rewrite (1.34) as*

---

[7] Specifically, it is Λ^{-1} which is the analogue of R in (1.12) and of $U(\theta)$ in (1.15).

[8] Thus, we now replace in (1.29) $\epsilon m^{\mu}{}_{\nu}$ by $\frac{1}{2}\lambda^{\rho\sigma} m_{[\rho\sigma]}{}^{\mu}{}_{\nu}$.

$$[m_A, m_B] = f_{AB}{}^C m_C \to [m_{[\mu\nu]}, m_{[\rho\sigma]}] = \tfrac{1}{2} f_{[\mu\nu][\rho\sigma]}{}^{[\kappa\tau]} m_{[\kappa\tau]}. \tag{1.36}$$

Under a symmetry, each group element is mapped to a transformation of the configuration space of the dynamical fields. This map must give a group homomorphism. For the Lorentz matrix Λ, the transformation of the scalar fields is defined as

$$\phi^i(x) \xrightarrow{\Lambda} \phi'^i(x) \equiv \phi^i(\Lambda x). \tag{1.37}$$

Using (1.24), we find that $\phi'^i(x') = \phi^i(x)$.

Exercise 1.5 *Show that the action (1.4) is invariant under the transformation (1.37).*

We now define differential operators which implement the coordinate change due to an infinitesimal transformation. A transformation in the $[\rho\sigma]$ 2-plane is generated by

$$L_{[\rho\sigma]} \equiv x_\rho \partial_\sigma - x_\sigma \partial_\rho. \tag{1.38}$$

The commutator algebra of these operators is isomorphic to (1.34), and we thus have a realization of the Lie algebra acting as differential operators on functions.

Exercise 1.6 *Compute the commutators $[L_{[\mu\nu]}, L_{[\rho\sigma]}]$ and show that they agree with that of (1.34) for matrix generators. Show that to first order in $\lambda^{\rho\sigma}$*

$$\phi^i(x^\mu) - \tfrac{1}{2}\lambda^{\rho\sigma} L_{[\rho\sigma]}\phi^i(x^\mu) = \phi^i(x^\mu + \lambda^{\mu\nu}x_\nu). \tag{1.39}$$

We then define the differential operator

$$U(\Lambda) \equiv \mathrm{e}^{-\frac{1}{2}\lambda^{\rho\sigma} L_{[\rho\sigma]}}. \tag{1.40}$$

Using this operator, the mapping (1.37) which defines the action of finite Lorentz transformations on scalar fields can then be written as

$$\phi^i(x) \to \phi'^i(x) = U(\Lambda)\phi^i(x) = \phi^i(\Lambda x). \tag{1.41}$$

Box 1.1 **Symmetries**

Symmetries are implemented by transformations that act on fields.

We see that both Lorentz and internal symmetries (see (1.16)) are implemented by linear operators acting on the classical fields, a differential operator for Lorentz and a matrix operator for internal. Both operators depend on group parameters in the same way.

By expanding the exponential, this defines the infinitesimal Lorentz transformation of the scalars:

$$\delta(\lambda)\phi^i(x) = \phi'^i(x) - \phi^i(x) = \phi^i(\Lambda x) - \phi^i(x) = \lambda^\mu{}_\nu x^\nu \partial_\mu \phi^i(x) = -\tfrac{1}{2}\lambda^{\mu\nu} L_{[\mu\nu]}\phi^i(x). \tag{1.42}$$

This definition does give a homomorphism of the group; namely the product of maps, first with Λ_2, then with Λ_1, produces the compound map associated with the product $\Lambda_1\Lambda_2$. This can be seen from the sequence of steps

$$\begin{aligned}\phi^i(x) \xrightarrow{\Lambda_2} \phi'^i(x) = U(\Lambda_2)\phi^i(x) \xrightarrow{\Lambda_1} \phi''^i(x) &= U(\Lambda_2)U(\Lambda_1)\phi^i(x)\\ &= U(\Lambda_2)\phi^i(\Lambda_1 x)\\ &= \phi^i(\Lambda_1\Lambda_2 x).\end{aligned} \tag{1.43}$$

As mentioned above, a symmetry transformation acts *directly on the fields*. This convention determines the order of operations in the first line. In the second and third lines, we use the action of the differential operators to arrive at a transformation with matrix product $\Lambda_1\Lambda_2$. This is exactly the same for internal symmetries in (1.23), where the action of U is obtained by matrix multiplication.

Exercise 1.7 *It is instructive to check (1.43) for Lorentz transformations which are close to the identity. Specifically, use the definition (1.40) to show that the order $\lambda_1\lambda_2$ terms in the product $U(\Lambda_2)U(\Lambda_1)\phi^i$ of differential operators acting on ϕ^i agrees with terms of the same order in $\phi^i(\Lambda_1\Lambda_2 x)$.*

Calculate the infinitesimal commutator $[U(\Lambda_2), U(\Lambda_1)]$ to order $\lambda_1\lambda_2$. Show that the commutator is a Lorentz transformation with (matrix) parameters $[\lambda_1, \lambda_2]$. Note that the second transformation acts on $\phi^i(x)$, and not on the x-dependent factor in (1.42).

It is important to extend the Lorentz transformation rules to covariant and contravariant vector fields, which are, respectively, sections of the cotangent and tangent bundles of Minkowski spacetime. The transformation of a general covariant vector field $W_\mu(x)$ can be modeled on that of the gradient of a scalar $\partial_\mu\phi(x)$. From (1.37) we find

$$\partial_\mu\phi(x) \to \partial_\mu\phi'(x) = \frac{\partial}{\partial x^\mu}\phi(\Lambda x) = \Lambda^{-1}{}_\mu{}^\nu(\partial_\nu\phi)(\Lambda x)\,, \tag{1.44}$$

where we have used the chain rule and (1.28) in the last step. Thus we define the transformation of a general covariant field as

$$W_\mu(x) \to W'_\mu(x) \equiv \Lambda^{-1}{}_\mu{}^\nu W_\nu(\Lambda x). \tag{1.45}$$

For contravariant vectors we assume a transformation of the form

$$V^\mu(x) \to B^\mu{}_\sigma V^\sigma(\Lambda x). \tag{1.46}$$

The matrix can determined by requiring that the inner product $V^\mu(x)W_\mu(x)$ transforms as a scalar. This fixes $B^\mu{}_\sigma = \Lambda^{-1\mu}{}_\sigma$, and we have the transformation rule

$$V^\mu(x) \to V'^\mu(x) \equiv \Lambda^{-1\mu}{}_\nu V^\nu(\Lambda x). \tag{1.47}$$

Next we define generators of Lorentz transformations appropriate to the covariant and contravariant vector representations. They are combined differential/matrix operators given by

$$\begin{aligned} J_{[\rho\sigma]}V^\mu(x) &\equiv (L_{[\rho\sigma]}\delta^\mu{}_\nu + m_{[\rho\sigma]}{}^\mu{}_\nu)V^\nu(x)\,, \\ J_{[\rho\sigma]}W_\nu(x) &\equiv (L_{[\rho\sigma]}\delta_\nu{}^\mu + m_{[\rho\sigma]\nu}{}^\mu)W_\mu(x). \end{aligned} \tag{1.48}$$

We avoid an overly decorative notation by suppressing row and column indices on $J_{[\rho\sigma]}$. For each case a finite Lorentz transformation is implemented by the operator

$$U(\Lambda) = \mathrm{e}^{-\frac{1}{2}\lambda^{\rho\sigma}J_{[\rho\sigma]}}. \tag{1.49}$$

Exercise 1.8 *Verify that* $J_{[\rho\sigma]}(V^\mu W_\mu) = L_{[\rho\sigma]}(V^\mu W_\mu)$.

The Lorentz group has many representations, both higher rank tensor and spinor representations (to be discussed in Ch. 2) and combinations thereof. Let $\psi^i(x)$ denote a set of fields where i is now an index of the components of a general representation. There is a corresponding Lie algebra representation with matrices $m_{[\rho\sigma]}$ which act on the indices and differential/matrix generators

$$J_{[\rho\sigma]} = L_{[\rho\sigma]}\mathbb{1} + m_{[\rho\sigma]}\,, \tag{1.50}$$

in which $\mathbb{1}^i{}_j = \delta^i_j$ is the unit matrix. A finite Lorentz transformation is then the mapping (suppressing the index i for simplicity of the notation)

$$\psi(x) \to \psi'(x) = U(\Lambda)\psi(x) = \mathrm{e}^{-\frac{1}{2}\lambda^{\rho\sigma}m_{[\rho\sigma]}}\psi(\Lambda x). \tag{1.51}$$

The precise forms of the operators $m_{[\rho\sigma]}$, $J_{[\rho\sigma]}$ and $U(\Lambda)$ depend on the representation under study.

Spacetime translations $x^\mu \to x'^\mu = x^\mu - a^\mu$ are much simpler because they are implemented in the same way in all representations of the Lorentz group, namely by the mapping

$$\psi^i(x) \to \psi'^i(x) = \psi^i(x+a) = U(a)\psi^i(x)\,, \tag{1.52}$$

$$U(a) = \mathrm{e}^{a^\mu P_\mu}\,, \tag{1.53}$$

$$P_\mu = \partial_\mu = \frac{\partial}{\partial x^\mu}. \tag{1.54}$$

In (1.52) we have defined the generator P_μ and the finite translation operator $U(a)$ which are differential operators. Finite transformations of the Poincaré group are implemented by the operator $U(a, \Lambda) \equiv U(\Lambda)U(a)$, which acts as follows:

$$\begin{aligned}\psi(x) \;\rightarrow\; \psi'(x) &\equiv U(a,\Lambda)\psi(x) = U(\Lambda)U(a)\psi(x)\\ &= \mathrm{e}^{-\frac{1}{2}\lambda^{\rho\sigma}m_{[\rho\sigma]}}\psi(\Lambda x + a).\end{aligned} \tag{1.55}$$

Exercise 1.9 *Prove that $U((\Lambda)^{-1}a)U(\Lambda) = U(\Lambda)U(a)$. Verify for operators which are close to the identity that*

$$\begin{aligned}U(a)\phi(\Lambda' x + b) &= \phi(\Lambda' x + \Lambda' a + b)\,,\\ U(\Lambda)\phi(\Lambda' x + b) &= \phi(\Lambda'\Lambda x + b).\end{aligned} \tag{1.56}$$

The Lie algebra of the Poincaré group contains the $D(D+1)/2$ generators $J_{[\mu\nu]}$, P_μ. The following commutation rules complete the specification of the Lie algebra:

$$\begin{aligned}[][J_{[\mu\nu]}, J_{[\rho\sigma]}] &= \eta_{\nu\rho}J_{[\mu\sigma]} - \eta_{\mu\rho}J_{[\nu\sigma]} - \eta_{\nu\sigma}J_{[\mu\rho]} + \eta_{\mu\sigma}J_{[\nu\rho]}\,,\\ [J_{[\rho\sigma]}, P_\mu] &= P_\rho\eta_{\sigma\mu} - P_\sigma\eta_{\rho\mu}\,,\\ [P_\mu, P_\nu] &= 0.\end{aligned} \tag{1.57}$$

Exercise 1.10 *Verify (1.57).*

We now discuss the implementation of this Lie algebra on fields. The treatment is parallel to the discussion of internal symmetry at the end of Sec. 1.2.2. The infinitesimal variation of the fields $\psi^i(x)$ is defined as the first order truncation of the exponential in (1.55):

$$\delta\psi = [a^\mu P_\mu - \tfrac{1}{2}\lambda^{\rho\sigma}J_{[\rho\sigma]}]\psi. \tag{1.58}$$

The $J_{[\rho\sigma]}$ operator appropriate to the representation is used, and representation indices are suppressed for simplicity. Consider now the transformation δ_2 with group parameters $(a_2,\,\lambda_2)$ followed by transformation δ_1 with parameters $(a_1,\,\lambda_1)$. The result is defined as

$$\begin{aligned}\delta_1\delta_2\psi &= \delta_1[a_2^\mu P_\mu - \tfrac{1}{2}\lambda_2^{\rho\sigma}J_{[\rho\sigma]}]\psi\\ &= [a_2^\mu P_\mu - \tfrac{1}{2}\lambda_2^{\rho\sigma}J_{[\rho\sigma]}][a_1^\nu P_\nu - \tfrac{1}{2}\lambda_1^{\kappa\tau}J_{[\kappa\tau]}]\psi.\end{aligned} \tag{1.59}$$

The second transformation acts only on the field variable. With some care one can calculate the commutator of two variations, which yields a third transformation with parameters $(a_3,\,\lambda_3)$, that is

$$\begin{aligned}[][\delta_1,\,\delta_2]\psi &= \delta_3\psi\,,\\ \lambda_3^{\rho\sigma} &= [\lambda_1,\,\lambda_2]^{\rho\sigma} = \tfrac{1}{4}f_{[\mu\nu][\kappa\tau]}{}^{[\rho\sigma]}\lambda_1^{\mu\nu}\lambda_2^{\kappa\tau}\,,\\ a_3^\mu &= a_{1\rho}\lambda_2^{\rho\mu} - a_{2\rho}\lambda_1^{\rho\mu} = \tfrac{1}{2}f_{\nu[\rho\sigma]}{}^{\mu}\left(a_1^\nu\lambda_2^{\rho\sigma} - a_2^\nu\lambda_1^{\rho\sigma}\right)\end{aligned} \tag{1.60}$$

(remember Ex. 1.4). Note that the parameters of infinitesimal transformations compose with the structure constants of the Lie algebra, exactly as in the case of internal symmetry.

Exercise 1.11 *Verify the rule of combination of parameters in (1.60).*

As in the discussion of internal symmetry at the end of Sec. 1.2.2, the product of two finite transformations of the Poincaré group, the first with parameters $(a_2,\ \lambda_2)$ followed by the second with parameters $(a_1,\ \lambda_1)$, is given by

$$\psi(x) \to \psi''(x) = U(a_2,\ \lambda_2)U(a_1,\ \lambda_1)\psi(x). \tag{1.61}$$

The compound map is a representation, as we discuss at the end of Sec. 1.5 below.

1.3 Noether currents and charges

It is well known that, using the Noether method, one can construct a conserved current for every continuous global symmetry of the action of a classical field theory. Integrals of the time component of the currents are conserved charges, and an infinitesimal symmetry transformation is implemented on fields by the Poisson bracket of charge and field. Poisson brackets and the correspondence principle provide a useful bridge to the quantum theory in which finite group transformations are implemented through unitary transformations. In this section and the next we review this formalism in order to show that the conventions for symmetries used are compatible with readers' previous study of symmetries in quantum field theory. The Noether formalism has other important applications in supersymmetry and supergravity which enter in later chapters of this book.

We assume that we are dealing with a system of scalar fields $\phi^i(x)$, $i = 1, \ldots, n$, whose Lagrangian density is a function of the fields and their first derivatives, as described by the action (1.17). The Euler–Lagrange equations of motion are

$$\frac{\partial}{\partial x^\mu}\frac{\delta \mathcal{L}}{\delta \partial_\mu \phi^i(x)} - \frac{\delta \mathcal{L}}{\delta \phi^i(x)} = 0. \tag{1.62}$$

We define a generic infinitesimal symmetry variation of the fields by

$$\delta\phi^i(x) \equiv \epsilon^A \Delta_A \phi^i(x)\,, \tag{1.63}$$

in which the ϵ^A are constant parameters. This formula includes as special cases the various internal and spacetime symmetries discussed in Sec. 1.2. In these cases each $\Delta_A\phi^i(x)$ is linear in ϕ^i and given by a matrix or differential operator applied to ϕ^i. Specifically,

$$\text{internal} \quad \epsilon^A \Delta_A \phi^i \to -\theta^A (t_A)^i{}_j \phi^j\,, \tag{1.64}$$

$$\text{spacetime} \quad \epsilon^A \Delta_A \phi^i \to \left[a^\mu \partial_\mu - \tfrac{1}{2}\lambda^{\rho\sigma}(x_\rho \partial_\sigma - x_\sigma \partial_\rho)\right]\phi^i. \tag{1.65}$$

If (1.63) is a symmetry of the theory, then the action is invariant, and the variation of the Lagrangian density is an explicit total derivative, i.e. $\delta\mathcal{L} = \epsilon^A \partial_\mu K^\mu_A$. This must hold for *all* field configurations, not merely those which satisfy the equations of motion (1.62). In detail, the variation of the Lagrangian density is

CHAPTER **3**

From the History of the Parallel Postulate

The history of the axiom of parallels affords the best approach to noneuclidean geometry. Familiarity with the Hilbert system of axioms will make it easier for us to understand the problem. However, we must begin with Euclid. Euclid's fifth postulate states:

(P) If a straight line falling on two straight lines makes the interior angles on the same side together less than two right angles, the two straight lines, if produced indefinitely, meet on that side on which the angles are together less than two right angles."

The word "parallel" is defined by Euclid as follows (def. 23):

> Parallel straight lines are straight lines which, being in the same plane and being produced indefinitely in both directions, do not meet one another in either direction.

For centuries mathematicians were convinced that the fifth postulate could be deduced from the others. If so, it should not, strictly speaking, be included among the postulates.

There were arguments which supported this point of view. Thus it was well known that the converse of the parallel postulate was a provable proposition. This converse can be formulated as follows:

(C) Consider a line falling on two intersecting lines. Then the sum of exactly one pair of interior angles on the same side is less than two right angles.

Proposition (C), i.e., the converse of the parallel postulate, is equivalent to Theorem 8 of the preceding chapter. Indeed, if Theorem 8 were false, then we could have $\alpha_1 \equiv \beta$ (cf. Fig. 14) or, what amounts to the same thing, $\alpha + \beta = 2R$ and g_1 could intersect g_2. But this would contradict (C) which asserts that if g_1 and g_2 intersect, then $\alpha + \beta < 2R$. Thus (C) implies Theorem 8. It is easy to prove that Theorem 8 implies (C).

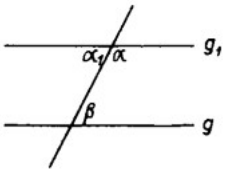

FIG. 14.

While mathematicians of past ages were not familiar with Hilbert's system, they could deduce Theorem 8 or (C) from Euclid's axioms and postulates without the use of the parallel postulate. (In proving Theorem 8 we did not make use of Axiom V.)

It was thought impossible for a geometric theorem not to be provable if its converse was provable. Indeed, in the case of most theorems of elementary geometry proving the converse of a theorem does not require the use of additional axioms. For example, the theorem on the congruence of base angles in an isosceles triangle and its converse (if two angles in a triangle are congruent then the sides opposite to these angles are congruent) are both provable by means of the congruence axioms. It is therefore understandable why mathematicians tried so eagerly for 2000 years to prove the axiom of parallels. In this they failed.

In many cases the "proofs" involved the use of an intuitive fact equivalent to the parallel postulate. For example, it is easy to prove the parallel postulate if we take it for granted that the sum of the angles in a triangle is equal to two right angles.

Other attempts at proof made use of the assertion that the length of the perpendicular from a point on a line to a parallel line is independent of that point. However, parallel lines are defined as nonintersecting lines (cf. above) and this does not automatically mean that the lengths in question are equal.

Of course, it is possible to prove this last assertion if we make use of the theorem on the alternate interior angles for parallel lines. But we would then be guilty of circular reasoning, since the theorem just mentioned cannot be proved without the use of the parallel postulate.

In 1763 G. S. Kluegel, a student of Kestner, wrote a dissertation [3] in which he brought together and criticized all significant attempts to prove the parallel postulate contributed by mathematicians over the 2000 years between the publication of the "Elements" and his own time. He found, correctly, that all 28 "proofs" were false.

Most of these attempts are of historical interest only. Some, however, pointed the way to new insights.

The first significant contribution is due to the Jesuit priest Saccheri (1667–1733). In his extensive work on parallels Saccheri studied a quadrilateral *ABCD* in which $AC \equiv BD$ and the angles at *A* and *B* are right angles (Fig. 15).

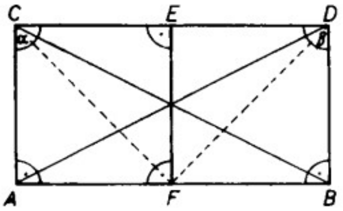

FIG. 15.

If we do not wish to make use of the parallel postulate, then it is not possible to prove that the angles *ACD* and *BCD* are right angles, i.e., that *ABDC* is a rectangle. However, we can use congruence considerations to prove that $\angle ACD \equiv \angle BDC$; namely,

$$\triangle ABC \equiv \triangle ABD \qquad \text{(sas)},$$

so that

$$AD \equiv BC.$$

Congruence of the diagonals implies

$$\triangle ACD \equiv \triangle BCD \qquad \text{(sss)}.$$

Hence

$$\alpha \equiv \beta.$$

Now we ask: Are the congruent angles α and β in the Saccheri quadrilateral acute, obtuse, or right angles?

First we establish a connection between this question and the sum of the angles in a triangle.

Let ABC (Fig. 16) be a triangle; let D, E be the midpoints of AC and BC; let F, G, H be the feet of the perpendiculars from C, A, B on to the line DE. Then

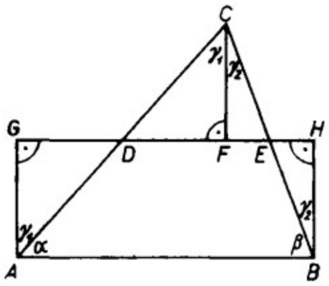

FIG. 16.

$$FC \equiv AG \equiv BH.$$

This follows from the congruence of the triangles DFC and ADG (saa) and the congruence of the triangles EFC and BEH.

The quadrilateral $ABHG$ is thus a Saccheri quadrilateral with right angles at G and H.

It follows that the the angles at A and B are congruent:

$$\alpha + \gamma_1 \equiv \beta + \gamma_2.$$

Since

$$\alpha + \beta + (\gamma_1 + \gamma_2) \equiv W$$

is the sum of the angles in the triangle ABC, it follows that each of the angles at A and B is equal to $W/2$.

"The hypothesis of the acute angle"—$W/2 < R$—implies that the sum of the angles in a triangle is $<2R$.

"The hypothesis of the obtuse angle"—$W/2 > R$—implies that the sum of the angles in a triangle is $>2R$.

"The hypothesis of the right angle"—$W/2 \equiv R$—implies that the sum of the angles in a triangle is $\equiv 2R$.

Saccheri attempted to eliminate the first two hypotheses by showing that they led to contradictions. If proved, this would imply that the sum of the angles in a triangle is equal to two right angles. But this would imply (cf. Theorem 12, below) the parallel postulate.

Saccheri succeeded in eliminating "the hypothesis of the obtuse angle." His proof is clumsy but correct. On the other hand, his proof of the inadmissibility of "the hypothesis of the acute angle" is not acceptable.

To sum up: Saccheri succeeded in showing that the sum of the angles in a triangle does not exceed two right angles.

Saccheri failed to show that the assumption

$$\alpha + \beta + \gamma < 2R$$

leads to a contradiction.

We shall see that there are deep reasons for these outcomes.

Instead of reproducing the clumsy argument of Saccheri we present Legendre's (1752–1833) version of the theorem on the sum of the angles in a triangle.

Thus, let α, β, γ be the angles of a given triangle ABC. Lay off the segment AB n times in succession on a line (Fig. 17) and construct over each of these segments a triangle $A_vA_{v+1}B_v$ congruent to the given triangle (all of the contructed triangles are to lie in the same plane).

We claim that $\gamma_1 \geqq \gamma$. If we have $\gamma_1 < \gamma$, then

$$A_v A_{v+1} > B_v B_{v+1}. \tag{1}$$

This conclusion can easily be deduced from the axioms of congruence. Further, the polygonal line $A_1B_1 + B_1B_2 + \cdots + B_nA_{n+1}$ is greater than the segment A_1A_{n+1}:

$$\begin{aligned} A_1B_1 + n \cdot B_1B_2 + B_nA_{n+1} &> n \cdot A_1A_2, \\ A_1B_1 + B_1A_2 &> n \cdot (A_1A_2 - B_1B_2). \end{aligned} \tag{2}$$

In view of (1) the difference $A_1A_2 - B_1B_2$ is equal to some segment ε. Hence (2) can be written in the form

$$n \cdot \varepsilon < A_1B_1 + B_1A_2. \tag{3}$$

Since n can be taken arbitrarily large, (3) contradicts Axiom IV, 1 (axiom of Archimedes).

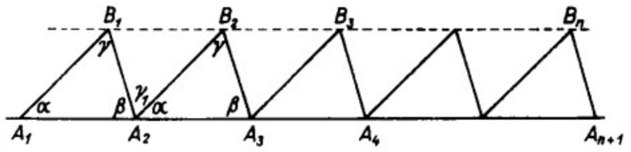

FIG. 17.

The assumption $\gamma_1 < \gamma$ is thus ruled out. But $\gamma_1 \geqslant \gamma$ implies $\alpha + \beta + \gamma \leqslant \alpha + \beta + \gamma_1 \equiv 2R$. This proves:

Theorem 11. The sum of the angles in a triangle is at most equal to two right angles.

Note that Theorem 11 was proved using the axioms in group I–III and the first continuity axiom (axiom of Archimedes) in group IV.

There is a very close connection between the sum of the angles in a triangle and the axiom of parallels. As noted before one can prove that:

Theorem 12. If the sum of the angles in a triangle is equal to two right angles, then the axiom of parallels holds.

We give a brief proof of this assertion.

Let A be the given point and g the given line (Fig. 18); B the foot of the perpendicular from A to g; C another point on g; h the perpendicular to AB at A. By Theorem 5, g and h cannot intersect. We shall show presently that h is the only parallel to g at A.

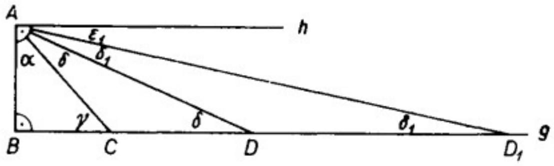

FIG. 18.

Thus let α and γ be the angles in the triangle ABC with vertices A and C. Then, in view of our assumption,†

$$\alpha + \gamma = R.$$

Choose D on g so that $AC \equiv CD$ and so that C lies between B and D. Then $\triangle ACD$ is isosceles and

$$\delta = \angle ADC = \gamma/2.$$

Again, let D_1 be a point on the extension of BD beyond D such that $AD \equiv DD_1$. Then

$$\delta_1 = \angle AD_1B = \delta/2 = \gamma/4.$$

Since $\angle D_1AB = R - \delta_1$, it follows that $\varepsilon_1 = \angle(h, AD_1) = \delta_1 = \gamma/4$.

By continuing this procedure we obtain segments AD_2, AD_3, ... which form with D_2B, D_3B, ... angles $\gamma/8$, $\gamma/16$, ... The corresponding angles $\varepsilon_2, \varepsilon_3, \ldots$ are likewise equal to $\gamma/8$, $\gamma/16$, ...

Now assume that $k \neq h$ is a ray emanating from A which does not intersect g. Let φ be the angle between k and h. If n is large enough, then the angle $\varepsilon_n = \gamma/2^{n+1}$ between the ray AD_n

---

† We shall sometimes refer to congruent angles as "equal". Equal angles have the same radian measure. Thus $\varphi = \psi$ is an equality between numbers.

and h will be smaller than φ. But then the ray k will lie in the interior of the angle BAD_n (Fig. 19) and, by the "triangle axiom" II, 4, will intersect BD_n and therefore the line g. A similar argument holds for the halfplane determined by AB and not containing the point C. Thus h is seen to be the only line through A parallel to g. This proves the parallel postulate under the assumption that the sum of the angles in a triangle is equal to two right angles.

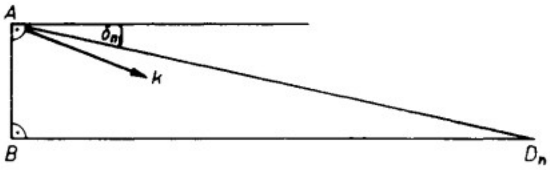

FIG. 19.

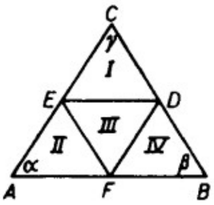

FIG. 20.

What follows is a quick "proof" that the sum of the angles in a triangle is equal to two right angles.

Thus, let D, E, F in Fig. 20 be the midpoints of the sides of a triangle, and I, II, III, IV the triangles determined by the segments DE, EF, DF. Let W be the (unknown) sum of the angles in a triangle. Then it is easy to see that

$$4W = (\alpha + \beta + \gamma) + 3\cdot 2R.$$

It follows that

$$3W = 6R, \qquad W = 2R.$$

According to Theorem 12 this implies the parallel postulate. Where is the error?

The careful reader will note that the only thing which has been proved is the following interesting assertion:

Theorem 13. If the sum of the angles in a triangle is the same for all triangles, then it is equal to two right angles.

To resume our narrative. As we saw, Legendre proved that the sum of the angles in a triangle could not exceed two right angles. It is understandable that he thought he was close to the solution of a problem which had kept mathematicians busy for more than 2000 years.

In 1823 Legendre thought that he had proved the parallel postulate. He reasoned as follows:

If $\alpha + \beta + \gamma < 2R$, then there exists an angle δ such that

$$\alpha + \beta + \gamma = 2R - \delta.$$

δ is called the "defect" of the triangle. The following is clear (Fig. 21): If we divide a triangle by means of a transversal through a vertex into two triangles ADC and BDC, then the defect of the whole triangle is the sum of the defects of its parts. Indeed, by consulting Fig. 21 we see that

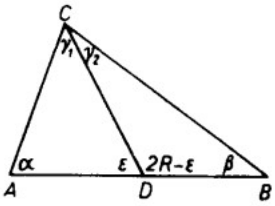

FIG. 21.

$$2R - (\alpha + \beta + \gamma) = 2R - (\alpha + \varepsilon + \gamma_1) + 2R - \\ - (\beta + \gamma_2 + 2R - \varepsilon).$$

This result remains true if the triangle is divided into more than two "subtriangles."

The additivity of the defect is at the heart of Legendre's argument. He reflects the triangle ABC about AB and draws through the image D of C a line which meets the rays CA and CB in E and F. The defect of the triangle CEF is at least equal to the sum 2δ of the defects of the triangles ACB and BAD (Fig. 22). Another reflection applied to $\triangle CEF$ yields a triangle with defect $\geqslant 4\delta$, etc. After n steps we obtain a triangle with defect $2^n \cdot \delta$. For n large enough $2^n \cdot \delta$ would exceed $2R$, which is impossible. Hence $\delta = 0$ and, in view of Theorem 12, the parallel postulate follows.

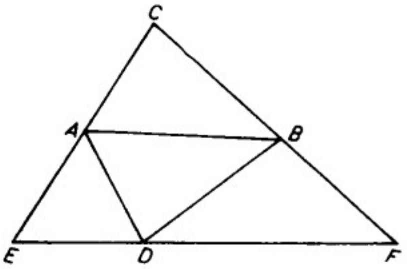

FIG. 22.

The reader is invited to study the argument carefully and detect the flaw in it.

The proof uses as an "axiom" the proposition that it is always possible to draw a line through a point (D) in the interior of an angle which intersects both sides of the angle. Legendre was fully aware of the fact that he was making use of this proposition as an "axiom."

One is likely to regard this proposition as being intuitively obvious. However, in trying to decide whether the available axioms imply this "obvious" result, we get into difficulties.

It is certainly not immediately apparent that this result is equivalent to the parallel postulate and we can hardly blame Legendre for thinking that it was independent of the parallel postulate.

To see that Legendre was mistaken we need only consult our pseudogeometry of Example 1. It is only fair to point out that this technique of testing independence of axioms was unknown to Legendre.

It is obvious that in the case of the point S, say (Fig. 2), there exists no "pseudoline" which intersects *both* sides of the angle α.

Legendre's axiom is seen to be another equivalent of the parallel postulate. Thus we end up with an interesting fact and an incorrect proof of the parallel postulate.

We cannot give here a more detailed history of the attempts to prove the parallel postulate and must leave many such interesting attempts unmentioned.

After 2000 years of vain effort many mathematicians began to show signs of skepticism. They began to doubt that a proof was at all possible. It should be noted that the persistence displayed by so many mathematicians was due to the fact that they viewed the unproved parallel postulate as a shocking flaw in geometry.

This statement is well illustrated by the following excerpt from a letter which the Hungarian mathematician Wolfgang Bolyai [21] wrote to his son, Johann:

> "It is unbelievable that this stubborn darkness, this eternal eclipse, this flaw in geometry, this eternal cloud on virgin truth can be endured."

At the same time the father is horrified by the thought that his son is attracted by the problem of parallels. Wolfgang Bolyai writes:

> "You must not attempt this approach to parallels. I know this way to its very end. I have traversed this bottomless night, which extinguished all light and joy of my life. I entreat you, leave the science of parallels alone ... . I thought I would sacrifice myself for the sake of the truth. I was ready to become a martyr who would remove the flaw from geometry and return it purified to mankind. I accomplished monstrous, enormous labors; my creations are far better than those of others and yet I have not achieved complete satisfaction. For here it is true that si paullum a summo discessit, vergit ad imum. I turned back when I saw that no man can reach the bottom of this night. I turned back unconsoled, pitying myself and all mankind."

And yet again:

> "I admit that I expect little from the deviation of your lines. It seems to me that I have been in these regions; that I have traveled past all reefs of this infernal Dead Sea and have always come back with broken mast and torn sail. The ruin of my disposition and my fall date back to this time. I thoughtlessly risked my life and happiness—aut Caesar aut nihil."

But this resignation of experienced mathematicians was not to be the last chapter in the exciting story of our geometric theorem. Owing in no small measure to the work of the younger Bolyai (1831) the issue took a surprising turn.

Most attempts to prove the parallel postulate employed the indirect method of proof: One argued that if the parallel theorem is false, then the sum of the angles in a triangle is less than two right angles. Then the triangle has a "defect." Then ... .

This mode of argument was expected to produce a contradiction. But none could be found. The thought suggested itself that it might after all be possible to construct a geometry in which the negation of the parallel theorem rather than the parallel theorem holds. After all, it is conceivable that the sum of the angles in a triangle is only approximately equal to two right angles.

Gauss followed up this thought. He used a transit to measure the sum of the angles of a huge triangle and found no significant deviation from two right angles. It was nevertheless possible to conceive of a geometry in which the parallel postulate did not hold and in which the sum of the angles in a triangle was less than two right angles.

Gauss was perhaps the first to have a clear conception of such a "noneuclidean" geometry. The thought struck him as being so revolutionary that he would not make it public. In 1829 he wrote to Bessel:

> "It may take very long before I make public my investigations on this issue; in fact this may not

> happen in my lifetime for I fear the scream of the dullards if I made my views explicit."

In a few places in his letters Gauss expresses the conviction that there exists a closed and consistent geometry in which the euclidean parallel postulate does not hold.

The first published accounts dealing with such a geometry are due to the Hungarian Johann Bolyai (1802–1860) and the Russian Lobachevski (1793–1856).

In 1823 Johann Bolyai could tell his father, who had tried so hard to make him give up his interest in the problem, that he was succeeding:

> "I am resolved to publish a work on parallels as soon as I can put it in order, complete it, and the opportunity arises. I have not yet made the discovery but the path which I have followed is almost certain to lead me to my goal, provided this goal is possible. I do not yet have it but I have found things so magnificent that I was astounded. It would be an eternal pity if these things were lost as you, my dear father, are bound to admit when you see them. All I can say now is that I have created a new and different world out of nothing. All that I have sent you thus far is like a house of cards compared with a tower."

His father advised him to publish his results as soon as possible. Johann Bolyai's comment follows:

> "He advised me that, if I was really successful, I should speedily make a public announcement and that for two reasons. One reason is that the idea might easily pass to someone else who would then publish it. Another reason—and one that seems valid enough—is that when the time is ripe for certain things, these things appear in different places in the manner of violets coming to light in early spring. And since scientific striving is like a war of which one does not know when it will be replaced by peace one

> must, if possible, win; for here preeminence comes to him who is first."

The advice was sound for, when Johann Bolyai published his work in 1831, he had been anticipated by Lobachevski who had presented his treatise to the physical-mathematical division of the University of Kazan on February 2, 1826.

Priority arguments are not important. The time was ripe for this particular insight and it is safe to say that Gauss, Bolyai, and Lobachevski independently drew the same conclusion from the impossibility of proving the parallel postulate.

Their contemporaries paid almost no attention to these new ideas. The view that euclidean geometry was the only possible geometry was so firmly rooted in thought that the new notion was hardly recognized. Although its discoverers developed the new geometry to the point of working out its trigonometry, this geometry lacked intuitive appeal and so was almost incomprehensible. A few decades passed before significant numbers of mathematicians took notice of the works of Bolyai and Lobachevski. The new geometry gained intuitive, appeal as a result of the "models" constructed by Felix Klein and Poincaré.

In our introduction we shall make use of the easy-to-follow Poincaré model.

We precede our exposition with a chapter containing results of elementary geometry which may not be known to some of our readers.

For $N = 972$, there are but two answers, the two small having coalesced. They are

9.00000 and 12.00000

For $N = 973$, there is again but one

12.10380

For all higher values of N, there is but one answer; so that a person examining only values of N that are multiples of 50 might easily overlook the circumstance that there ever are more than one answer.

CHAPTER IV

PROJECTION

Art. 117. *Scholium* 26. When we look upon any scene, a ray from each visible point is the path of light to the eye. Let a plane of glass be set up between, and let the point where each ray to the eye cuts the plane of the glass be marked upon the latter. Then, as far as the shapes of things are concerned, the picture so produced, seen from just that relative point of view, will look just like the natural scene viewed with one eye, disregarding focal accommodation of the eye, diffraction, etc. The art of placing the points of a picture so that they will appear to the spectator as if the rays from the natural objects pierced the picture as a glass window is called *Linear Perspective.*

This art is not only useful to the artist, but is still more indispensable to a person who may wish to interpret a scene before him and judge how the different objects he sees are really situated. But what most concerns us as students of geometry is, that it is through the study of perspective, and the problems it suggests, that we can most easily attain an understanding of space, and that we gain a philosophical comprehension of the relations of its different properties.

Nor is the reason of this far to seek. As long as we restrict ourselves to the intrinsic idea of space as a three-dimensional continuum, we cannot readily advance beyond the sort of propositions of which we have had a specimen in the Book on Topology.

The most beautiful part of geometry is Graphics, and this relates to the properties of planes and rays. Now planes and rays, though ideal, are ideas suggested by visual experiences. We call them optical homaloids. Naturally, therefore, the directest and most efficient way of thinking about them is to call up mental images of light, and its paths and the perspective pictures, based on the regularities of the ways of illumination.

Before we undertake to set forth the proceeding of making a perspective drawing, we must take up the different problems it involves one by one, and so gain a thorough mastery of its principles.

Art. 118. *Definition* 164. A *correspondence* is a system of relationship between two sets of objects which connects all the objects of the first set each with the same number of objects of the second set; and all the objects of the second set each with the same number of objects of the first set. If the two numbers are *M* and *N*, the correspondence is called an *M* to *N* correspondence. Thus, if in a school every pupil has 3 teachers and every teacher 20 pupils, there is a 20 to 3 correspondence between pupils and teachers.

The word *projection* is used in mathematics in several senses. A system by which the points on the surface of the earth, or other surface, are made to correspond one to one to the points of a map, or other plane, and the lines of the former surface are made to correspond one to one to the lines of the plane, is called, by cartographers, a *projection*.[73] Moreover, the operation or result of constructing a figure on a surface which represents a figure in space as if rays were drawn to the eye from all the points (or all the visible points) of the spacious figure and were then cut by the surface of the constructed figure and their points of intersection with it were marked, is called a *central projection*, or, since this is the only kind of projection with which Projective Geometry deals, a *projection* simply. Sig. Professor Cremona, a celebrated Italian geometer, whose beautiful treatise on Projective Geometry has been translated into our barbarous tongue, has used the word *projection* for the first part of the whole operation of central projection. But this is better called production.

Definition 165. From every point of a figure, called the *original* figure (whether plane or spacious) let rays be drawn to one point, called the *eye* of the production or projection, so that from every point is produced a ray and from every ray a plane. Then this operation is called a *production to* the eye *from* the original figure *of* the new spacious figure.

Definition 166. The operation of *plane section* (called section, for short) consists in intercepting a solid, or spacious, figure by a plane, called the plane of section or of delineation, so that every plane is reduced to a ray, and every ray to a point.

---

[73] Peirce was well acquainted with such problems having invented a quincuncial map in 1876 which has proved useful in recent times. See "Charles S. Peirce and the Problem of Map-Projection" by the editor in the *Proceedings of the American Philosophical Society*, vol. 107, 4, August 1963.

Definition 167. The operation of *perspective delineation* consists in the production from the original figure to the eye of a spacious figure, followed by the plane section of the latter by the plane of delineation.

Scholium 27. We here use the traditional phraseology which speaks as if lines and surfaces were something we make. This is not strictly correct. The lines and surfaces are *places* which are *there*, whether we think of them or not. They are quite ideal, it is true. But they are there, in this sense, that we can think of them as being there without being drawn into any absurdity. The ordinary diction however which represents us as *drawing*, — or technical language "describing," — lines and surfaces, and which talks of a moving line as *generating* a surface, with other such expressions, is rather convenient, and can hardly mislead.

Art. 119. *Definition* 168. In perspective the eye of production is generally called the *station point*. The plane of the section is called the *plane of delineation*. The original figures are called *natural*, or *original*.

Art. 120. *Theorem 17.* Two rays in one plane have a point in common.

Demonstration. Let {*b*} and {*c*} be two different rays in one plane (*bc*). Then, I say, they have a common point [*bc*].

For take any point [A] not in (*bc*). Then there is a plane (A*b*) and a plane (A*c*); and these two are different planes. For were they the same, the ray

{(A*b*)(*bc*)}

would be the same as the ray

{(A*c*)(*bc*)}.

But one of these is {*b*}, while the other {*c*}, which are distinct rays. Hence the planes (A*b*) and (A*c*) have in common a ray

{(A*b*)(A*c*)};

and this ray is not in (*bc*), for if it were, it would be common to (A*b*) and (*bc*), and therefore the only ray they have in common. It would be {(A*b*)(*bc*)}; and it would also be common to (A*c*) and (*bc*), and therefore the only ray they have in common. It would be {(A*c*)(*bc*)}. And thus {(A*b*)(*bc*)} and {(A*c*)(*bc*)} would be the same ray. Since then {(A*b*)(A*c*)} is not in (*bc*) it has a point in common with (*bc*).

But [(*bc*){(A*b*)(A*c*)}] is in (A*b*) since it is in the ray {(A*b*)(A*c*)} which

is in this plane. It is in (A*c*) for the same reason. It is in (*bc*). Hence it is in the common ray of (A*b*) and (*bc*) or {(A*b*)(*bc*)}, which is {*b*}, and in the common ray of (A*c*) and (*bc*), or {(A*c*)(*bc*)}, which is {*c*}. It is therefore a point common to {*b*} and {*c*}. Consequently there is such a point. Q.E.D. The student can prove that if two rays have a common point they lie in one plane.

Art. 121. *Theorem 18. The delineation of a straight line is a straight line.* For the original straight line and the station-point lie in one plane (as any point and ray do), and this plane is cut by the plane of delineation in a straight line (as any plane is cut by another in a ray).

Theorem 19. The delineation of a point is a point. For the original point and the station point lie in one ray (as any two points lie), and this ray pierces the plane of delineation in one point (as any ray cuts a plane).

Art. 122. *Scholium* 28. When a spectator stands upon the sea-shore with his eye about 12 feet above the sea-level, the line between sea and sky, owing to the combined effects of the earth's curvature and the refraction of light, appears lower than his eye by the breadth of a line $\frac{1}{100}$ inch thick viewed at a distance of ten inches. And this which is called the *dip of the horizon* will be more, if the spectator's eye is higher, in the proportion of the square root of that height.

If there were no refraction and the earth's surface, instead of being curved, were plane, there would practically be a similar line between sea and sky, only a trifle higher. Whether if vision were perfect, and no objects intervened, such a line would exist, we will not here inquire. Suffice it that for pictorial purposes it may be assumed that there would be such a line at the height of the eye.

Corollary 25. The delineation of three lines which meet in one point is three lines meeting at one point.

Art. 123. *Theorem 20. The delineation of a ray cuts the original ray.*

Demonstration. The delineation lies in the plane of the station point and the original ray. But two rays in one plane have a point in common.

Art. 124. *Theorem 21. The points at which the delineations of three rays which intersect in three points respectively cut their originals lie on one ray (are collinear).*

Demonstration. The three points lie in one plane; and the three original

rays lie in that plane. Their delineations lie in the plane of delineation. Hence, the intersections of the original rays with their delineations lie both in the plane of the three points and in the plane of delineation. But two planes have only a ray in common. Hence, those three intersections lie in the ray in which those two planes intersect.

Art. 125. *Scholium* 29. In order to draw a straight line, the student provides himself with a straight edge. And looks along the edge to make sure it coincides with a ray of light.

In order to draw a line which meets a given line at the firmament, we make use of a ruler along which slides one side of a triangle, another side being a straight edge. Keeping the ruler fixed we slide the triangle into a new position for every new line, and the lines so drawn may be assumed to meet at the firmament, for when continued to a very great distance they will appear to meet there [Fig. 60].

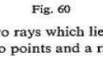

Fig. 60

Art. 126. *Definition* 169. Two rays which lie in one plane, or four points which lie in one plane, or two points and a ray which lie in one plane are said to be *coplanar*.

Definition 170. Two rays through a point, or four planes through one point, or two planes and a ray having a common point are said to be *concurrent*, or *copunctual*.

Definition 171. Three points on one ray, or three planes through one ray, or two points with a plane through them, or two planes with a point on their intersection are said to be *collinear*, or better, *coradial*.

Art. 127. *Theorem 22. If six points lie two by two on three concurrent rays, and six other rays join each point to one of the points on each of the concurrent rays on which that point does not itself lie, then the three intersections each of two rays joining points on one pair of the three concurrent rays are coradial.*

That is (the capital letters standing for points) if the following triplets are collinear OCG, OIJ, OUV, then (pairs of letters standing for rays through the points denoted by those letters) the intersections of {CI} and {GJ}, of {CU} and {GV}, of {IU} and {JV} are coradial.

Demonstration. First, suppose the three concurrent rays are not coplanar. Then the plane of the three points (CIU) contains the rays {CI}, {CU}, and {IU} and the plane of the three points (GJV) contains the rays {GJ} {GV} {JV}. Consequently, the intersections of {CI} and {GJ}, of {CU} and {GV}, of {IU} and {JV} lie at once in the plane (CIU) and in the plane (GJV). But two planes have only one ray in common. Hence, those three intersections lie in that ray.

Second, suppose the concurrent rays are coplanar. Then the three concurrent rays are a perspective delineation of three concurrent rays not coplanar. Namely, we can assume the plane (OCI) as the plane of delineation, taking for the station-point, which we may denote by [O′], any point not in that plane. Then, in the plane (O′OU), we may assume any line through [O] of which {OU} becomes the delineation. We draw the ray {O′U} and denote the point where it cuts the new ray through [O] by [U′]. We draw the line {O′V} and denote the point where it cuts the new ray through [O] by [V′]. Then [U] is the delineation of [U′] and [V] of [V′]; while [C], [G], [I], [J] are delineations from the same centre of themselves. But we have just seen that the intersections of {CI} and {GJ}, of {CU′} and {GV′}, of {IU′} and {JV′} will lie on one ray. The delineation of this ray will be a ray. Hence, the intersections of {CI} and {GJ}, of {CU} and {GV}, of {IU} and {JV} will also lie on one ray, since these are the delineations of the other set of intersections.

Scholium 30. *Geometrical Nets.* The last part of the above demonstration, though perfectly conclusive, is unsatisfactory, or rather betrays an unsatisfactoriness in the statement of the properties of space, inasmuch as it proves something about a plane, having nothing to do with a third dimension, by means of a perspective delineation involving a third dimension. This is unavoidable, because we have not stated what the course of a ray is in a plane, in such a way that anything can be deduced from it directly. There are various ways, none of them all we could desire, for remedying this defect.

One way is to say that when we draw a figure by first assuming certain points and rays arbitrarily, and afterwards marking certain *junctions* (or rays containing two points already marked) and *intersections* (or points contained in two rays already marked), all the arbitrarily taken elements may be considered and treated as if they were in as many dimensions as their number would admit of their extending into. For example, our three collinear lines may be reasoned about exactly as if they were in three dimensions. After them, the six points are taken on them and can therefore not be in additional dimensions. This is a way of perfectly describing the course of a ray.

Corollary 26. The above theorem gives by the principle of duality the following proposition. Through each of three coplanar rays, $\{a\}$, $\{b\}$, $\{c\}$ (which may or may not belong to one aster), we take two planes, planes (α) and (α') in $\{a\}$, planes (β) and (β') in $\{b\}$, planes (γ) and (γ') in $\{c\}$. The intersection of (α) and (β) will lie in one plane with that of (α') and (β'). The same will be true of $\{\beta\gamma\}$ and $\{\beta'\gamma'\}$, of $\{\alpha\gamma\}$ and $\{\alpha'\gamma'\}$. The three planes of those pairs of intersections are coradial.

Corollary 27. The converse of theorem 22 also holds, namely that if the first three rays are not concurrent, the last three intersections are not collinear. In the case of the plane figure, this follows by the principle of plane duality (which interchanges points and rays). In the case of the solid it is evident; for if from three points in the range of the hinge-ray of two planes be drawn from each two rays in the two planes respectively, it follows from [Cor. 15] that the three pairs of rays lie in three planes; and these intersect in one point.

Corollary 28. The converse of the first corollary is also true, being derivable from the last corollary by the principle of duality. The proposition is that if through a ray we take three planes (α), (β), (γ), and draw three rays $\{a\}$ in (α), $\{b\}$ in (β), $\{c\}$ in (γ), so that $\{a\}$, $\{b\}$, $\{c\}$, are concurrent, and if we draw three other concurrent rays $\{a'\}$ in (α), $\{b'\}$ in (β), $\{c'\}$ in (γ), (whether these are concurrent with all the other rays or not), then the three planes of (ab), (ac), (bc), will respectively intersect the planes of $(a'b')$, $(a'c')$, $(b'c')$, and the three rays of intersection will be coplanar.[74]

Art. 128. *Scholium* 31. Suppose a spectator to stand upon a boundless plane, — in geometrical strictness [Fig. 61]. Then, according to the idea of space adopted in graphics every ray through his eye will cut that plane. But graphics is non-committal as to the distances at which these rays cut. The question whether there be any parts of the plane at an infinite distance is beyond its purview.

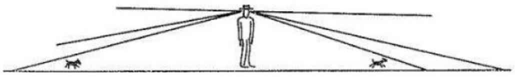

Fig. 61

---

[74] P. 235 of Peirce's MS. is missing.

Perhaps, for ought graphics can say, a dog running off along a ray would after a number of days reappear from behind, having completed the circuit of space. Perhaps, on the contrary, the observer standing on the plane would see a circle lower than his eye which was at an infinite distance so that time would not be long enough to carry light any further. Perhaps, as is generally assumed, all parts of the plane below his eye are at a finite distance, but the ray on a level with his eye would strike the "horizon" or limit between earth and sky. In this case, the parts of space at an infinite distance form the limit of planes, and it is perfectly proper and true to say they are a plane at an infinite distance. Now this may not be quite true: We shall discuss this somewhat under Metrics: but it is certainly excessively close to the truth. It would be quite nonsensical to draw a perspective picture on any other supposition.

Definition 172. The plane at infinity is called the *Absolute*, or the *firmament*.

Definition 173. The perspective delineation of the intersection of a plane with the firmament is called the *vanishing-line* of that plane. The perspective delineation of the intersection of a ray with the firmament is called the *vanishing-point* of that ray.

Art. 129. *Scholium* 32. The art of linear perspective is not merely useful in drawing, for which purpose a perfect theoretical knowledge of it is not indispensable to an artist of keenly accurate perceptions and vivid imagination. It is also valuable in enabling us accurately to interpret a perspective picture or a scene before us, and from the appearance to understand how the different objects are really situated. But what renders it most important to the student of geometry is that in it lies the best key to the science of space. There is no other way of learning geometry comparable to that by the road of projections for facility and for philosophical insight into the true relations of different theorems.

Scholium 33. Two great faults of perspective are ordinarily committed by artists. The first is that of exaggeration. The treatises on the subject inculcate this. A perspective picture is drawn to be looked at with one eye (for binocular perspective is impossible without a stereoscope) from a particular stand-point. If the picture is otherwise viewed, its perspective is falsified. Now, artists have the habit of constructing their linear perspective as if the picture were to be viewed from a distance of a foot or less, while the whole treatment is such that it requires to be seen from a distance five times as great. Whether this is justifiable by artistic principles, or not, it is not for the mere geometrician to say. Perhaps the effect is to partially compensate for the absence of the binocular perspective. But certainly *true* perspective should first be learned.

In the second place, artists usually paint landscapes with figures so that to be viewed rightly they should be placed almost on the floor, while the spectator squats like a tailor on a low stool. For the horizon line which must be very nearly on the level of the observer's eye (being lower by only about $\frac{1}{100}$ of the distance of the plane of delineation from the point of view, even if the spectator be supposed to be 1200 feet above the level of the horizon) is often represented as cutting figures standing on the level ground of the spectator at about their waists.

Art. 130. *Scholium* 34. To draw a picture in perspective, the paper should be set up in the position in which it is to be viewed and the most important planes should first be treated, two lines being drawn for each, first, the *intersecting line*, or ray in which each cuts the plane of delineation, and second, the *vanishing line*, or the intersecting line of its vanishing plane, that is, the line in which the plane through the eye that cuts the original plane in a ray of the firmament cuts the plane of delineation.

The most important plane is the plane on which the observer stands and which is level under his feet. The intersecting line of this plane cannot be drawn on the paper, but it should be drawn on the floor. The vanishing line of the ground plane is the horizon and is a level line about five feet above the floor.

We next mark upon the horizon the *centre of the picture*, which is the point of the plane of delineation nearest the observer's eye. From the centre of the picture, by means of a plummet we draw a plumb line to the floor. It will now be convenient to divide the ground into squares. For this purpose, we may proceed as follows. We mark on the floor the point plumb beneath the station point. Then, on the intersecting line of the ground and plane of delineation we lay off to the left $\frac{3}{4}$ of the distance of the eye from the picture, and to the right $1\frac{1}{3}$ of the same distance. From these two points we draw lines to the point plumb under the eye. The left hand line will be $1\frac{1}{4}$ times as long as the distance of the eye from the picture, while the right hand one will be $1\frac{2}{3}$ as long as the same distance [Fig. 62].[75]

---

[75] This section is incomplete. For Peirce writes a note to himself to "finish later."

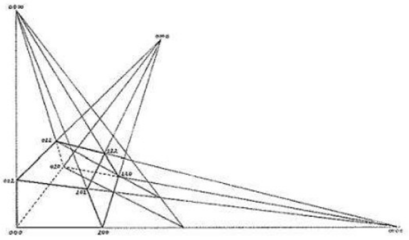

Fig. 62

Art. 131. *Theorem 23. Let any point be designated as* 000. *Let three rays be drawn through this point, and two points be taken on each and marked, those on one* 200 *and* ∞00, *those on another* 020 *and* 0∞0, *and those on the third* 002 *and* 00∞. *Let other rays be drawn and their intersections marked, but only when their marks can be determined by the rule that any point marked on a ray drawn between two points must have all its three numbers weighted means of the corresponding numbers of the other points, the weights being the same for all the numbers. Then, every triplet of numbers will belong to one point and one only, and if the first three rays are not coplanar every point of space is designated by one triplet of numbers and one only.*

Explanation. Some points in this statement require explanation.

Not every intersection will receive any mark. It is easy to find these in practice, so that the algebraic condition that an intersection shall be marked is hardly required. But the condition is that if the numbers attached to the points on one of the intersecting rays are x_1 y_1 z_1 and x_2 y_2 z_2 and those of the points on the other one of the intersecting rays are X_1 Y_1 Z_1 and X_2 Y_2 Z_2, then the intersection cannot be marked unless

$$\begin{aligned}&(x_1y_2-x_2y_1)(Z_1-Z_2) + (y_1z_2-y_2z_1)(X_1-X_2)\\ &+(z_1x_2-z_2x_1)(Y_1-Y_2)+(x_1-x_2)(Y_1Z_2-Y_2Z_1)\\ &+(y_1-y_2)(Z_1X_2-X_2X_1)+(z_1-z_2)(X_1Y_2-X_2Y_1)=0.\end{aligned}$$

Denoting the numbers of the intersection by x, y, z,

$$x = \frac{(X_2-X_1)(x_1y_2-x_2y_1)+(x_2-x_1)(X_2Y_1-X_1Y_2)}{(x_1-x_2)(Y_2-Y_1)-(y_1-y_2)(X_2-X_1)}$$

$$y = \frac{(Y_2-Y_1)(y_1z_2-y_2z_1)+(y_2-y_1)(Y_2Z_1-Y_1Z_2)}{(y_1-y_2)(Z_2-Z_1)-(z_1-z_2)(Y_2-Y_1)}$$

$$z = \frac{(Z_2-Z_1)(z_1x_2-z_2x_1)+(z_2-z_1)(Z_2X_1-Z_1X_2)}{(z_1-z_2)(X_2-X_1)-(x_1-x_2)(Z_2-Z_1)}$$

But these cumbrous formulae are seldom of any use; for the calculation is perfectly simple.

When one of the numbers is ∞, the corresponding number of the other point has to be changed alone.

By the "weighted mean" of two numbers is meant their sum after multiplying them respectively by two fractions whose sum is 1, or their difference after multiplying them respectively by two numbers whose difference is 1. It must be understood that ∞ multiplied by 0 may give any number as product.

After the first seven points have been laid down, namely, 000, 200, ∞00, 020, 0∞0, 002, 00∞, we next lay down 220 which is the intersection of the ray joining 020 and ∞00 ($220 = 1.020 + 0.\infty 00$) and the ray joining 200 and 0∞0; we lay down 202 which is the intersection of the ray joining 002 and ∞00 and the ray joining 200 and 00∞; and we lay down 022 which is the intersection of the ray joining 020 and 00∞ and the ray joining 002 and 0∞0. Also 222 which is the intersection of the ray joining 022 and ∞00 and the ray joining 202 and 0∞0. It also should by the rule be on the ray joining 220 and 00∞; and so it is found to be. This is an example of how the theorem contains a statement of a truth about space, and is not merely a system of designating points, for which it might be mistaken. At the intersection of the ray joining 202 and 220 and the ray joining 222 and 200 is the point 211. At the intersection of the ray joining 211 and 00∞ and of the ray joining 202 and 222 is the point 212. At the intersection of the ray joining 211 and 00∞ and of the ray joining 200 and 220 is the point 210. At the intersection of the ray joining 212 and 022 and of the ray joining 002 and 202 is the point 302. At the intersection of the ray joining 210 and 020 and of the ray joining 000 and 200 is the point 300. The point 300 should also lie on the ray joining 302 and 00∞; and so it is found to do. In that way we can with the greatest ease go on adding points and designating them without end. The meaning of the theorem having thus been rendered clear, it would be in order to demonstrate its truth.

Scholium 35. But the strict demonstration is difficult just now, while after the barycentric notation is mastered, the student will be able to make it out for himself. The object of enunciating the theorem here is to show how perspective may be used to obtain truths of this sort.

It is necessary here to use a proposition, which will also not be strictly proved, called the *fundamental theorem of axonometry*. This proposition is substantially that a cube, or die, may be so represented in perspective that three edges meeting in one corner have for their delineations any three lines meeting at a point, no matter how inclined to one another, or of what lengths, they may be. The fact that a solid body has six degrees of freedom while six numbers are sufficient and necessary to define the directions and lengths of the three lines suggests that this is probably true, as it is in fact.

But regarding the figure drawn on the paper as the perspective representation of a cube, we see that the above theorem is equivalent to saying that space can be cut up into indefinitely small cubes, a familiar fact, though a proposition not of graphics but of metrics. The theorem itself, however, is purely graphical.

CHAPTER V

NOTATIONS FOR GRAPHICS

Art. 132. We shall use square brackets, [ ], to denote the *point* anyway determined by the places denoted by the letters written within the brackets. Thus

$$[\alpha\beta\gamma]$$

will denote the point contained at once in the planes α, β, γ

$$[\beta c]$$

will denote the point where the ray, c, cuts the plane β.

We shall use parentheses, ( ), to denote a plane. Thus

$$(\mathrm{B}c)$$

will denote the plane containing the point B and the ray c.

We shall use braces, { }, to denote rays. Thus,

$$\{\alpha\beta\}$$

will be the ray contained in the two planes α and β. So

$$\{\mathrm{AB}\}$$

will be the ray through the two points A and B.

Theorem 24. If two rays a and b are concurrent with two others, c and d, then

$$\{[ac][bd]\} = \{(ad)(bc)\}.$$

Demonstration.

For $[ac]$ write P for $[bd]$ write Q;
For $[ad]$ write R for $[bc]$ write S.

Then $\{[ac][bd]\} = \{\mathrm{PQ}\}$. Since a contains P and also R,

$$a = \{\mathrm{PR}\};$$

(*%) !3 & 0

The notation represents these triplets to be *coradial* (in one ray) for taking the first, twice the first added to the third gives the second. Thus

$$\begin{array}{llll} 2\mathrm{O} & +8\mathrm{X} & -6\mathrm{Y} & \\ 7\mathrm{O} & & +6\mathrm{Y} & +5\mathrm{Z} \\ 9\mathrm{O} & +8\mathrm{X} & & +5\mathrm{Z} \end{array}$$

CHAPTER VI

THE PHIMUS

Art. 140. *Intersections of Rays.*

Theorem 25. Space contains a quadruply continuous multitude of rays.

Demonstration. Every ray cuts every plane, except the book of planes hinged about it. Take two planes and a point in each; then just one ray exists through each such pair of points (except that there is only one ray for all the pairs of points which are both in both planes, and only one ray for all the pairs of points of which one is any one point in both planes), and these are all the rays of space. Hence, since there is a doubly continuous multitude of points in each plane, there is a quadruply continuous multitude of rays in space.

Art. 141. *Theorem 26. Cutting every ray there is a triply continuous multitude of rays.*

Demonstration. Through every ray there is a singly continuous multitude of planes. In each of those planes there is a doubly continuous multitude of rays, all of which are different and all cut the hinge ray, except one in each plane which coincides with it. The double continuity of the rays in one plane, together with the single continuity of planes, makes up a triple continuity.

Art. 142. *Theorem 27. Cutting every pair of rays is a doubly continuous multitude of rays.*

Demonstration. Each ray of a pair of rays contains a singly continuous multitude of points, and through any pair of points, one in each of the two rays, there is just one ray.

Remark that it makes no difference whether the first pair of rays cut one another or not.

Art. 143. *Theorem 28. Cutting every trio of rays is a singly continuous*

multitude of rays and a straight fibre successively occupying those positions *generates a ruled surface.*

Demonstration. For consider a flat lamina through one of the fixed rays. This flat lamina is cut by the other two fixed rays in two points. Through these two points is a ray, which ray cuts every other ray in the same plane, of which the first fixed ray is one. As the flat lamina turns round the first ray, the straight fibre cutting the three fixed rays moves; and a moving fibre generates a surface.

Definition 175. A surface generated by a moving straight fibre is called a *regulus*, or *ruled surface*. If the successive generators cut one another, it has an edge of regression and is called a *developable*, because a lamina of that form may be bent flat without stretching. Otherwise, it is called a *torus*.

Definition 176. A torus generated by a straight fibre which constantly cuts three fixed rays is called a *phimus* [Fig. 63].

Phimus (φίμος) is the Greek for dice-box. That surface resembles a somewhat flattened dice-box extending to infinity.

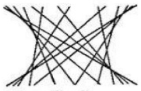

Fig. 63

Art. 144. *Theorem 29. If all of three rays are cut by each of three other rays and if a seventh cuts the first three and an eighth the second three, then the seventh and eighth intersect.*

Demonstration. Let i, j, k, be the first three rays, and p, q, r, the second three, s the seventh and l the eighth.

Use the following notation

$$[ip] = \mathrm{A}, \qquad [ir] = \mathrm{B},$$
$$[kp] = \mathrm{C}, \qquad [kr] = \mathrm{D}.$$

We are now free to call any point we like $[\mathrm{A}+\mathrm{B}+\mathrm{C}+\mathrm{D}]$. We will apply that designation to $[jq]$.

It follows that

$$[iq] = [\mathrm{A}+\mathrm{B}], \qquad [jp] = [\mathrm{A}+\mathrm{C}],$$
$$[kq] = [\mathrm{C}+\mathrm{D}], \qquad [jr] = [\mathrm{B}+\mathrm{D}].$$

Suppose the seventh ray which cuts $j = \{[\mathrm{A}+\mathrm{C}][\mathrm{B}+\mathrm{D}]\}$ cuts it in the point $[p[\mathrm{A}+\mathrm{C}]+(1-p)[\mathrm{B}+\mathrm{D}]]$
and that the eighth ray, which cuts $q = \{[\mathrm{A}+\mathrm{B}][\mathrm{C}+\mathrm{D}]\}$, cuts it in the point $[q[\mathrm{A}+\mathrm{B}]+(1-q)[\mathrm{C}+\mathrm{D}]]$.
Then the seventh ray cuts $i = \{\mathrm{AB}\}$ in

$$[p\mathrm{A}+\overline{1-p}\,\mathrm{B}],$$

and cuts $k = \{\mathrm{CD}\}$ in

$$[p\mathrm{C}+\overline{1-p}\,\mathrm{D}];$$

and the eighth ray cuts $p = \{\mathrm{AC}\}$ in

$$[q\mathrm{A}+\overline{1-q}\,\mathrm{C}],$$

and cuts $r = \{\mathrm{BD}\}$ in

$$[q\mathrm{B}+\overline{1-q}\,\mathrm{D}].$$

The general point of the seventh ray is got by varying x in the syzygy

$$[xp\,\mathrm{A}+x\overline{1-p}\cdot\mathrm{B}+\overline{1-x}\cdot p\,\mathrm{C}+\overline{1-x}\cdot\overline{1-p}\cdot\mathrm{D}].$$

The general point of the eighth ray is got by varying y in the syzygy

$$[qy\,\mathrm{A}+q\cdot\overline{1-y}\cdot\mathrm{B}+\overline{1-q}\cdot y\,\mathrm{C}+\overline{1-q}\cdot\overline{1-y}\cdot\mathrm{D}].$$

If we put $x = q$ and $y = p$, we get for a point on both rays

$$[qp\,\mathrm{A}+q\cdot\overline{1-p}\cdot\mathrm{B}+\overline{1-q}\cdot p\,\mathrm{C}+\overline{1-q}\cdot\overline{1-p}\cdot\mathrm{D}].$$

Thus the seventh and eighth rays have a point in common.

Art. 145. *Theorem 30. Every phimus has two sets of generators.*

Demonstration. Let i, j, k be the three fixed rays which every generator of the phimus intersects. Let p, q, r be three generators. Then there is a phimus through these generators, of which i, j, k are generators. Let l be another generator of it and s any generator of the first phimus. Then l and s intersect. Thus, every generator of either is cut by a generator of the other. That is, all the phimi through three generators of the first phimus are identical. But the first phimus is itself such a phimus. Hence, there is no other through the three rays i, j, k. This phimus has, therefore, two sets of generators, all of the first cutting i, j, k, and all of the second cutting p, q, r.

Art. 146. *Definition* 177. A curve [which is] the section of a phimus by a plane is called a *conic*.

Theorem 31. (*Pascal's Hexagram.*) If A, B, C, D, E, F are six points on a conic the points

$$[\{AB\}\{DE\}],$$
$$[\{BC\}\{EF\}],$$
$$[\{CD\}\{FA\}],$$

lie in one ray.

Demonstration. Let i, j, k be three generators of the phimus of one set through A, C, E. Let p, q, r be three generators of the phimus of the other set through B, D, F. Then $\{AB\}$ is in the plane (ip) and $\{DE\}$ is in the plane (kq). Hence $[\{AB\}\{DE\}]$ is in the ray $\{(ip)(kq)\} = \{[iq][kp]\}$.

In like manner $\{BC\}$ is in (jp), and $\{EF\}$ is in (kr) and hence $[\{BC\}\{EF\}]$ is in $\{(jp)(kr)\} = \{[jr][kp]\}$. And in like manner $\{CD\}$ is in (jq) and $\{FA\}$ is in (ir), and hence $[\{CD\}\{FA\}]$ is in $\{(jq)(ir)\} = \{[iq][jr]\}$. Now the three rays

$$\{[iq][kp]\},$$
$$\{[jr][kp]\},$$
$$\{[iq][jr]\},$$

are all in the plane $([iq][jr][kp])$. Hence the intersections of these planes with the plane of the conic which are

$$[\{AB\}\{DE\}],$$
$$[\{BC\}\{EF\}],$$
$$[\{CD\}\{FA\}],$$

lie in the intersection of those two planes, which is a ray. Q.E.D.

Corollary 29. We may join the 6 points in any order we please. Thus taking any one, this may be directly joined to any of the ten pairs among the remaining five, and the other three may be taken in 6 orders, so that there are 60 Pascal lines, as they are called, for each hexagram.

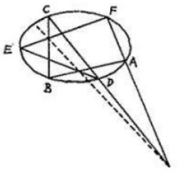

Fig. 64

Corollary 30. The Pascal hexagram, when five points on the conic are given, enables us to find as many more as we please [Fig. 64]. Thus, suppose F is unknown. We draw $\{AF\}$ in any direction we please. We shall thus take

$$[\{CD\}\{FA\}]$$

wherever we like upon $\{CD\}$. The point

$$[\{AB\}\{DE\}]$$

will be given, and through these we shall draw the Pascal line. The point where this cuts $\{BC\}$ will be

$$[\{BC\}\{EF\}]$$

We shall now draw $\{EF\}$ and this will cut $\{AF\}$ in F, which will thus be ascertained.

Corollary 31. One conic, and one only, passes through any one set of five points in a plane, no four of them coradial.

Art. 147. Imagine the three *directrices*, or fixed rays defining a phimus, to move, so that the phimus changes shape, in the following way [Fig. 65]. Let a point, V, be selected not in either of the three directrices. Let

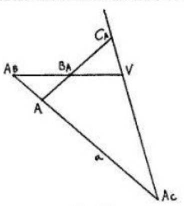

Fig. 65

the three directrices be a, b, c. Consider the plane (aV). Denote by B_A and C_A the points

$$B_A = [b(aV)]$$
$$C_A = [c(aV)]$$

Denote by A_B and A_C the points

$$A_B = [a(bV)]$$
$$A_C = [a(cV)]$$

Denote by A the point

$$A = [a\{B_A C_A\}].$$

Now a is moving to continue in the plane (aV), b in the plane (bV), c in the plane (cV). The directrix a is to continue to pass through A as a fixed point; and b and c are to continue to pass through their corresponding points and the relative speed of motion is to be such that B_A and C_A in their motion continue to be in one ray through A. And so with A_B and C_B, and with A_C and B_C.

Let us see what sort of change this will make in the shape of the phimus. The ray $\{B_A C_A\}$ is plainly the generator which is in the plane (aV). Thus the two rays a and $\{B_A C_A\}$ lie in the plane (aV). Then it follows from the explanation of contact given in Book II that where these rays intersect is the point where the plane (aV) is in contact with the *phimus*. As this is not to move, and is to continue the intersection of the directrix and generator, it follows that the same three planes are to continue to be in contact with the phimus at the same points.

The three planes will come together at [V], and the motion can be made in such sense that the phimus will become more and more [contracted] toward V; and as the limit of the endless series of shapes, the three directrices will pass through V.

Definition 178. A surface generated by a straight fibre which in moving constantly passes through a fixed point, V, and always touches a fixed phimus, is called a *quadric cone*. The point, V, is called the *vertex* of the cone.

Corollary 32. A pair of concurrent rays is a limiting case of a conic. For a pair of rays is the section of a quadric cone by a plane through the vertex. Now a quadric cone is the limit of an endless series of phimi; and the plane section of a phimus is a conic.

Definition 179. A limiting case of any regular place which suddenly becomes two or more regular places of simpler nature is called a *degenerate* place.

Corollary 33. A pair of concurrent rays is a degenerate conic.

Corollary 34. Pascal's hexagram holds good of a pair of concurrent rays [Fig. 66].

Corollary 35. Every section of a cone is a conic or limit of conics, because the cone is the limit of an endless series of phimi; and a conic is by definition the plane section of a phimus.

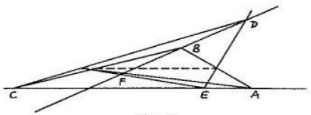

Fig. 66

It has hitherto been the practice to *define* a conic as the plane section of a cone. But the definition here used is more convenient and accurate, and facilitates the development of the subject.

Corollary 36. By applying the principle of duality to the proposition about Pascal's hexagram we get the following. Any six planes tangent to a quadric cone, as $\alpha, \beta, \gamma, \delta, \varepsilon, \zeta$, giving a cycle of six rays of intersection $\{\alpha\beta\}$, $\{\beta\gamma\}$, $\{\gamma\delta\}$, $\{\delta\varepsilon\}$, $\{\varepsilon\zeta\}$, $\{\zeta\alpha\}$, the planes through the three most distant pairs, that is,

$$(\{\alpha\beta\}\{\delta\varepsilon\}),$$
$$(\{\beta\gamma\}\{\varepsilon\zeta\}),$$
$$(\{\gamma\delta\}\{\zeta\alpha\}),$$

contain one ray in common.

Art. 148. *Corollary* 37. Since a section of a cone is a conic, by cutting the cone of the last corollary by a plane, we get the following, called *Brianchon's theorem*. The intersections of the three most distant pairs of any six tangents to one conic meet in one point. "Most distant," here, means most distant in any cyclical order in which the tangents may be taken [Fig. 67].

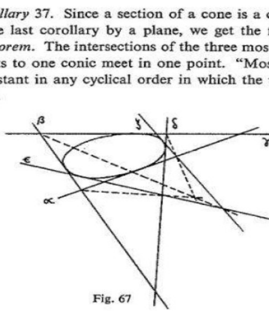

Fig. 67

Corollary 38. It follows that a duality exists between the properties of points on and tangents to a conic.

Corollary 39. In the case of Pascal's Theorem if A and B are the limit of points indefinitely near and the same is true of D and E, the proposition becomes that [of] taking any two tangents to the conic, and joining the points of tangency A and D with any two other points C and F of the conic [Fig. 68]. The intersection of the tangent is coradial with

[{AC}{DF}]
and [{AF}{DC}].

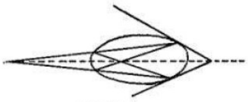

Fig. 68

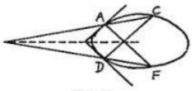

Fig. 69

Corollary 40. It is very important in geometry to take care that propositions are completely stated and considered. The last corollary may be otherwise stated as follows. If A, C, D, F are four points on a conic then

[{AC}{DF}]
and [{AF}{DC}]

are coradial with the intersection of the tangents at A and D. But this must be equally true of the tangents at C and F, for the lettering of A and C, D and F might be interchanged [Fig. 69].

Art. 149. Take any two points upon a phimus. Let the generators of one set through those points be *a* and *b*, and those of the other set *p* and *q*. Then the points will be

[*ap*] and [*bq*]

joined by the ray

{[*ap*][*bq*]}.

But *a* also cuts *q* and *b* cuts *p*. So that there is another ray

{[*bp*][*aq*]}.

These rays are *conjugate*, that is, each has the same relation to the other.[77]

---

[77] Peirce probably intended to add more material on conics at this point.

Map Projection

Pág. 497 (269) Appendix No. 15

A Quincuncial Projection of the Sphere

Orthomorphic, or conform projection formed by transforming the stereographic projection, with a pole at infinity, by means of an elliptic function.

For that purpose, l being the latitude, and θ the longitude, we put —

$$\cos^2\varphi = \frac{\sqrt{1-\cos^2 l\cos^2\theta} - \sin l}{1+\sqrt{1-\cos^2 l\cos^2\theta}},$$

and then $\frac{1}{2}F\varphi$ is the value of one the rectangular co-ordinates of the point on the new projection.

This is the same as taking —

$\cos \mathrm{am}(x+y\sqrt{-1})$ (angle of mod. = 45°) = $\tan\frac{p}{2}(\cos\theta+\sin\theta\sqrt{-1})$, where

+,-.+ + +/ !+* ! P ! 2 A 0
u A ! ! &&&P ! : ! ! ! ! ! &&&
4 :D ! %) 3#
(*%") % !3 7

is constant. Then number the meridians and also the parallels. Then draw curves through the intersections of meridians with meridians, the sums of numbers of the intersecting meridians being constant on any one curve. Also do the same thing for the parallels. Then these curves will represent the meridians and parallels of a new projection having north poles and south poles wherever the component projections had such poles.

Functions may, of course, be classified according to the pattern of the projection produced by such a transformation of the stereographic projection with a pole at the tangent points. Thus we shall have —

1. Functions with a finite number of zeroes and infinites (algebraic functions).
2. Striped functions (trigonometric functions). In these the stripes may be equal, or may vary progressively or periodically. The stripes may be simple, or themselves compounded of stripes. Thus, sin (a sin z) will be composed of stripes each consisting of a bundle of parallel stripes (infinite in number) folded over onto itself.
3. Chequered functions (elliptic functions).
4. Functions whose patterns are central or spiral.

I. *Table of rectangular co-ordinates for construction of the "quincuncial projection."*

x (for longitudes in upper line). y (for longitudes in lower line).

[2] The map is found as the frontispiece of Volume 3. Among so-called "fragments" in the Peirce Collection at the Houghton Library is a quincuncially-ruled chart on which Peirce plotted details of the celestial sphere. The constellation *Virgo* is sketched in quite distinctly, wings and all.

B. P.S. OF A LETTER TO J. M. PEIRCE (L 339: 5 APRIL 1894)

My chart is a skew Mercator, that is, a Mercator with the poles of an oblique great circle at infinity. Its value is great. The formulae are pretty. Start with a stereographic centred at the pole of that circle. Then the equation of every circle (meridian or parallel) is in polar coordinates

$$(r\cos\theta - M)^2 + r^2\sin^2\theta = N^2$$

or

$$2M\cos\theta = r + (M^2 - N^2)\,r^{-1}$$

But if x and y are the coördinates on the skew mercator $x = \theta$, $y = \log r$.

Hence

$$\cos x = \frac{\operatorname{Cosh}(y - A)}{B}$$

To take account of the compression *exactly* is a problem I have not quite solved. First, to make the angles preserved, for r a complicated function has to be substituted. But then the geodesic line does not return into itself and consequently is not a circle on the stereographic and it is necessary to take such a function of $r\mathfrak{S}^{\theta i}$ as to render it a circle. This is possible, and the approximate solution is easy. The exact solution would require some days of calm leisure. As it would evidently involve elliptic functions, the whole earth would be represented ∞^2 times but probably not in rectangular checkers. Nor is it quite clear to me that the scale of the map would be uniform over the whole of the geodesic taken as central and reduced to a straight line.

My notion about Father's geometry would be to make an introduction of three chapters. The first on the nature of mathematical reasoning and how to perform it. The second on projective geometry, especially perspective. The third on the metrical properties of space and the justification of the idea that an angle is a difference of directions.

I don't know that the body of the book would require any correction.

The thing would be to preserve its leading characteristic, which is to lay hold of and render definite our instinctive or natural ways of considering space, especially in reference to moving about in it.

I think, that done, the work would be a master-piece and would be much admired. Its sale would be good, too. Plimpton is anxious to have us do it. You and I should do it together, n'est-ce pas? What say you?

I don't know that I would not reform and enlarge the part relating to plane problems and append a chapter on Descriptive Geometry, and perhaps an appendix on Modern Geometry.

Rambling back to my chart again, the formulae are like this. For the meridians, I take Θ and H and η subsidiary quantities and have

$$\tan\Theta = \cos 51^\circ \tan \text{longitude}$$
$$H = \sin\Theta \tan 51^\circ$$
$$\sin(x - \Theta) = H\tan\eta = H \operatorname{Sinh} y$$
$$y = \frac{180^\circ}{M\pi}\log\tan\left(45^\circ + \frac{\eta}{2}\right)$$

For the parallels I have the subsidiary quantity ♈

$$♈ = -\frac{1}{M}\log(\cos 51^\circ + \sin \text{latitude})$$

$$\operatorname{Cosh}(y - ♈) = \sin 51^\circ \cos x = \sec\eta$$

$$y = \frac{180^\circ}{M\pi}\left\{\log(\cos 51^\circ + \sin \text{lat}) + \log\tan\left(45^\circ + \frac{\eta}{2}\right)\right\}$$

The approximate solution taking account of compression. In order to preserve the angles, all the books say that on the polar stereographic you must multiply r by

$$\left(\frac{1 + \varepsilon\sin\varphi}{1 - \varepsilon\sin\varphi}\right)^{\varepsilon/2}$$

where ε is the eccentricity of a meridian $= 0.08227$. If we make

$$\sin\varphi' - \varepsilon\sin\varphi$$

this is to say that in place of

$$r = \tan\left(45^\circ - \frac{\varphi}{2}\right)$$

we have

$$r = \tan^{\varepsilon}\left(45^\circ + \frac{\varphi'}{2}\right)\tan\left(45^\circ - \frac{\varphi}{2}\right)$$

latitude south, not while it traverses 180° of longitude, but before it has quite got round so far, so that if the geodetic be indefinitely prolonged it will from a grating of its own cycles over all that part of the globe intermediate between its extreme latitudes, or more properly speaking a reticulation.

"5. In the Skew Mercator one oblique geodetic, which we may designate as A, is represented by a straight line, say a, on the plane, and is so represented that to equal distances on A correspond equal distances on a. Moreover, letting M represent any geodetic line on the ellipsoid (or other surface) which cuts A at right angles, this geodetic (and every one like it) is to be represented on the plane by a straight line, m, cutting a at right angles at the point that represents the point at which M cuts A at right angles. And the scale of the map is at every point the same in all directions."

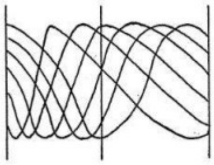

Fig. 1

D. FORMULAE AND TABLES FOR CONSTRUCTING TWO DIFFERENT CONFORMAL MAP-PROJECTIONS SUITABLE TO THE EXHIBITION OF ALL THE TERRITORY AND POSSESSIONS OF THE UNITED STATES OF AMERICA (1350)

EXPLANATION OF THE PROJECTIONS

A map is to be conceived as showing a part on the whole of a vertical projection of the Earth's surface as projected vertically (i.e. above the plane of gravity) upon the mean sea-level.

A "Conformal," or "Orthomorphic" map-projection is usually defined as one that shows all angles in their true magnitudes at their vertices; but perhaps a clearer definition is that one that has the same scale in all directions. This is not exactly true of any other kind of map nor even approximately so if the region represented covers as considerable part of the Earth's surface, as the possessions of the United States.

The form of the mean surface of the sea must, indisputably, always be regarded, by the cartographer, as ellipsoidal. For though departures from such a form may be made out by geodesists with more or less plausibility they will certainly be so minute, so irregular, and so liable to revision, that any correction of the distance between two points on such a basis will be far preferably made by means [of] an independent table of double entry rather than by a modification of the map-projection.

Everybody who has ever taken a course in Coördinatal Geometry (less precisely called *Analytical*, or *Algebraic Geometry*) may recall that the equation of an ellipsoid is

$$\left(\frac{x}{X}\right)^2 + \left(\frac{y}{Y}\right)^2 + \left(\frac{z}{Z}\right)^2 = 1,$$

where X, Y, Z are X the largest, Z smallest semidiameters, and Y is the semidiameter perpendicular to both the others; while x, y, z are the rectangular coordinates of any one point of the surface measured parallel respectively to the semi-axes X, Y, Z, from the centre of the ellipsoid.

In the case of the mean surface of the sea Z will be the distance from the centre of the earth to either pole (often called its polar *semi-axis*). As to X and Y, the only proper assumption in the present state of geodetical measurement is that they are equal. For the only attempt that I know of to determine their longitudes and relative length, that of Colonel Clarke, in 1878, being, I presume, deemed premature. Anyway he made their difference of length to be only 1524 feet, or say $\frac{2}{7}$ of a mile, each being about 4000 miles in length. If their difference can be neglected in geodetic calculations, it certainly ought to be neglected for any map on paper, which is liable, however great be the care taken of it, to shrink and swell unequally in different directions; while to take account of variations of the radius of the equator would multiply the number of oblique spherical triangles that have to be solved in making the table of coördinates for the projection, — would require this number of calculations, I say, to be multiplied by the number of meridians laid down in 45° of longitude. The labor (other complications being considered) would be from ten to twenty times as great, to save an error of one part in fourteen thousand. Now, who is so simple as to attempt to make measurement on paper accurate to one part in fourteen thousand?

E. [MATHEMATICAL NOTES ON THE SHAPE OF THE EARTH] (1071)

It is generally assumed that the earth's mean sea surface is an ellipsoid of revolution, and it has been generally regarded as proved that, neglecting tidal effects, such a surface might belong to a body in stable equilibrium. Poincaré, however, seems to have proved, or nearly proved, that other forms of stable equilibrium were possible. There is an interesting popular account of the matter in Sir George Howard Darwin's book entitled "*The Tides*," 1898 (Houghton, Mifflin, & Co.). In connection with this Sir G. H. Darwin has put forth the theory that our large moon, which is unparalleled in the solar system, originated by separation from the earth before the latter had acquired a stable equilibrium. This seems a reasonable conjecture, and if it be true, the earth probably must, after the separation, have gradually assumed a form approximately that of an ellipsoid with three unequal axes. Col. A. R. Clarke, an eminent geodesist, had undertaken (rather prematurely, perhaps, I think) to compute in 1878 what would be the ellipsoid, not necessarily one of revolution, that would best satisfy the geodetic observations. His result was that the difference between the greatest and least semi-diameters of the equator was only $\frac{1}{13721.2}$ part of the former being only about a quarter of a mile, and this supposed form did not satisfy the observations very much better than an ellipsoid of revolution would.

If the three semiaxes of an ellipsoid be denoted by X, Y, Z, and if x, y, z, be the sides of a rectangular parallelopipedon respectively parallel to those axes and having one vertex at the centre and the opposite vertex at any point on the ellipsoidal [at the sea-level] surface, these quantities will satisfy the equation

$$(1) \qquad \left(\frac{x}{X}\right)^2 + \left(\frac{y}{Y}\right)^2 + \left(\frac{z}{Z}\right)^2 = 1$$

which equation may be regarded as a definition of what is meant by an

Map Projection

Pág. 497 (269) Appendix No. 15

A Quincuncial Projection of the Sphere

Orthomorphic, or conform projection formed by transforming the stereographic projection, with a pole at infinity, by means of an elliptic function.

For that purpose, l being the latitude, and θ the longitude, we put —

$$\cos^2\varphi = \frac{\sqrt{1-\cos^2 l\cos^2\theta} - \sin l}{1+\sqrt{1-\cos^2 l\cos^2\theta}},$$

and then $\frac{1}{2}F\varphi$ is the value of one the rectangular co-ordinates of the point on the new projection.

This is the same as taking —

$\cos \operatorname{am}(x+y\sqrt{-1})$ (angle of mod. $= 45^\circ$) $=$ $\tan\frac{p}{2}(\cos\theta + \sin\theta\sqrt{-1})$, where

Jandaia

where x and y are the coordinates on the new projection, p is the north polar distance!.

Hence if rectangular geodesics are drawn between great circles whose northernmost (cujo norte extremo) points are constant, the difference of the squares of the sines of the reduced latitudes of their extremities is constant, or

(" "

In the case of the mean surface of the sea Z will be the distance from the centre of the earth to either pole (often called its polar *semi-axis*). As to X and Y, the only proper assumption in the present state of geodetical measurement is that they are equal. For the only attempt that I know of to determine their longitudes and relative length, that of Colonel Clarke, in 1878, being, I presume, deemed premature. Anyway he made their difference of length to be only 1524 feet, or say $\frac{2}{7}$ of a mile, each being about 4000 miles in length. If their difference can be neglected in geodetic calculations, it certainly ought to be neglected for any map on paper, which is liable, however great be the care taken of it, to shrink and swell unequally in different directions; while to take account of variations of the radius of the equator would multiply the number of oblique spherical triangles that have to be solved in making the table of coördinates for the projection, — would require this number of calculations, I say, to be multiplied by the number of meridians laid down in 45° of longitude. The labor (other complications being considered) would be from ten to twenty times as great, to save an error of one part in fourteen thousand. Now, who is so simple as to attempt to make measurement on paper accurate to one part in fourteen thousand?

E. [MATHEMATICAL NOTES ON THE SHAPE OF THE EARTH] (1071)

It is generally assumed that the earth's mean sea surface is an ellipsoid of revolution, and it has been generally regarded as proved that, neglecting tidal effects, such a surface might belong to a body in stable equilibrium. Poincaré, however, seems to have proved, or nearly proved, that other forms of stable equilibrium were possible. There is an interesting popular account of the matter in Sir George Howard Darwin's book entitled "*The Tides*," 1898 (Houghton, Mifflin, & Co.). In connection with this Sir G. H. Darwin has put forth the theory that our large moon, which is unparalleled in the solar system, originated by separation from the earth before the latter had acquired a stable equilibrium. This seems a reasonable conjecture, and if it be true, the earth probably must, after the separation, have gradually assumed a form approximately that of an ellipsoid with three unequal axes. Col. A. R. Clarke, an eminent geodesist, had undertaken (rather prematurely, perhaps, I think) to compute in 1878 what would be the ellipsoid, not necessarily one of revolution, that would best satisfy the geodetic observations. His result was that the difference between the greatest and least semi-diameters of the equator was only $\frac{1}{13721.2}$ part of the former being only about a quarter of a mile, and this supposed form did not satisfy the observations very much better than an ellipsoid of revolution would.

If the three semiaxes of an ellipsoid be denoted by X, Y, Z, and if x, y, z, be the sides of a rectangular parallelopipedon respectively parallel to those axes and having one vertex at the centre and the opposite vertex at any point on the ellipsoidal [at the sea-level] surface, these quantities will satisfy the equation

$$(1) \qquad \left(\frac{x}{X}\right)^2 + \left(\frac{y}{Y}\right)^2 + \left(\frac{z}{Z}\right)^2 = 1$$

which equation may be regarded as a definition of what is meant by an

ellipsoid. If two of the semi-axes, say X and Y are equal, we may replace them by the single letter, R, when the equation will become

$$(2) \qquad \frac{x^2+y^2}{R^2} + \frac{z^2}{Z^2} = 1.$$

If we are to regard this as representing the mean surface of the sea, the arduous and triumphant investigation of Mr. J. F. Hayford, which has rendered all other attempts to define the form of the mean sea-level obsolete (as far, at least, as the part of it covered by the United States is concerned), and which defines not the mean sea surface itself but a surface [with]

(3) R, the semidiameter of the equator

and

(4) (Z being the polar semiaxis) $R = \left(1 + \frac{1}{294}\right) Z.$

But instead of z, the distance of any point of the surface from the equator, it will be more convenient to use a differently shaped zed, $\mathscr{Z}$, which is measured not from the plane of the equator, but from a parallel plane touching the ellipsoid at the North Pole, so that

$$(5) \qquad z = \mathscr{Z} - Z$$

while instead of $x^2 + y^2$ I will write r, the distance of any point of the surface from the polar axis. With these substitutions, equation (2) becomes

$$(6) \qquad r^2 = \left(1 + \frac{1}{294}\right)^2 \quad (2Z\mathscr{Z} - \mathscr{Z}^2)$$

$$(7) \qquad r = \left(1 + \frac{1}{294}\right) \sqrt{2Z\mathscr{Z} - \mathscr{Z}^2}.$$

Differentiating (7) we get

$$(8) \qquad dr = \left(1 + \frac{1}{294}\right) \frac{Z - \mathscr{Z}}{\sqrt{2Z\mathscr{Z} - \mathscr{Z}^2}} (d\mathscr{Z})$$

whence

$$(9) \qquad (dr)^2 = \left(1 + \frac{1}{146\frac{2}{3}}\right)\left(\frac{Z^2}{2Z\mathscr{Z} - \mathscr{Z}^2} - 1\right)(d\mathscr{Z})^2$$

and adding $(d\mathscr{Z})^2$

$$(10) \qquad (dr)^2 + (d\mathscr{Z})^2 = \frac{1}{146\frac{2}{3}}\left(147\tfrac{2}{3}\,\frac{Z^2}{2Z\mathscr{Z} - \mathscr{Z}^2} - 1\right)(d\mathscr{Z})^2.$$

[Another version of this problem follows]

$$(1) \qquad \left(\frac{x}{X}\right)^2 + \left(\frac{y}{Y}\right)^2 + \left(\frac{z}{Z}\right)^2 = 1.$$

(2) If $X = Y, \dfrac{(x^2+y^2)}{X^2} + \dfrac{z^2}{Z^2} = 1.$

If we denote $x^2 + y^2$ by r^2 and adopt Hayford's value of the compression of the earth

(2) becomes

$$(3) \qquad (0.99323 \pm V)\, r^2 + z^2 = Z^2$$

where $V = 10^{-5}$

Changing the origin to the N pole, by putting $z = \mathscr{Z} - Z$

$$(4) \qquad (0.99323 \pm V) r^2 = 2Z\mathscr{Z} - \mathscr{Z}^2$$

or

$$(5) \qquad (0.99661 \pm \tfrac{1}{2}V) r = \sqrt{2\mathscr{Z}Z - \mathscr{Z}^2}$$

or

$$(6) \qquad r = (1.003401 \pm .6V) \sqrt{2\mathscr{Z}Z - \mathscr{Z}^2}$$

Differentiating, we get

$$(7) \qquad dr = (1.003401 \pm .6V) \frac{\mathscr{Z}(Z - \mathscr{Z})}{\sqrt{2\mathscr{Z}Z - \mathscr{Z}^2}} d\mathscr{Z}$$

squaring

$$(8) \qquad (dr)^2 = (1.006814 \pm 1.1V) \left(\frac{Z^2}{2\mathscr{Z}Z - \mathscr{Z}^2} - 1\right)(d\mathscr{Z})^2$$

$$\begin{aligned}(9) \qquad (d\mathscr{Z})^2 + (dr)^2 &= (1.006814 \pm 1.1V) \frac{Z^2}{2\mathscr{Z}Z - \mathscr{Z}^2} (d\mathscr{Z})^2 - \\ &\qquad - (0.006814 \pm 1.1V) \\ &= \left[\frac{Z^2}{2\mathscr{Z}Z - \mathscr{Z}^2} + (0.006814 \pm 1.1V) \frac{(Z - \mathscr{Z})^2}{2\mathscr{Z}Z - \mathscr{Z}^2}\right](d\mathscr{Z})^2 \\ &= \frac{Z^2}{2\mathscr{Z}Z - \mathscr{Z}^2}\left[1 + 0.006814 \pm 1.1V)\left(1 - \frac{\mathscr{Z}}{Z}\right)^2\right](d\mathscr{Z})^2\end{aligned}$$

which will give nearly

$$(10) \qquad \sqrt{(d\mathscr{Z})^2 + (dr)^2} = \frac{Z}{\sqrt{2\mathscr{Z}Z - \mathscr{Z}^2}}\left[1 + .003407\left(1 - \frac{\mathscr{Z}}{Z}\right)^2\right] d\mathscr{Z}$$

F. NEW THEORY OF THE SKEW MERCATOR (1353)

1894 March 27

Suppose a geodesic line to be represented by a straight line and equal arcs by equal lengths, and that the projection is conform. The straight lines perpendicular to this central line will represent geodesics. For if from neighboring points on a geodesic, geodesic perpendiculars of equal length be erected (on the same side of the first) the junction of their extremities will by a known theorem be perpendicular to them. Therefore the angles will be preserved in making these perpendicular straight lines represent geodesics.

Therefore the poles will not lie on any of them except those that are meridians.[1]

THE MATHEMATICAL THEORY

§0. It is a comfort to me, who am reading mathematics constantly, to get a subject treated *ab ovo* provided the elementary part is abridged, even if I am quite familiar with it. Hence, I hope the navigators for whom this exposition is intended will not object to my going into elementary explanations.

§1. A map is a representation of a round surface upon a plane, by which we mean that,

1st. In a general way, *points* upon the round surface are represented by *points* on the map-plane, and *vice versa*,

2nd. *Continuous series* of points on the round surface are represented by *continuous series* of points on the map-plane.

Let us first imagine that

(1) Every point on the round surface is represented on the map-plane;

(2) Every point on the map-plane represents a point on the round surface;

(3) No point on the round surface is represented by more than a single point on the map-plane;

(4) No point on the map-plane represents more than one point on the round surface.

These things being assumed, imagine that round any point on the map-plane is drawn an oval, by which I mean a curve returning into itself without cutting itself. This oval will represent an oval on the round surface. Let the oval on the map-plane be itself enclosed in another oval. This second oval will represent an oval on the round surface not intersecting the first oval and not on the same [side] of the latter as the [origin point] represented by the point originally taken on the map-plane. Imagine an endless series [of] ovals to be drawn on the map-plane each enclosing the previous one and not approximating closer and closer to any finite oval. These will represent an endless series of ovals on the round surface enclosing or enclosed by one another not approximating to any oval. Then, these ovals on the round must either approximate to a point or a limited line. This point, or limited line, is represented by the infinitely distant parts of the plane. We may hold ourselves at liberty to assume anything we please about them, provided it involves no contradictory result. Hence we must either assume for our purpose that the parts of the plane infinitely distant are one point, or that they are a limited line. I shall not examine the latter assumption, but shall assume that for our purpose the infinitely distant parts of the plane are to be regarded as a single point.

[ADDITIONAL] MATHEMATICAL THEORY

§1. The position of a point may be expressed in rectangular coördinates, x and y, or polar coördinates r and θ having the same origin. But I reckon θ as on a clock from vertically up round to the right.

For the purposes of the conform projections, or those which preserve the angles, it is convenient to make one imaginary expression define the position of a point. Namely

$$z = re^{\theta i} = r\cos\theta + r\sin\theta . i \ = y + xi.$$

§2. If a projection have these two properties

1st, that for each place, there is some right angle in nature (I mean, the surface represented, earth, heavens or what) having its vertex there which is represented by a right angle on the map,

2nd, that along the two legs of such [a] right angle the scales are the same,

then the projection preserves all the angles. For let XOY be such a right angle in nature, represented by the right angle $X'O'Y'$ on the map. Imagine the portion seen to be infinitesimal, so that there shall be no curves. Then, completing the rectangle [to a fourth vertex Z and Z'], if $\frac{OY}{O'Y'} = \frac{OX}{O'X'}$ that is to say, if the scale of the map is the same along the two legs, it is plain that the angles $ZOY = Z'O'Y'$. Hence, obviously, all angles having their vertices at O are represented by equal angles.

---

[1] In the worksheets on the geodesic Peirce makes use of Hoüel (Recueil, p. lxiii).

THE SKEW MERCATOR PROJECTION

It is well known that the polar stereographic projection of the sphere is produced by making

$$r = R \tan\left(45° - \frac{\varphi}{2}\right)$$

where r is the radius vector on the map from the pole as origin, and φ is the latitude [λ is the longitude so reckoned].

Upon this projection, every circle is projected into a circle.

It is also known that in order to preserve the angles taking account of the compression of the earth we may put

$$r = \left(\frac{1 - \varepsilon \sin \varphi}{1 + \varepsilon \sin \varphi}\right)^{\frac{\varepsilon}{2}} \tan\left(45° - \frac{\varphi}{2}\right)$$

where ε is the eccentricity of a meridian $= 0.08227$.* (*For (Clarke's *Geodesy*, p. 104) the radius of curvature of a meridian is $\frac{a(1-\varepsilon^2)}{(1-\varepsilon^2 \sin^2\varphi)^{3/2}}$ and that of a normal section perpendicular to the meridian is $\frac{a}{(1-\varepsilon^2 \sin^2 \varphi)^{\frac{1}{2}}}$.)

But upon this projection geodesic lines no longer appear as circles. The reason is that the difference of longitude between the intersection of a geodesic line with the equator and its northernmost point is not 90°, but is

Maximum Latitude	Diff Long
18°	90°-17′
36°	90°-15′
54°	90°-12′
72°	90°- 6′

A change $\delta\lambda$ in longitude, in passing along the outline of the last section makes a rotation of the normal equal to $\cos\varphi \cdot \delta\lambda$.[2] Hence, if $\frac{\delta s}{\delta \lambda}$ is constant for all latitudes (as for a regular Mercator's chart)

$$\frac{\delta s}{\delta \varphi} = \frac{1}{\cos\varphi} \frac{1-\varepsilon^2}{1-\varepsilon^2 \sin^2\varphi}$$

$$\frac{\delta s}{\delta \varphi} - \frac{1}{\cos\varphi} = \frac{1}{\cos\varphi}\left(\frac{1-\varepsilon^2}{1-\varepsilon^2\sin^2\varphi} - 1\right)$$

$$= \frac{1}{\cos\varphi}\left(\frac{-\varepsilon^2 \cos^2\varphi}{1-\varepsilon^2\sin^2\varphi}\right)$$

$$= \frac{-\varepsilon^2\cos\varphi}{1-\varepsilon^2\sin^2\varphi}$$

$$\frac{\delta s}{\delta\varphi} = \frac{1}{\cos\varphi} - \varepsilon^2 \frac{\cos\varphi}{1-\varepsilon^2\sin^2\varphi}$$

Now $\quad D\varphi \log \frac{1-\varepsilon \sin\varphi}{1+\varepsilon\sin\varphi} = \frac{-\varepsilon\cos\varphi}{1-\varepsilon\sin\varphi} - \frac{\varepsilon\cos\varphi}{1+\varepsilon\sin\varphi} =$

$$= -\varepsilon\cos\varphi \frac{2}{1-\varepsilon^2\sin^2\varphi}$$

And $\quad D\varphi \log\tan\left(45° + \frac{\varphi}{2}\right)$

$$= \frac{1}{2\tan\left(45° + \frac{\varphi}{2}\right)} \frac{1}{\cos^2\left(45° + \frac{\varphi}{2}\right)} = \frac{1}{\sin(90° + \varphi)} = \frac{1}{\cos\varphi}$$

Hence

$$s = \log\tan\left(45° + \frac{\varphi}{2}\right) + \frac{\varepsilon}{2}\log\frac{1-\varepsilon\sin\varphi}{1+\varepsilon\sin\varphi}$$

(This agrees with Craig's Projections, p. 65.)[3]

Hence we must have an angular motion along that section, equal to $\cos\varphi \cdot \delta\lambda$, represented in the map by a line whose ratio to $d\varphi$ is $\frac{1-\varepsilon^2}{1-\varepsilon^2\sin^2\varphi}$.

---

[2] On another fragment Peirce writes, "Hence we must have an angular motion along that section equal to cos φ.dλ, represented on the map by a line whose ratio to dφ is $\frac{1-\varepsilon^2}{1-\varepsilon^2 \sin^2\varphi}$."

[3] Craig was a member of the Mathematics Department at the Johns Hopkins University during Peirce's association with that institution and was later Editor-in-Chief of the *American Journal of Mathematics*. He had also served in the Coast and Geodetic Survey.

THE SKEW MERCATOR

On the Stereographic, the equation of a meridian is

$$(\xi - A)^2 + (\eta - B)^2 = C^2$$

When $\xi = 0$

$$\eta_1 = B + \sqrt{C^2 - A^2} = S \tan 25^\circ \cdot 5$$
$$\eta_2 = B - \sqrt{C^2 - A^2} = S \cot 25^\circ \cdot 5$$
$$(\xi - A)\,d\xi + (\eta - B)\,d\eta = 0$$

When $\xi = 0$ $\quad \frac{d\xi}{d\eta} = \frac{\sqrt{C^2 - A^2}}{A} = \tan \text{long}$

$$B = -S \cot 51^\circ$$
$$\sqrt{C^2 - A^2} = S \operatorname{cosec} 51^\circ$$
$$A = S \operatorname{cosec} 51^\circ \cot \text{long} \qquad C = S \operatorname{cosec} 51^\circ \operatorname{cosec} \text{long}$$

Putting $\xi = r \sin\theta \qquad \eta = r\cos\theta$
the equation is

$$(r \sin\theta - S \operatorname{cosec} 51^\circ \cot \text{long})^2 + (r\cos\theta + S \cot 51^\circ)^2 = S^2 \operatorname{cosec}^2 51^\circ \operatorname{cosec}^2 \text{long}$$
$$S^{-1}r - Sr^{-1} = 2(\sin\theta \operatorname{cosec} 51^\circ \cot \text{long} - \cos\theta \cot 51^\circ)$$
$$= 2\,\frac{\sin\theta \cot \text{long} - \cos\theta \cos 51^\circ}{\sin 51^\circ}$$

Putting $\tan\Theta = \cos 51^\circ \tan \text{long}$ and $E = \frac{\sqrt{\cot^2 \text{long} + \cos^2 51^\circ}}{\sin 51^\circ}$

$$S^{-1}r - Sr^{-1} = 2E \sin(\theta - \Theta)$$

Now $r = \epsilon^y \qquad \theta = x$

Put $\qquad S = \epsilon^Y$

$$\frac{r}{S} = \epsilon^{y-Y} = \operatorname{Cosh}(y - Y) + \operatorname{Sinh}(y - Y)$$
$$-\frac{S}{r} = \epsilon^{Y-y} = -\operatorname{Cosh}(y - Y) + \operatorname{Sinh}(y - Y)$$
$$\operatorname{Sinh}(y - Y) = E \sin(\theta - \Theta)$$

On the Stereographic the equation of a parallel is

$$\xi^2 + (\eta - \beta)^2 = \gamma^2$$

When $\xi = 0$

$$\eta_1 = \beta + \gamma = S \tan\frac{90^\circ - \text{lat} + 51^\circ}{2}$$
$$\eta_2 = \beta - \gamma = -S \tan\frac{90^\circ - \text{lat} - 51^\circ}{2} = S \tan\frac{51^\circ - 90^\circ + \text{lat}}{2}$$

$$\beta = \frac{S \sin 51^\circ}{\cos 51^\circ + \sin \text{lat}} \qquad \gamma = \frac{S \cos \text{lat}}{\cos 51^\circ + \sin \text{lat}}$$
$$r^2 \sin^2\theta + \left(r\cos\theta - S\,\frac{\sin 51^\circ}{\cos 51^\circ + \sin \text{lat}}\right)^2 = S^2 \frac{\cos^2 \text{lat}}{(\cos 51^\circ + \sin \text{lat})^2}$$

[Incomplete]

VARYING SCALE OF SKEW MERCATOR

a Azimuth of geodesic
u Reduced lat
U ditto of northernmost points of geodesic
ε Eccentricity of meridian

$$\sin\alpha = \frac{\cos U}{\cos u}$$
$$\alpha' = 90^\circ - \alpha$$
$$\sin\alpha' = \sqrt{1 - \frac{\cos^2 U}{\cos^2 u}}$$
$$\cos U' = \sqrt{\cos^2 u - \cos^2 U}$$
$$\sin\alpha_2' = \frac{\sqrt{\cos^2 u - \cos^2 U}}{\cos u_2}$$
$$\alpha_2 = 90^\circ - \alpha_2'$$
$$\sin\alpha_2 = \frac{\sqrt{\cos^2 u_2 - \cos^2 u + \cos^2 U}}{\cos u_2}$$
$$\cos U'' = \sqrt{\cos^2 u_2 - \cos^2 u + \cos^2 U}$$
$$\therefore \sin^2 U'' = \sin^2 U - \sin^2 u + \sin^2 u_2 \quad \text{[Fig. 1]}$$

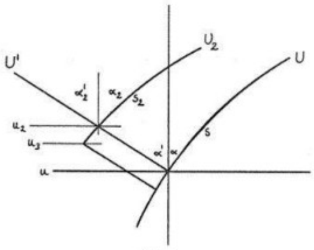

Fig. 1

Hence if rectangular geodesics are drawn between great circles whose northernmost points are constant, the difference of the squares of the sines of the reduced latitudes of their extremities is constant, or

$$\sin u \cdot d \sin u = \sin u_2 \, d \sin u_2$$

Let two such be drawn infinitely near, and compare the infinitestimal segments

$$ds = a\frac{\sqrt{1-\varepsilon^2\cos^2 u}}{\sqrt{1-\dfrac{\cos^2 U}{\cos^2 u}}}\,du = a\frac{\sqrt{1-\varepsilon^2\cos^2 u}}{\sqrt{\sin^2 U-\sin^2 u}}\,d\sin u$$

$$= a\frac{\sqrt{1-\varepsilon^2+\varepsilon^2\sin^2 u}}{\sqrt{\sin^2 U-\sin^2 u}}\,d\sin u$$

$$ds_2 = a\frac{\sqrt{1-\varepsilon^2+\varepsilon^2\sin^2 u_2}}{\sqrt{\sin^2 U_2-\sin^2 u_2}}\,d\sin u_2$$

$$= a\frac{\sqrt{1-\varepsilon^2+\varepsilon^2\sin^2 u_2}}{\sqrt{\sin^2 U-\sin^2 u}}\,d\sin u_2$$

$$= a\frac{\sqrt{1-\varepsilon^2+\varepsilon^2\sin^2 u_2}}{\sqrt{\sin^2 U-\sin^2 u}}\,\frac{\sin u}{\sin u_2}\,d\sin u$$

$$\frac{ds_2}{ds} = \frac{\sqrt{1-\varepsilon^2+\varepsilon^2\sin^2 u}}{\sin u_2}\cdot\frac{\sin u}{\sqrt{1-\varepsilon^2+\varepsilon^2\sin^2 u}}$$

$$= \frac{\sin \mathrm{lat}}{\sin \mathrm{lat}_2}$$

Though this is not what was wanted, it is a curious result. It is also puzzling.

[C. S. PEIRCE'S SKEW MERCATOR I]

C. S. Peirce's "Skew Mercator" is a projection *of the sphere* (i.e. not corrected for the compression of the Earth, since in measuring distances on a map of any considerable fraction of the earth's surface it will always be necessary to use numerical computation, either to assure oneself that the number read from the scale used sufficiently represents what one ought to mean for the special purpose in view, by the "distance" between two points on the earth's surface, or else to deduce this "distance" from the measure on the map) upon the plane of the great circle passing through latitude 60°, this projection being of the same kind as that of the ordinary Mercator's Projection, which ought to be a conform projection *of the sphere*.

But a map of a large fraction of the Earth's surface ought not to be regarded as intended to measure upon closer than to the first significant figure of our customary numerical notation, but rather to be viewed with the unaided eye. Now if any figure is drawn upon a plane surface held square before the eyes, and this figure is then turned in its own plane through a right angle, so that what was, before the turning, its height becomes its width right and left and *vice versa*, its *apparent* shape to a spectator not specially trained, will undergo a change ascribed to the greater effort required to turn our eyes up and down than to turn them right or left. But this change of apparent shape is not found to be a great inconvenience. Now that apparent change is just about double the exaggeration of [the] linear scale of Mercator's chart for a small area at 23° of latitude compared with a like object on the equator. Thus, to use the phrases of conscientious parlance, the accuracy of Mercator's chart within say 30° of the equator is truly astonishing, as compared with any visual aspect of it from without.

Now it happens that all parts and possessions of the United States of America, from Puerto Rico to Alaska and straight on to the Philippines lie within that distance of a Great Circle excepting Hawaii on one side and the Panama Canal on the other; and these are not very far outside of 30° from that central circle.

[C. S. PEIRCE'S SKEW MERCATOR II]

... If the sum of the orders of North poles is not equal to that of South poles, the point at infinity must make up the deficiency of the lesser sum. We, then, find a function which has these zeros and infinities; and finally we are free to multiply by a constant which serves to fix the latitude and longitude of any other selected point on the map. In this way, formulae can be obtained with great facility. For instance, suppose we wish the formulae for the stereographic projection when the plane of projection is tangent to a certain place. We calculate r and θ for that place, and denote them by r_0 and θ_0. Then we wish a function of $re^{\theta i}$ which shall vanish for $re^{\theta i} = r_0 e^{\theta_0 i}$ and shall become infinite for $re^{\theta i} = \frac{1}{r_0} e^{-\theta_0 i}$. This gives ($r_1$ and θ_1 being the coördinates on the new map)

$$r_1 e^{\theta_1 i} = C \frac{re^{\theta i} - r_0 e^{\theta_0 i}}{re^{\theta i} - \frac{1}{r_0} e^{-\theta_0 i}}$$

In the case of Mercator's projection the North pole is at $+\infty$ and the South pole at $-\infty$. Obviously, therefore,

$$x_1 + y_1 i = \log (\mathrm{re}^{\theta i})$$

or

$$x_1 = \log r$$
$$y_1 = \theta.$$

A map may in the first place have a finite number of North and South poles. In this case, it is connected with an algebraic function. If the number of poles is infinite, they cannot be specified singly and only the law of their arrangement can be described. The map may show the whole earth repeated over and over in stripes. These stripes may be all alike or they may be broader and broader indefinitely in one direction. Each stripe may show the whole earth but once, or several times, or even an infinite number of times. An example of the last case is the map resulting from the function sin · sin $a\varphi$, of which a sketch is given.[1] The map instead of being striped may be checkered. In this case, we have to do with a doubly periodic function. The pattern whether striped or checkered may be disturbed by irregularities, as in the case of the sum of a periodic function and an algebraic one. Finally, the map may have a pattern neither striped nor checkered. Thus, the whole earth might be represented in concentric rings, as by the function

$$\prod_{m=1}^{m=\infty} \quad \frac{m-x}{m+x}$$

---

[1] No sketch accompanies this fragment. In another fragment Peirce writes: "The idea of the [Skew Mercator Map] is that since Mercator's Chart preserves the shapes and sizes of the globe within 40° of the equator sufficiently for comparison by the unaided and not excessively critical eye and since all the possessions of the United States (except Hawaii) lie within that angular distance of a certain great circle (namely one inclined 60° to the equator and cutting it in 35° West Longitude), it follows that a map which represents that great circle by a straight line, and preserves all angles unchanged, will give the best possible eye-view of those possessions."

G. [NOTES FOR] THE SKEW MERCATOR ON THE SPHERE (1584)

§1. Property of the Stereographic.

If a point in space X, Y, Z be projected from the origin upon the plane of $Z = 1$, its projection x, y will be

$$x = \frac{X}{Z} \qquad y = \frac{Y}{Z}$$

If we imagine the sphere through the origin

$$X^2 + Y^2 + (Z-1)^2 = 1$$

to be cut by the plane

$$\frac{X}{A} + \frac{Y}{B} + \frac{Z}{C} = 1$$

we have

$$\frac{x^2}{Z^2} + \frac{y^2}{Z^2} = -1 + \frac{2}{Z}$$
$$\frac{X}{AZ} + \frac{Y}{BZ} = \frac{1}{Z} - \frac{1}{C}$$

or eliminating Z

$$x^2 + y^2 + 1 = \frac{2}{A}x + \frac{2}{B}y + \frac{2}{C}$$

which is the equation of a circle.

If $C = \frac{1}{2}$, the plane passes through the centre of the sphere.

That the angles are preserved is evident from this: that the tangent plane to the sphere is as much inclined to the radius of projection as is the plane of the map.

In the case of the polar projection it is plain that

$$\frac{\sqrt{x^2 + y^2}}{Z} = \tan\left(45^\circ - \frac{\varphi}{2}\right)$$

where φ = latitude.

§2. The Skew Mercator

We transpose to another pole on the sphere, distant we will say by an angle a from the a [Fig. 1]. The first pole we call B the second C.

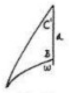

Fig. 1

Then the latitude $= 90° - C$
Longitude $= 180° - B$

reckoning longitude from the line of junction of the poles.

We might solve spherical triangle given $B = 180° - a$

$$a$$
$$c = 90° - \varphi$$

to find C and c.

We have two sides and included angle and could apply formulae of spherical trigonometry.

Namely,

$$\tan\tfrac{b}{2} = \sqrt{\frac{\dfrac{\tan\frac{a}{2}}{\tan\frac{c}{2}} + \dfrac{\tan\frac{c}{2}}{\tan\frac{a}{2}} + \frac{1}{2}\cos\omega}{\dfrac{1}{\tan\frac{a}{2}\tan\frac{c}{2}} + \tan\frac{a}{2}\tan\frac{c}{2} + \frac{1}{2}\cos\omega}}$$

$$\tan C = \frac{\sin\omega}{\tan\varphi\sin a + \cos a\cos\omega}$$

More simply

$$r'\,\mathfrak{S}^{\theta' i} = r\,\mathfrak{S}^{\theta i} + R = \sqrt{R^2 + r^2}\left(\frac{r(\cos\theta + R)}{\sqrt{R^2 + r}} + \frac{r\sin\theta}{\sqrt{R^2 + r^2}}\,i\right)$$

$$\log r' + \theta' i = \log\sqrt{R^2 + r^2} + \text{arc}\tan\frac{\tan\theta}{1 + \dfrac{R}{r}\sec\theta}$$

Geodetic Line
ω Longitude
q Shortest distance station to axis ret.
s arc of geodesic
a azimuth
$q^2 d\omega = C ds$

$C = q\sin a$
φ Latitude
u Reduced latitude
a Semiaxis major

$$\sin\varphi = \frac{\sin u}{\sqrt{1 - e^2\cos^2 u}}$$

$q = a\cos u$
e is eccentricity of meridian .08227
Compressed Earth

$$\frac{q^2}{a^2} + \frac{z^2}{b^2} = 1$$

To preserve angles on polar projection

$$\begin{aligned} r &= q + (b - z)\tan\left(45° + \frac{\varphi}{2}\right) \\ &= a\cos u + b(1 - \sin u)\tan\left(45° + \frac{\varphi}{2}\right) \\ &= \frac{a\cos\varphi}{\sqrt{1 - e^2\sin^2\varphi}} + b\frac{\sqrt{1 - e^2\sin^2\varphi} - \sqrt{1 - e^2}\sin\varphi}{\sqrt{1 - e^2\sin^2\varphi}} \end{aligned}$$

$$\tan\left[45° + \frac{\varphi}{2}\right] = \frac{\cos\varphi}{1 - \sin\varphi}$$

where x and y are the coordinates on the new projection, p is the north polar distance'.

A Conformed Projection

Look: Fig. 2

The Projection is thus established (Hyperbolic stereographic projection).

We have an *apriori* or natural idea of space, which by some kind of evolution has come to be very closely in accord with observations. But we find in regard to our natural ideas, in general, that while they do accord in some measure with fact, they by no means do so to such a point that we can dispense with correcting them by comparison with observations.

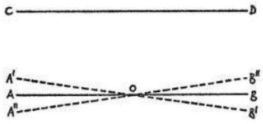

Fig. 1

Given a line *CD* and a point *O* [Fig. 1]. Our natural (Euclidean) notion is that

1st there is a line *AB* through *O* in the plane *OCD* which will not meet *CD* at any finite distance from *O*.

2nd that if any line *A'B'* or *A''B''* through *O* in the plane *OCD* be inclined by any finite angle, however small, to *AB*, it will meet *CD* at some finite distance from *O*.

Is this natural notion *exactly* true?

A. This is not certain.

B. We have no probable reason to believe it so.

C. We *never* can have positive evidence lending it any degree of likelihood. It *may* be disproved in the future.

D. It may be true, perhaps. But since the chance of this is as $1:\infty$ or $\frac{0}{1}$, the logical presumption is, and must ever remain, that it is not true.

E. If there is some influence in evolution tending to adapt the mind to nature, it would probably not be completed yet. And we find other natural ideas require correction. Why not this, too? Thus, there is some reason to think this natural idea is *not* exact.

F. I have a theory which fits all the facts as far as I can compare them, which would explain how the natural notion came to be so closely approximate as it is, and how space came to have the properties we find it has. According to this theory, this natural notion would not be exact.

To give room for the non-Euclidean geometry, it is sufficient to admit the first of these propositions.

Either the first or the second of the two natural propositions on page 1 of this article may be denied, giving two corresponding kinds of non-Euclidean geometry. Though neither of these is quite so easy as ordinary geometry, they can be made intelligible. For this purpose, it will suffice to consider plane geometry. The plane in which the figures lie must be regarded in perspective.

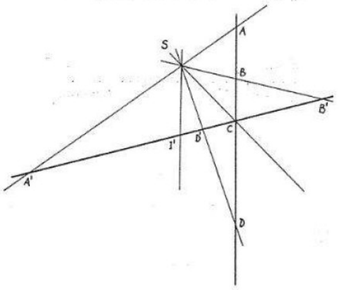

Fig. 2

Let *ABCD* be this plane, which I call the natural plane,* (* merely because so-called by writers on Perspective. Nothing to do with the "natural assumptions" of page 1) seen edgewise [Fig. 2]. Let *S* be the eye, or point of view, or centre of projection. From every point of the natural plane, rays, or straight lines proceed to the point of view, and are continued beyond it if necessary. If three points in the natural plane lie in one straight line, the rays from them through the point of view will lie in one plane. Let *A'B'* be the plane of the delineation or picture seen edgewise. It cuts all the rays through *S* in points, and so many of these rays as lie in one plane it cuts in a straight line; for the intersection of two planes is a straight line. The points in which this plane cuts those rays are the perspective delineations of the natural points, i.e. the corresponding points in the natural plane. We extend this to cases in which the point of view is between the natural and the delineated points.

It is readily seen that the delineation of a *point* is a *point*, and that to every point in the picture corresponds a point in the natural plane. And to a straight line in the natural plane corresponds a straight line in the picture. For the first straight line and the point of view lie in one plane, and the intersection of this plane by the plane of the picture is a straight line.

All this is just as true for the non-Euclidean as for the Euclidean geometry.

But now let us consider the parts of the natural plane which lie at an infinite distance and see how they look in perspective.

First suppose the natural, Euclidean, or parabolic geometry to be true. Then all the rays through *S* from infinitely distant parts of the plane, themselves lie in one plane. For let *SI'* be such a ray, then if *SI'* be turned about *S* the least bit out of the plane parallel to the natural plane it will cut the latter at a finite distance.

These rays through *S* from the infinitely distant parts of the natural plane, since they lie in one plane, will cut the plane of the picture in a straight line, called the vanishing line of the natural plane.

The delineations of any two parallel lines will cross one another on this vanishing line.

Next, suppose that the 2nd natural proposition on p. 1 [of this article] is false and that *SI'* may be tilted through a finite angle without cutting the natural plane at a finite distance.

Then, I will *state*, what there is no difficulty in proving, that the delineation of the infinitely distant parts of the natural plane will occupy a space on the picture bounded by a conic section.

The picture looks exactly as before, *only* that the *real distances* of certain parts which on the first assumption were finite, now become infinite.

The following two figures [Fig. 3 and Fig. 4] show the straight line which on the first assumption alone represents parts *really* infinitely distant, as well as the conic which on the second assumption bounds

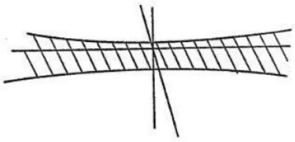

Fig. 3

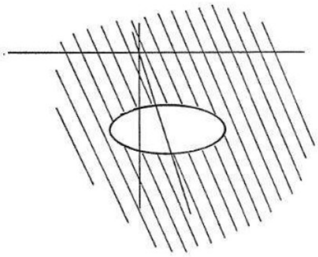

Fig. 4

the delineation of the really infinitely distant parts. With two lines parallel on the first assumption.

In this case, space is *limited*. But though *limited*, it is *immeasurable*. Imagine, for instance, that every kind of unit of linear measure, should shrink up as it was removed from a fixed centre, and perhaps differently according as it was radially or peripherally placed, so that it never could in any finite number of repetitions, get beyond a certain spherical surface. Then that surface would be at an infinite distance and no moving body could ever traverse it, for the distance moved over in a unit of time would be a unit of distance. But unless this linear unit were to shrink according to a peculiar law, the result would be that different parts of space would be unlike. That is to say, for example, if we were to draw the plane figure *ABCD*, by means of given lengths *AB*, *AC*, *AD*, *BC*, we should find the resulting length of *CD* to be different in different parts of space [see Fig. 5]. Now, geometers assume, perhaps with little reason, that

the fact that rigid bodies move about readily in space without change of proportions, shows that all the parts of space are alike.

With this condition, I will *state*, what is again readily proved that the law of the representation of equal distances and equal angles is in this second or hyperbolic geometry for the distances [see Fig. 6]. Let the conic be the "absolute," or the perspective representation boundary of infinitely distant regions. Let *AB* be a unit of distance. Through *AB* draw the line *IJ*, let *I'J'* be any other line. Draw straight lines through their intersections *II'* and *JJ'* with the absolute. Let *O* be the point where these lines intersect; from *O* draw rays to *A* and *B*. Then the distance *A'B'* cut off by these rays on the line *I'J'* is equal to *AB*.

The rule for angles is this. Let the conic be the absolute [Fig. 7]. Let *ACB* be a given angle. From *C* draw *CI* and *CJ* tangent to the absolute. Take any other vertex *C'*, and draw tangents *C'I* and *C'J* to the absolute. Through *I* the intersection of *CI* and *C'I* and *J* the intersection of *CJ* and *C'J* draw the straight line *IJ* cutting *AC* and *BC* in *A* and *B*. Then *AC'B* = *ACB*.

The third kind of geometry, which denies the 1st natural assumption supposes space to be *unlimited* but *finite*, that is, measurable. It is as if the linear unit so expanded in departing from a centre as to enable us to pass through what is naturally supposed to be at an infinite distance.

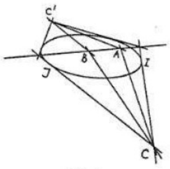

Fig. 7

B. REFLECTIONS ON NON-EUCLIDEAN GEOMETRY (118)

Although the ideas of imaginaries and of the absolute are the creation of algebra, yet I think it quite in the spirit of modern algebra, the ideas once gained, to treat them as synthetically as possible.

The non-Euclidean geometry treats exclusively of the projective relations of a certain individual surface, the absolute.

This surface is a quadric, so that every line either lies wholly within this surface, all its points and planes being elements of the surface, or else it has but two points and two planes in common with the surface. If either pair coalesces, both coalesce. Taking a plane and point incident the one on the other, in that plane through that point there are but two lines tangent to the surface, unless all such lines are so, and in that case, there are but two which lie wholly within the surface. Either of the pairs of lines spoken of may coalesce.

No definition of a plane is possible except that it is a linear surface. All transportation of a rigid body is representable by the result of a series of projections. These are subject only to the condition that they must not move the absolute away from itself or bring any other surface into tangency with it.

A pair of points or planes may have 9 singular positions in reference to the absolute.

1. It may coalesce on the absolute.
2. It may be distinct, but on a generator of the absolute.
3. It may be on the absolute but not on one generator.

4. One terminal only may lie on the absolute, and the other on a tangent line having that same point or plane of tangency.
5. One terminal may lie on the absolute, but the pair not on a tangent line.
6. Neither terminal lying on the absolute, the line may be a tangent line.
7. The pair may be harmonically situated with reference to the absolute.
8. One terminal and one common point of the line of the pair and the absolute may be harmonically situated with reference to the other two.
9. The pair may be equianharmonic relatively to the absolute.

In reference to the principles of measurement.

1. A spread which can be transported so as more than to cover a former place is infinite.
2. A spread which can be transported so as partly to fall short or partly extend beyond a former place but cannot more than cover a former place is finite.

Commensurable ratios of magnitude are determined by counting successive superpositions.

Incommensurable ratios depend on approximations which require us to take notice that of magnitudes not coincident one is more nearly so than another.

The section of the absolute by a plane, as well as any segment of it, is infinite. A sector is also infinite. But the area of a triangle inscribed in the absolute is finite. (In fact, a triangle cannot be infinite.) For it may partly fall short of and partly overlap a former position but cannot more than cover it. Moreover, all such triangles are plainly equal; since any one may be superposed on any other [Fig. 1]. All the angles of such triangles are zero. If such a triangle is separated into two by a

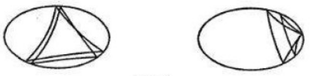

Fig. 1

line from the vertex to an opposite side, their angles are supplements. The areas of such triangles are determined as follows. Let α and β be respectively the angles of two triangles whose other vertices are on the absolute. Place the triangles side by side with their finite angles at [a] coincident vertex. From the quadrilateral so formed we may subtract a triangle having three vertices on the absolute or else we may subtract the quadrilateral from the triangle. The result will be a triangle with two vertices on the absolute and its finite angle equal to $\alpha + \beta$, in the first case or to $360° - (\alpha + \beta)$ in the second. It follows that the areas of triangles having two vertices on the absolute are proportionate to the difference of the sum of the angles from 180°. The difference between one such triangular area and another is equal to the area of a triangle having one vertex on the absolute, and the difference of the areas of two such triangles is equal to the area of a triangle with all its vertices.

So far we have assumed the triangle inside the absolute, the angles measuring round and round through 360°. In like manner, we might have set out from a triangle circumscribing the absolute having all its angles infinite, and all its sides zero [Fig. 2]. We easily prove that area is the sum of the three sides subtracted from the total length of a line.

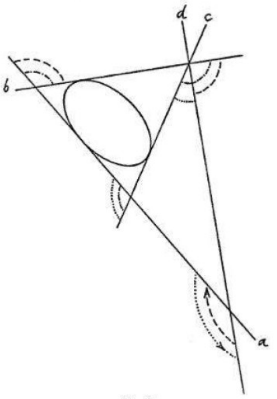

Fig. 2

C. NON-EUCLIDEAN GEOMETRY (122)

Suppose the parts of a line are displaced along that line in any way so long as the continuity of points (including those that are imaginary) is not broken and so that the new position of each point shall coincide with the old position of just one point, and *vice versa*. Then, let x and y be the homogeneous coordinates of a point on the line, these quantities being connected by a linear equation, but otherwise distributed over the line in any continuous and [ordinal] manner. If then (x', y') is a point which in its new position coincides with the old position of the point (x, y), we have a lineolinear equation between the two pairs of coordinates which may be written

$$axx' + exy' + iyx' + oyy' = 0.$$

Putting $x = x'$ and $y = y'$ we get the quadratic

$$ax^2 + (e + i)xy + oy^2 = 0,$$

which defines a pair of points on the line which remain unmoved by the displacement.

The manifoldness of displacements is evidently ∞^3, because there are 3 independent constants in the equation. There are ∞^2 positions of the unmoved points and ∞ displacements for each. But considering imaginaries, all the exponents must be doubled. All the displacements having any one position of the unmoved points are iterations of one infinitesimal displacement, and may collectively be called an area of displacement.

Let the equation of a displacement be written

$$xx' - \tfrac{1}{2}(\alpha + \beta + \tau)x - \tfrac{1}{2}(\alpha + \beta - \tau)x' + \alpha\beta = 0$$

or, writing Fx for x',

$$Fx = \frac{\tfrac{1}{2}(\alpha + \beta + \tau)x - \alpha\beta}{x - \tfrac{1}{2}(\alpha + \beta - \tau)}$$

This gives the equation of finite differences

$$F^{n-1}\cdot F^{n}-\tfrac{1}{2}(\alpha+\beta+\tau)F^{n-1}-\tfrac{1}{2}(\alpha+\beta-\tau)F^{n}+\alpha\beta=0,$$

the general solution of which (that in Boole's Finite Differences is wrong) is (α and β being unequal)

$$F^{n}=\frac{C_1\alpha(\tau+\alpha-\beta)^{n}+C_2\beta(\tau-\alpha+\beta)^{n}}{C_1(\tau+\alpha-\beta)^{n}+C_2(\tau-\alpha+\beta)^{n}}$$

To determine the ratio of the arbitrary constants, we have

$$F^{\circ}x=x=\frac{C_1\alpha+C_2\beta}{C_1+C_2}$$

and so finally

$$F^{n}=\frac{\alpha(x-\beta)(\tau+\alpha-\beta)^{n}+\beta(\alpha-x)(\tau-\alpha+\beta)^{n}}{(x-\beta)(\tau+\alpha-\beta)^{n}+(\alpha-x)(\tau-\alpha+\beta)^{n}}$$

If the moduli of $\tau+\alpha-\beta$ and $\tau-\alpha+\beta$ are not equal assume the former to be the larger. Then, $F^{\infty}x=\alpha$, $F^{-\infty}x=\beta$.

If the moduli in question are equal, then for some real value of ω, and in any case for some imaginary value

$$F^{\omega}x=x.$$

Considering the plane of imaginary quantity, every displacement of a given area of displacements may be conceived of composed of two different kinds. The displacements of the first kind are those for which $\tau+\alpha-\beta$ and $\tau-\alpha+\beta$ have the same argument, so that $x-\beta$ and $\alpha-x$ retain the same argument, and these displace all the points along circumferences through the unmoved points. The displacements of the second kind are those which displace points along circumferences orthogonal to the last, $\tau+\alpha-\beta$ and $\tau-\alpha+\beta$ having the same modulus.

The only general mathematical condition to which the rigid displacement of a line along itself is subject is, that a positive or negative, integral or fractional, but real number of repetitions of any such displacement will carry any real point to some real point and not to any imaginary point. Such a path of displacement must therefore appear as a straight line upon the plane of imaginary quantity. But there are only two straight lines among the system of circles just considered. Either therefore α and β are conjugate imaginaries, and a finite number of rigid displacements brings all the points of the line back to their original positions, or α and β are real and then they are absolute limits to rigid displacement.

SKETCH OF A SYNTHETIC TREATMENT

Chapter I. Geometry of points on a line

1. Taking any three points A, B, C, any fourth point X is either 1st on the way from A to B not passing C, 2nd on the way from B to C not passing A, or 3rd on the way from C to A not passing B.

2. In each of these divisions the multitudes of points is such that they cannot in any way be placed in one-to-one correspondence with the integral numbers.

This does not say that there is a continuous succession; but I do not see that the idea of continuity is possible without a second dimension.

Chapter II. Correspondences between 2 lines of points

Only a few topics of this vast subject to be noticed.

A *consecutive* correspondence is one in which every four points on one line have the same order of succession as the corresponding four points on the other.

A two-to-one consecutive correspondence is either pursuing or meeting. The pursuing correspondence has nothing particular, except that going once round one line corresponds to going twice round the other. But in the meeting correspondence, as a point moves part way round one line the corresponding point moves all the way round the other and then as the first point finishes the circuit of the first line the corresponding point returns and makes its circuit in the opposite direction; so that these ought to be self-evident, and indubitable apart from experience; and then many attempts were made to replace Euclid's assumption by one which should seem undeniable. General Perronet Thomson enumerated thirty of these, which the reader will find in an appendix to this treatise in an article by DeMorgan from the *English Cyclopædia*. Perhaps the two most successful of these attempts are those of Playfair. The first adopted in his edition of Euclid assumes that of two intersecting straight lines one or other must cut every third straight line in the same plane. The second is that a figure turned completely round in a plane, although not always turning round the same point must be rotated through four right angles; and this is substantially the assumption in my father's geometry. But all such premises were felt, after all, to be assumptions which might or might not be exactly true; and finally Lobachevski produced a geometry in which they were assumed to be false in some unknown measure. The falsity might, as a special case of his general admission, be nothing.

But all this time another demonstration by Euclid which is completely fallacious, had been admitted as sound reasoning. It still appears in the best treatises [Euclid's *Elements*. Book I. Prop. XVI]. ...

ON THE NON-EUCLIDEAN GEOMETRY

In this geometry there is a fixed quadric surface (it might be called a sphere, or rather the exemplar of a sphere) called the absolute. Every superposition or rigid displacement is by projection and section which does not move the absolute, unless in its own surface.

Thus the distance *AB* becomes in this way superposed upon *AC* (Fig. 1). In like manner the angles *ab* and *ac* are superposed (Fig. 2).

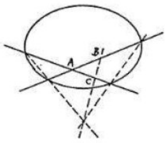

Fig. 1

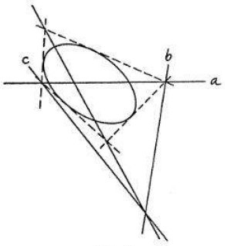

Fig. 2

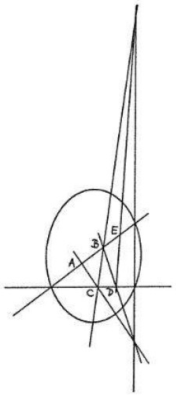

Fig. 3

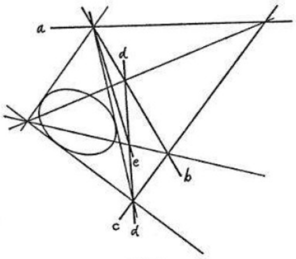

Fig. 4

So also (Fig. 3) *AB* is superposed first on *CD* and then on *BE*. And in like manner the angle *ab* is superposed first on *cd* and then on *be*.

THE PRINCIPLES OF NON-EUCLIDEAN GEOMETRY

This geometry treats of the projective relations of a certain individual quadric surface called the absolute.

This quadric surface, like every other, has in common with every line two points and two tangent planes, and has in every plane through every point in it two tangent lines. Only, in every tangent plane, intersecting at the point of tangency are two lines lying wholly in the surface.

Every transformation of this geometry is composed of displacements each of which carries any two points into new positions such that all four lie in one plane and carries any two planes into new positions so that all four pass through one point; and no point, line, or plane is carried to or from the absolute. In such displacement, all points at first in one plane continue in one plane, and all planes at first through one point continue to meet in one point.

There are six singular positions which a pair of points or a pair of planes may have, as follows:

1st, they may be in coincidence.

2nd, their line may be a tangent line. In this case a displacement may bring them into coincidence. They are then called "parallel."

3rd, one of the pair may belong to the absolute.

4th, they may be harmonically situated each on the polar or pole of the other.

5th, one of them may be harmonically situated towards one of the absolute points or planes of their line with reference to the other and the other absolute point or plane of their line. [In Fig. 1], *ABC* are harmonically situated.

6th, they may be equianharmonically situated with reference to the absolute.

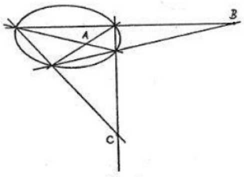

Fig. 1

The mode of superposition is as follows: Given the point *O*. Draw two lines through it, and through the intersections two lines meeting at two points *P*, *Q*, harmonic to *O*. Then by projection from *Q*, *OA* is superposed upon *OB*, by projection from *P*, *OB* is superposed on *OC*, and by projection again *OA* or *OC* is superposed upon *OD* [see Fig. 2].

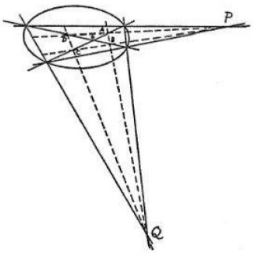

Fig. 2

D. THE ELEMENTS OF NON-EUCLIDEAN GEOMETRY. PREFACE (120)

The attempted proof by Euclid that the sum of the angles of a triangle cannot be less than two right angles was never regarded as satisfactory, not even, it is safe to say, by himself. For he baldly begs the question in his fifth postulate (often, owing to a bad text, called the 11th axiom) which is as follows:

"If two straight lines in a plane are crossed by a third, so as to make the sum of the inner angles on one side of the last less than two right angles, then those two lines will meet, if sufficiently produced, on that side of the third on which the sum of those angles is less than two right angles."

But this, I say, is begging the question; for if anybody thinks that the sum of the angles of a triangle can be less than two right angles, he will naturally hold this to be case for all triangles, and in fact it can be proved that the proposition must be true of all or of none. He will therefore hold that on a given base there will be a maximum value which the sum of two angles cannot exceed.

Euclid calls his premise a postulate, that is, an assumption; and he seems purposely to have stated it in a form in which the importance of it could be recognized. He did not seek to entrap his pupils. But the idea arose that the principles of geometry should be self evident, and indubitable apart from experience; and accordingly many attempts were made to replace Euclid's assumption by one which should seem undeniable. We reprint in an appendix a valuable article by DeMorgan from the *English Cyclopædia* enumerating some 30 of these. The most successful was that of Playfair that two straight lines which intersect must one or other cut every third straight line in the same plane.

E. [FROM A PAPER FOR THOMAS S. FISKE] (121)

... had told him had made it clear to him that the *strict geometrical truth* is that the sum of the three angles of a triangle is 180° *minus* a hypothetical correction.[1] (He should have said a constant proportion of the area.) He adds that the Euclidean geometry is practically true, at least for terrestrial figures. The limitation is significant, considering that the business of Bessel's life was with non-terrestrial figures. Gauss, after fourteen months interval, expresses his delight at learning that Bessel had come to that conclusion. The certainty of arithmetic and algebra, he adds, is absolute; but then they do not relate to anything but our own creations (unseres Geistes Product). But space has a reality without us (the Newtonian, anti-Leibnizian, anti-Kantian doctrine), and its laws cannot be known a priori. In other words, Gauss divides Geometry into Physical Geometry, a branch of physics which inquires what the properties of real space are, and all whose conclusions are affected with a probable error, and Mathematical Geometry, which in consequence of the suggestions of physical geometry, develops certain ideas of space. I do not merely say to trace out the consequences of hypotheses; for certainly Gauss would have held that it was part of the mathematician's function to invent the n-dimensional and other varieties of the space-idea.

It is singular that two fallacies in the reasoning of the first book of Euclid should have remained unnoticed to our day. One of these, in the 16th proposition, is that in the figure, where $AE\Gamma$ are coradial (a word I prefer to collinear), BEZ are coradial, $B\Gamma\Delta$ are coradial, $AE = E\Gamma$, and $BE = EZ$. Euclid assumes

$$\angle E\Gamma\Delta > \angle E\Gamma Z \quad \text{[Fig. 1].}$$

---

[1] Professor Fiske's name is written in C.S.P.'s hand on the back of the last page of manuscript, which had been folded as if once sent to him. Peirce had read a paper entitled "Rough Notes on Geometry, Constitution of Real Space" at a meeting of the American Mathematical Society on 24 November 1894. It is highly probable that this paper was the basis of his remarks at that time.

The missing first page apparently referred to a letter to Gauss from Bessel.

D. THE ELEMENTS OF NON-EUCLIDEAN GEOMETRY. PREFACE (120)

The attempted proof by Euclid that the sum of the angles of a triangle cannot be less than two right angles was never regarded as satisfactory, not even, it is safe to say, by himself. For he baldly begs the question in his fifth postulate (often, owing to a bad text, called the 11th axiom) which is as follows:

"If two straight lines in a plane are crossed by a third, so as to make the sum of the inner angles on one side of the last less than two right angles, then those two lines will meet, if sufficiently produced, on that side of the third on which the sum of those angles is less than two right angles."

But this, I say, is begging the question; for if anybody thinks that the sum of the angles of a triangle can be less than two right angles, he will naturally hold this to be case for all triangles, and in fact it can be proved that the proposition must be true of all or of none. He will therefore hold that on a given base there will be a maximum value which the sum of two angles cannot exceed.

Euclid calls his premise a postulate, that is, an assumption; and he seems purposely to have stated it in a form in which the importance of it could be recognized. He did not seek to entrap his pupils. But the idea arose that the principles of geometry should be self evident, and indubitable apart from experience; and accordingly many attempts were made to replace Euclid's assumption by one which should seem undeniable. We reprint in an appendix a valuable article by DeMorgan from the *English Cyclopædia* enumerating some 30 of these. The most successful was that of Playfair that two straight lines which intersect must one or other cut every third straight line in the same plane.

E. [FROM A PAPER FOR THOMAS S. FISKE] (121)

... had told him had made it clear to him that the *strict geometrical truth* is that the sum of the three angles of a triangle is 180° *minus* a hypothetical correction.[1] (He should have said a constant proportion of the area.) He adds that the Euclidean geometry is practically true, at least for terrestrial figures. The limitation is significant, considering that the business of Bessel's life was with non-terrestrial figures. Gauss, after fourteen months interval, expresses his delight at learning that Bessel had come to that conclusion. The certainty of arithmetic and algebra, he adds, is absolute; but then they do not relate to anything but our own creations (unseres Geistes Product). But space has a reality without us (the Newtonian, anti-Leibnizian, anti-Kantian doctrine), and its laws cannot be known a priori. In other words, Gauss divides Geometry into Physical Geometry, a branch of physics which inquires what the properties of real space are, and all whose conclusions are affected with a probable error, and Mathematical Geometry, which in consequence of the suggestions of physical geometry, develops certain ideas of space. I do not merely say to trace out the consequences of hypotheses; for certainly Gauss would have held that it was part of the mathematician's function to invent the *n*-dimensional and other varieties of the space-idea.

It is singular that two fallacies in the reasoning of the first book of Euclid should have remained unnoticed to our day. One of these, in the 16th proposition, is that in the figure, where $AE\Gamma$ are coradial (a word I prefer to collinear), BEZ are coradial, $B\Gamma\Delta$ are coradial, $AE = E\Gamma$, and $BE = EZ$. Euclid assumes

$$\angle E\Gamma\Delta > \angle E\Gamma Z \quad \text{[Fig. 1]}.$$

---

[1] Professor Fiske's name is written in C.S.P.'s hand on the back of the last page of manuscript, which had been folded as if once sent to him. Peirce had read a paper entitled "Rough Notes on Geometry, Constitution of Real Space" at a meeting of the American Mathematical Society on 24 November 1894. It is highly probable that this paper was the basis of his remarks at that time.

The missing first page apparently referred to a letter to Gauss from Bessel.

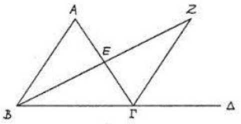

Fig. 1

That this does not follow was overlooked by Saccheri, and is overlooked by the Society for the Improvement of Geometrical Teaching, and by many other authors; but it is pointed out by Stäckel. The other, in the 7th proposition, where the construction is $A\Gamma = A\Delta$, $B\Gamma = B\Delta$, consists in inferring that $\angle A\Delta\Gamma > \angle\Delta\Gamma B$, because $\angle A\Gamma\Delta = \angle A\Delta\Gamma$ [Fig. 2]. This is overlooked even by Stäckel. Yet it is not true, even in Euclidean geometry, when Γ and Δ are at infinity; and it is not generally true in that variety of non-Euclidean geometry in which the intersection of the plane with the absolute is a point. It is true, that simple observations refute that geometry; but they are not put forward by Euclid.

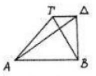

Fig. 2

Both of these fallacies arise from Euclid's confidence in his 8th Axiom, that the whole is greater than its part. These are the only places in the first book in which he makes use of that axiom, except in 18, 20, 24, and 26, which, properly understood, are equally fallacious. It has been abundantly shown by Cauchy, G. Cantor, and others, that the whole is only necessarily greater than its part when that part is finite and positive. Were the logic of relatives, either with or without any of the algebras I have proposed to facilitate its study, made use of, such fallacious reasoning would be impossible.

I maintain that Euclid was himself a non-Euclidean geometer. I do not mean, in the complete, Gaussian and Besselian sense, but more so than Saccheri and Lambert. I proceed to state the evidence of this. In the first place, the effort of all writers on the theory parallels, all defenders of the Euclidean geometry, was to produce some proposition in place of the 5th Postulate which should be more readily acceptable. This was very easy. It was so easy that Euclid could not but have known it.

For instance, he must manifestly have known that it was sufficient to say that if of three rays in one plane one was perpendicular to a second while the third was not perpendicular to that second, then the first and third must meet on the side of the acute interior angle. But Euclid disdains every effort to gloss over his assumption, and prefers to state it in the form in which its hypothetical character is most apparent. The only reasonable explanation is that he was fully alive to the hypothetical character of the proposition, and thought truth demanded its being presented in that light. Besides, consider the order of propositions in the first book. The first six are valid for all varieties of non-Euclidean geometry. The next eight (that is, to I.14, inclusive) are false in case the intersection of the plane with the absolute is a point, and in no other case. Proposition 15, that vertical angles are equal seems to the modern geometer no theorem at all; but Euclid's treatment of it is as if he conceived it to be of the same class as the preceding eight. All the next twelve propositions, in the sense in which Euclid, no doubt, would understand them, are false of the elliptic geometry alone. Owing to the confusion between internal and external angles, some of these would now be considered true in all cases. Finally, all the remaining propositions of the book are false both of elliptical and of hyperbolical geometry. It seems, therefore, that the propositions of the first book, which is, of course, the book of Fundamenta, are arranged in reference to the different kinds of non-Euclidean geometry. It seems to me that the most probable, and I might almost say the only rational, explanation of this arrangement is to suppose that Euclid had studied the non-Euclidean geometries.

In this connection let me ask: is it possible that Euclid, the author of the Data and Porisms, was unaware that metrical geometry is not the real basis of geometry?

The following count of the different kinds of propositions of the elements may be useful.

Book I, on Fundamentals, contains 23 definitions, 5 postulates, 9 (5 genuine) axioms, and 48 demonstrated propositions, of which 1, 2, 3, 9, 10, 11, 12, 22, 23, 31, 40 (11 in all) are problems.

Book II, on Areas, contains 2 definitions, and 14 demonstrated propositions, of which the 14th is a problem.

Book III, on Circles, contains 11 definitions, and 37 demonstrated propositions, of which 1, 17, 30, 33, 34 (5 in all) are problems, and 1, 16, 31 have corollaries.

Book IV, on Polygons, has 7 definitions, and 16 demonstrated propositions, all problems, of which 5 and 15 have corollaries.

Book V, on Proportions, has 18 definitions and 25 demonstrated propositions, all theorems, of which the 7th has a corollary.

Book VI, has 5 definitions and 33 demonstrated propositions, of which 9, 10, 11, 12, 13, 18, 25, 28, 29, 30, 31 (11 in all) are problems, and the 8th, 19th, 20th have corollaries. There is a lemma before the 23rd.

Book VII, on Arithmetic, has 22 definitions and 39 demonstrated propositions, all theorems, of which the 2nd has a corollary.

Book VIII, on Arithmetic, has 27 demonstrated propositions, all theorems, of which the 2nd has a corollary.

Book IX, has 36 demonstrated propositions, all theorems, of which the 11th has a corollary.

Book X, has 4 definitions before the first proposition, 6 more before the 48th, and 6 more before the 85th, 115 regular propositions all theorems, of which the 3rd, 4th, 6th, 9th, 23rd, 111th, 114th have corollaries. There are lemmas before 10, 14, 17, 19, two before 29, before 23, 42, 54, 60. There is a scholium, or remark, before the 72nd.

Book XI, on Stereometry, has 28 definitions, 39 regular propositions, of which 11, 12, 23, 26, 27 (5 in all) are problems, and 33 and 35 have corollaries. There is a lemmatic problem before the 24th.

Book XI has 18 regular propositions of which 16 and 17 (two in all) are problems, and 7, 8, 17 have corollaries. There are lemmas before the 3rd and 5th.

Book XIII has 18 regular propositions, all theorems, of which 16 and 17 have corollaries. There are so-called Lemmas before the 3rd and 14th and at the end. There is also a scholium, or remark, at the end.

Total: 132 definitions, 465 regular propositions, 27 corollaries, 17 "lemmas," 2 remarks, 5 postulates, and 9 axioms.

It is worth notice that Ptolemy's theorem (which lies at the foundation of the Brocard geometry) holds good for every form of non-Euclidean geometry.

The properties of Space may be stated (more fully, I believe, than has hitherto been done) as follows:

I. *Intrinsic Properties of Space.*

1. Space is continuous.

2. Space is tridimensional.
3. Space has no topical singularities, that is, no surfaces, lines, or points from which it extends in more or less multiple ways than from neighboring surfaces, lines, or points.
4. Space is perissid; that is, there are innumerable multitudes of unbounded surfaces of which any three have an odd number of points in common.
5. The chorisis (number of separate point-regions), cyclosis, periphraxis, and immensity of space are as small as the fourth property allows, namely, each 1.

II. *Property of the Image of Space, or the Optical Property of Space.*

6. Through any three points there is just one plane surface; and the place common to two planes is a ray, or free path of vision; and any plane and ray not lying in that plane have just one point in common.* (* The point of intersection of two rays in one plane is, in one sense, a real point, even though such a system of measurement be adopted that its distances from other real points of those rays be imaginary. We conceive of vision as making the complete circuit of the ray, irrespective of the length.)

III. *Property of the Displacement of Rigid Bodies in Euclidean Space, or the Metrical Property of Euclidean Space.*

7. When Space is measured by a rigid body, there is a plane firmament, or surface which no particle can either leave or arrive at.

It follows from what Bessel implies, in the letter above referred to, that the physical geometry of celestial triangles needs examination, in order to ascertain whether the constant of space may not have a sensible magnitude. I have undertaken such an examination. I began by forming a list of all possible methods of determining this quantity by means of the following observations: 1st, the parallaxes of stars; 2nd, the numbers of stars of each parallax; 3rd, the proper motions of stars; 4th, the numbers of stars of different proper motions; 5th, the spectroscopic determinations of the motions of stars in the line of sight; 6th, the magnitudes of stars; 7th, the numbers of stars of each magnitude. My list of possible methods was long. All of them, it is true, involved some hypothetical element; but that is true of any research, whatever, into the value of a physical quantity; and it is possible so to modify the methods that the hypotheses that appear the most dangerous may probably be eliminated. I applied several methods: they seemed to indicate a hyperbolic space with a constant far from insignificant. The best method seemed to be by proper motions. We know that our ordinary dynamics gives a definite value to absolute, or nonrelative velocity of rotation. Thus, Foucault's pendulum experiment shows that the earth has an absolute motion of rotation, and not merely a rotation relatively to the sphere of the heavens. All German attempts to escape this conclusion are metaphysical word-spinning. In the Euclidean geometry, translation is an infinitesimal rotation about an axis lying in the firmament. In the non-Euclidean geometry there is no plane firmament and, consequently, no translation. In every rotation, every particle lying in the ray which is the polar conjugate with respect to the absolute of the axis of rotation moves along that ray. All other particles describe circles. Consequently, there is an absolute velocity in all motion. The same apparent effect cannot be produced by a motion of the stars and an opposite motion of the solar system. The proper motion due to the absolute motion of a star varies inversely as the sine of the product of the distance by the square root of a constant. The proper motion due to the absolute motion of the sun varies inversely as the tangent of the product of the distance by the square root of the same constant. If, therefore, we had all the proper motions plotted upon a globe, and if we were first to throw out all those which are excessively large, as probably belonging to stars so near the sun that they may be supposed sensibly to partake of the system of motion to which the sun's motion belongs, — whether they move in the same direction or with the same velocity or not, — we should expect to find the remaining proper motions presenting one or other of two appearances. Namely, if space is elliptical (that is, finite), and by consequence the square root by which the distance is multiplied be real, the proper motions due to the sun's motion would for very distant stars become insensible (because divided by indefinitely great tangents) and therefore those stars whose proper motions were very small would be moving about in every direction quite irrespective (or, at least, relatively irrespective) of the motion of the sun. If, however, space is hyperbolical, and that square root aforesaid imaginary, we should expect to find that those stars whose proper motions were very small would (except for the effect of errors of observation) move more directly away from the apex of the sun's motion than those whose proper motions were relatively large. I made the necessary computations for a selection of stars from Newcomb's catalogue. Only, instead of judging which were the most distant stars by the proper motions alone, I formed my judgment by combining the evidence from proper motion and from magnitude.

The result was most markedly in favor of the hyperbolical geometry. A rough calculation of probabilities showed that it could not be with probability attributed to chance. I was in hopes sufficient interest would be excited by this result to enable me to obtain the funds to employ a computer for a few months to extend the calculations to all the proper motions of Auwers. But as the question has no immediate relation either to business or comfort, this has not hitherto been the case. Its decision must strongly influence the scientific conception of the universe; and might thus lead to practical results sooner than one might, at first sight, suppose possible. I have now laid out a new plan of the work; so that for $150, a rough graphical result may be obtained; and if this should be of a convincing character, $500 more may be expended in computations, without the determination of any connected constants. It might ultimately be thought worth while to work in a more fundamental way. It will be remarked, that if a constant value results from such calculations, as the work I have already done gives me no room to doubt, then that constant must mean *something*. Even if I am wrong in thinking that it can only be attributed to a property of space, it still must have some significance for the visible universe. I shall be happy to receive subscriptions payable when enough have been received to cover the expense of the graphical solution.[1]

C.S. Peirce

[1] At this point the reader is referred to pp. 421-424 of "The Charles S. Peirce–Simon Newcomb Correspondence" by the editor in *The Proceedings of the American Philosophical Society*, 101:5 (October 1957), 409-433.

F. ON TWO MAP-PROJECTIONS OF THE LOBATSCHEWSKIAN PLANE[1]

The proper motions of the stars show very strong indications that our space is really hyperbolic, or, what comes to the same thing, that the law of dynamics, or kinematics, is such that if two stars move in the same plane with the same uniform velocity, without being acted upon by any forces, and each appears at one moment as seen from the other to be abreast with it, then as time goes on each will fall behind the other. Other indirect arguments tend to confirm me in this opinion; and thus, entertaining for this species of geometry something closely approaching belief, I have found it convenient to give it intuitional shapes by map-projections.

I use two, both very simple. To avoid confusion, I will write all formulae applying to the noneuclidean space in *red* (in printing, Old English can be used), all formulae applying to the representation of that space in Euclidean space in *blue* (in printing, Roman type), all formulae relating to the connection between the two in *brown* (in printing, heavy-faced type; on the blackboard, yellow chalk), and all formulae applicable everywhere since they merely relate to algebra in *black* (in printing, Italics; on the blackboard, white chalk.) I also use the sign $\backsim$ to mean "represents," or "corresponds to."

The formulae of Lobatchewskian trigonometry can be obtained by the following system of correspondences.

$$(1)\quad \begin{cases} \mathbf{A}\text{ (an angle in spherical trig.) } \backsim \mathbf{A}\text{ (in Lobat. plane trig.)} \\ \sin \mathbf{a}\text{ (a being a side in sph. trig.) } \backsim -\mathbf{i}\operatorname{Sinh} \mathbf{a}\text{ (in Lob. pl. tr.)} \\ \cos \mathbf{a}\text{ (a being a side in sph. trig.) } \backsim \operatorname{Cosh} \mathbf{a}\text{ (in Lob. plane trig.)} \end{cases}$$

Although only a few of the following formulae will be needed, the others are given for convenience.

Right Triangles

$$\operatorname{Cosh} \mathfrak{h} = \operatorname{Cosh} \mathfrak{a}.\ \operatorname{Cosh} \mathfrak{b}$$

$$(2)\qquad \operatorname{Cosh} \mathfrak{h} = \cot \mathfrak{A}.\ \cot \mathfrak{B}$$

$$(3)\qquad \cos \mathfrak{A} = \operatorname{Cosh} \mathfrak{a}.\ \sin \mathfrak{B}$$

$$\operatorname{Sinh} \mathfrak{h} = \frac{\operatorname{Sinh} \mathfrak{a}}{\sin \mathfrak{A}}$$

$$(4)\qquad \operatorname{Tanh} \mathfrak{h} = \frac{\operatorname{Tanh} \mathfrak{a}}{\cos \mathfrak{B}}$$

$$\operatorname{Sinh} \mathfrak{b} = \frac{\operatorname{Tanh} \mathfrak{a}}{\tan \mathfrak{A}}$$

Oblique Triangles

$$\frac{\operatorname{Sinh} \mathfrak{a}}{\sin \mathfrak{A}} = \frac{\operatorname{Sinh} \mathfrak{b}}{\sin \mathfrak{B}} = \frac{\operatorname{Sinh} \mathfrak{c}}{\sin \mathfrak{C}}$$

$$(5)\qquad \operatorname{Cosh} \mathfrak{c} = \operatorname{Cosh} \mathfrak{a}.\ \operatorname{Cosh} \mathfrak{b} - \operatorname{Sinh} \mathfrak{a}.\ \operatorname{Sinh} \mathfrak{b}.\ \cos \mathfrak{C}$$

$$\cos \mathfrak{C} = -\cos \mathfrak{A} \cos \mathfrak{B} + \sin \mathfrak{A} \sin \mathfrak{B} \operatorname{Cosh} \mathfrak{c}$$

$$\operatorname{Sinh} \mathfrak{a}.\ \operatorname{Coth} \mathfrak{b} = \cot \mathfrak{B}.\ \sin \mathfrak{C} + \operatorname{Cosh} \mathfrak{a}.\ \cos \mathfrak{C}$$

A few formulae of hyperbolic functions may also be added, as follows.

$$(6)\qquad \operatorname{Tanh} x = \frac{\operatorname{Sinh} x}{\operatorname{Cosh} x} \qquad \operatorname{Coth} x = \frac{\operatorname{Cosh} x}{\operatorname{Sinh} x}$$

$$(7)\qquad \operatorname{Sech} x = \frac{1}{\operatorname{Cosh} x} \qquad \operatorname{Cosech} x = \frac{1}{\operatorname{Sinh} x}$$

$$(8)\qquad \begin{cases} \operatorname{Sinh} 0 = 0 \\ \operatorname{Sinh} \infty = \infty \end{cases} \qquad \begin{matrix} \operatorname{Cosh} 0 = 1 \\ \operatorname{Cosh} \infty = \infty \end{matrix} \qquad \begin{matrix} \operatorname{Tanh} 0 = 0 \\ \operatorname{Tanh} \infty = \infty \end{matrix}$$

$$\operatorname{Sinh} x = \frac{\mathfrak{e}^{x} - \mathfrak{e}^{-x}}{2} \qquad \operatorname{Cosh} x = \frac{\mathfrak{e}^{x} + \mathfrak{e}^{-x}}{2}$$

$$\operatorname{Cosh}^2 x = 1 + \operatorname{Sinh}^2 x$$

$$(9)\qquad \operatorname{Tanh}^2 x + \operatorname{Sech}^2 x = 1$$

---

[1] This manuscript is to be found in the archives of the Smithsonian Institution. For details on Peirce's association with that Institution when Samuel P. Langley was the Secretary see "The Scientist-Philosopher C. S. Peirce at the Smithsonian" by the editor in the *Journal of the History of Ideas* XVIII:4 (October 1957). Filed with the manuscript at the Smithsonian are two letters. Peirce's covering letter to Langley dated 18 April 1901 reads: "If the Academy is in session when this reaches you I should like to have it presented. I fear it is too trifling to be printed as a Memoir, though I know not where else to print it ...." It was received at the Smithsonian on April 20.

Langley's reply was written on 22 April 1901 and reads: "Your paper 'On two Map-Projections of the Lobatschewskian Plane' only reached me the day after the Academy had completed its session. What would you like to have me do with it?"

MS. 114 at the Houghton Library is a partial draft of this paper. It is entitled "On Hyperbolic Geometry."

A CONFORMED PROJECTION.

Let us now proceed to construct a projection, fulfilling the following conditions:

1st, all angles to be preserved unchanged;

2nd, there is to be a centre of projection all straight lines through which are represented by straight lines [Fig. 1].

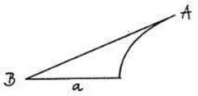

Fig. 1

Let B be at the centre of projection, and denote the angle between two straight lines by the same letter. Upon one of these lines, at a distance a from the centre, erect a perpendicular, intersecting the other line in an internal angle, A. Then (3) applies.

Upon the map, let the point corresponding to B be taken as an origin of polar coordinates. Let the other extremity of a be represented by a point whose coordinates are:

(18) $\boldsymbol{\theta = 0} \qquad \mathbf{r = Fa = l}$

Then, by (3),

(19) $\cos A = \mathrm{Cosh}\,a \cdot \sin\theta$

Upon the map, we shall have a plane triangle having, at the origin, an angle $d\theta$, included between two sides whose lengths are r and $r+dr$, while one of the other angles is A. Then, by plane trigonometry, we shall have

$$\tan A = \frac{r\cdot\sin d\theta}{r+dr-r\cdot\cos d\theta} = r\frac{d\theta}{dr}$$

whence

(20) $$\frac{d\log r}{d\theta} = \cot A = \frac{\cos A}{\sqrt{1-\cos^2 A}} = \frac{\mathrm{Cosh\,a}\cdot\sin\theta}{\sqrt{1-\mathrm{Cosh}^2\mathrm{a}\cdot\sin^2\theta}} = \frac{\sin\theta}{\sqrt{\cos^2\theta-\mathrm{Tanh}^2\mathrm{a}}}$$

[see (9)]. Multiply both sides by $\dfrac{d\theta}{d\cos\theta} = -\dfrac{1}{\sin\theta}$; and we have

(21) $$\frac{d\log r}{d\cos\theta} = -\frac{1}{\sqrt{\cos^2\theta-\mathrm{Tanh}^2\mathrm{a}}}$$

The integral of this is

(22) $$\frac{\mathrm{C}}{r} = \frac{\cos\theta}{\mathrm{Tanh\,a}} + \sqrt{\frac{\cos^2\theta}{\mathrm{Tanh}^2\mathrm{a}}-1}$$

It is obvious that the two values resulting from the ambiguous sign of the square root are reciprocals of one another; for

$$(x+\sqrt{x^2-1})(x-\sqrt{x^2-1}) = x^2-(x^2-1) = 1.$$

Multiplying (22) by r, and putting

(23) $r\cos\theta = x \quad r^2 = x^2+y^2,$

we get

(24) $$\left(x-\frac{\mathrm{C}}{\mathrm{Tanh\,a}}\right)^2 + y^2 = (\mathrm{C\,Cosech\,a})^2;$$

so that the equation represents a circle.

In order to determine the value of C, we use (18) and find from (22)

(25) $$\frac{\mathrm{C}}{l} = \mathrm{Coth\,a} \pm \sqrt{\mathrm{Coth}^2\mathrm{a}-1} = \begin{cases}\mathrm{Coth\,a} + \mathrm{Cosec\,a} = \mathrm{Coth}\,\frac{a}{2}\\ \mathrm{Coth\,a} - \mathrm{Cosec\,a} = \mathrm{Tanh}\,\frac{a}{2}\end{cases}$$

[see (10), (11). (12)]. Substituting this in (24), we get, by (14), (15), (16), (17),

(26) $$[x - \tfrac{1}{2}l(1 + \mathrm{Coth}^2\tfrac{a}{2})]^2 + y^2 = \left(\frac{l}{2\,\mathrm{Sinh}^2\frac{a}{2}}\right)^2$$

$$[x - \tfrac{1}{2}l(1 + \mathrm{Tanh}^2\tfrac{a}{2})]^2 + y^2 = \left(\frac{l}{2\,\mathrm{Cosh}^2\frac{a}{2}}\right)^2$$

The difficulty of conceiving a straight line to be represented by a circle which is topically untransformable into a straight line will be considered below, and shown not to be serious.

Since the leg b of the triangle is represented by a circle, it follows that, as B increases, the angle A must ultimately become zero. In fact, by (2), when $A = 0$, $\mathrm{Cosh}\, h = \infty$, $h = \infty$. But the circle representing the leg b is a finite one, and thus the locus of points infinitely distant from the centre must be represented by a finite circle. Let the equation of the circle representing the absolute be

(28) $$r = L$$

Then, every circle orthogonal to this circle on the map will represent a straight line in the Lobatchewskian plane. The general equation of such a circle is

(29) $$\left(x - \frac{L^2 + l^2}{2l}\right)^2 + y^2 = \left(\frac{L^2 - l^2}{2l}\right)^2$$

The same equation precisely would hold if l, instead of representing the minimum distance of the circle representing leg b from the origin, represented the maximum distance. If (29) be compared with (26) and with (27), each of these last two equations affords two ways of determining the value of l. From (26), we have

(30) $$\frac{L^2}{l^2} = \mathrm{Coth}^2\tfrac{a}{2}, l = L\,\mathrm{Tanh}\tfrac{a}{2}; \text{and } \frac{L^2}{l^2} - 1 = \mathrm{Cosech}^2\tfrac{a}{2}, l = L\,\mathrm{Tanh}\tfrac{a}{2}$$

while from (27) we have

(31) $$\frac{L^2}{l^2} = \mathrm{Tanh}^2\tfrac{a}{2}, \mathrm{l} = L\,\mathrm{Coth}\tfrac{a}{2}; \text{and } \frac{L^2}{l^2} - 1 = -\mathrm{Sech}^2\tfrac{a}{2}, l = L\,\mathrm{Coth}\tfrac{a}{2}.$$

In order to make the last right, since a hyperbolic tangent of a real quantity is essentially less than 1, we have to assume that l is the maximum distance of the circle representing the leg b, from the origin. The circle on the map is cut twice by the radius vector, although the straight line it represents is cut but once by the hypotheneuse represented by the radius vector. In short, one point on the Lobatchewskian plane is represented twice over on the map; and generally, all that part of the map outside

the circle representing the absolute only represents again what is represented inside. Equations (26) and (30) refer to the inside map; equations (27) and (31) to the outside map. On comparing (25) with (30) and (31), we get

(32) $$C = L.$$

It is now proved that (30) gives the rule for the projection, if there is any such projection; but it is perhaps not proved that that rule does not lead to contradictory results. At any rate, it will be worthwhile to test it by applying (4). Substituting (13) in this, we get

(33) $$\mathrm{Tanh}\frac{\mathfrak{h}}{2} + \mathrm{Coth}\frac{\mathfrak{h}}{2} = \left(\mathrm{Tanh}\frac{\mathfrak{a}}{2} + \mathrm{Coth}\frac{\mathfrak{a}}{2}\right)\cos\mathfrak{B}$$

In the figure [2], the distance between 0, the origin, and C, the centre of the circle representing the leg b is $\frac{L^2 + l^2}{2l}$ and the radius of that circle is $\frac{L^2 - l^2}{2l}$. Hence, by plane trigonometry,

(34) $$\left(\frac{L^2 - l^2}{2l}\right)^2 = \left(\frac{L^2 + l^2}{2l}\right)^2 + r^2 - 2\frac{L^2 + l^2}{2l} r\cos\theta$$

which reduces at once to

(35) $$\frac{L}{r} + \frac{r}{L} = \left(\frac{L}{l} + \frac{l}{L}\right)\cos B$$

Now since we know, by (30), that

(30) $$\frac{\mathbf{l}}{\mathbf{L}} = \mathrm{Tanh}\,\frac{\mathbf{a}}{2}$$

it follows from the comparison of (33) and (35) that

(36) $$\frac{\mathbf{r}}{\mathbf{L}} = \mathrm{Tanh}\,\frac{\mathbf{h}}{2}$$

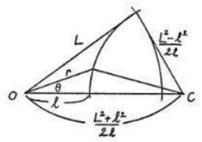

Fig. 2

The projection is thus established. It may be very appropriately called the hyperbolic stereographic projection, since its rule of construction only differs from that of the stereographic projection of the elliptic plane in that the radii vectores are proportional to $\text{Tanh}\,\frac{h}{2}$ instead of to $\tanh\frac{h}{2}$, where h is the distance of the point to be represented from the centre. It also agrees with the elliptic stereographic projection in preserving the angles. The other important property of the latter is that every circle represents a circle (or straight line), and conversely. In order to ascertain whether the hyperbolic stereographic projection has this property or not, we assume the equation of a circle, which by plane trigonometry is

$$R^2 = r^2 + Q^2 - 2rQ\cos\theta \tag{37}$$

Now, of course, the circle cannot represent a real circle unless

$$L > Q + R \tag{38}$$

so that $\sqrt{(L+Q+R)(L-Q-R)(Q-R-L)(R-L-Q)}$ is real. Call this square root V for the sake of brevity, $\frac{L+Q-R}{V}$ and $\frac{L-Q+R}{V}$ will, in case of reality, be positive quantities greater than 1 and, therefore, of the nature of hyperbolic cosines. We may assume, then,

$$\text{Cosh}\,\mathbf{b} = \frac{\mathbf{L}+\mathbf{Q}-\mathbf{R}}{V} \tag{39}$$

$$\text{Cosh}\,\mathbf{c} = \frac{\mathbf{L}-\mathbf{Q}+\mathbf{R}}{V} \tag{40}$$

Solving these equations for Q and R, we find

$$\mathbf{Q} = \frac{\mathbf{L}\,\text{Sinh}\,\mathbf{b}}{\text{Cosh}\,\mathbf{b} + \text{Cosh}\,\mathbf{c}}$$

$$\mathbf{R} = \frac{\mathbf{L}\,\text{Sinh}\,\mathbf{c}}{\text{Cosh}\,\mathbf{b} + \text{Cosh}\,\mathbf{c}}$$

Putting also

$$\boldsymbol{\theta} = \mathbf{C}$$
$$\mathbf{r} = \mathbf{L}\,\text{Tanh}\,\tfrac{\mathbf{a}}{2}$$

the equation (37) of the circle becomes

$$\begin{aligned}\text{Sinh}^2\,\mathfrak{c} = {} & \text{Tanh}^2\tfrac{\mathfrak{a}}{2}\,(\text{Cosh}\,\mathfrak{b} + \text{Cosh}\,\mathfrak{c})^2 + \text{Sinh}^2\mathfrak{b}\\ & -2\text{Tanh}\tfrac{\mathfrak{a}}{2}\cdot\text{Sinh}\,\mathfrak{b}\,(\text{Cosh}\,\mathfrak{b} + \text{Cosh}\,\mathfrak{c})\cos\mathfrak{C}\end{aligned}$$

or, dividing by $\text{Cosh}\,b + \text{Cosh}\,c$, and observing that

$$\text{Sinh}^2 c - \text{Sinh}^2 b = (\text{Cosh}\,c - \text{Cosh}\,b)(\text{Cosh}\,c + \text{Cosh}\,b)$$

we get

$$\text{Cosh}\,\mathfrak{c} - \text{Cosh}\,\mathfrak{b} = \text{Tanh}^2\tfrac{\mathfrak{a}}{2}(\text{Cosh}\,\mathfrak{b} + \text{Cosh}\,\mathfrak{c}) - 2\text{Tanh}\tfrac{\mathfrak{a}}{2}\cdot\text{Sinh}\,\mathfrak{b}\cdot\cos\mathfrak{C}$$

Dividing by $1 - \text{Tanh}^2\frac{a}{2}$, and observing that

$$\text{Cosh}\,a = \frac{1 + \text{Tanh}^2\frac{a}{2}}{1 - \text{Tanh}^2\frac{a}{2}}$$

$$\text{Sinh}\,a = \frac{2\,\text{Tanh}\frac{a}{2}}{1 - \text{Tanh}^2\frac{a}{2}}$$

we get

$$\text{Cosh}\,\mathfrak{c} = \text{Cosh}\,\mathfrak{a}\cdot\text{Cosh}\,\mathfrak{b} - \text{Sin}\,\mathfrak{a}\cdot\text{Sin}\,\mathfrak{b}\cdot\cos\mathfrak{C}$$

which, when a and C are variable is, by (5), the equation of a circle. Hence, this projection represents circles (and straight lines) by circles, and conversely. Summing up its properties:

1st. All angles are preserved.

2nd. Representing any point on the hyperbolic plane by the origin on the map, all straight lines through that centre are represented by straight lines.

3rd. A point distant by h from the centre is represented by a point distant by L $\text{Tanh}\,\frac{h}{2}$ from the original.

4th. Every straight line in the hyperbolic plane is represented by a circle orthogonal to the circle of radius L with its centre at the origin.

5th. Every circle lying wholly within that absolute circle on the map represents a real circle of the hyperbolic plane with a real radius, and conversely. Straight lines not through the origin and circles cutting the absolute circle represent real circles of imaginary radius, a sort of locus peculiar to hyperbolic geometry.

Practically, this projection is distinctly more convenient even than the ordinary stereographic; but theoretically it presents greater inconveniences. As the elliptic stereographic represents every point twice over, so also does the hyperbolic stereographic projection. This arises from the fact that it is conformal. For conformal projections are exclusively between artiad surfaces, that is, surfaces of even cyclosis, while the projective plane, or plane upon which unbounded lines can intersect in an odd number of points, cannot by any distortion be brought into coincidence with an artiad surface. In the hyperbolic plane, we have to distinguish between imaginary points and points at imaginary distances from the origin. That every pair of real rays in a plane intersect in a real point is a proposition of projective geometry, which no mode of measurement, that is, no system of designating the points, can falsify. The elliptic stereographic divides the plane along the whole extent of a ray and there joins it to a similarly cut copy of itself turned upside down;

so that every part of the elliptic plane is twice represented in relatively perverted images. The hyperbolic stereographic cuts a disk out of the plane, along the absolute conic, and joins that to a perverted image of itself, leaving all real points at imaginary distances entirely unrepresented. It obviously cannot represent those points conformedly since the angles are there imaginary. This is a grave inconvenience for many purposes.

The projection is subject to another grave inconvenience which manifests itself, for example, if we attempt to apply the projective definition of a circle as a conic having double contact with the absolute. Since the real part of the absolute circle is shown in the projection, we might naturally expect to find some traces of the double contact of circles with the absolute, although the plane of a conformal projection has no imaginary parts, being, on the contrary, itself the representation of a single imaginary variable. But Cayley's theory of distance, beautiful as it is, takes but a narrow view of the subject. The system of distances is the expression of the law which defines the possibilities of displacement of a rigid body. In our universe, a part of that law is that rigid bodies can receive no imaginary displacements. Nor need imaginaries be called in to define the law in general terms, as I intend to show in another paper.

A CENTRAL PROJECTION OF THE LOBATCHEWSKIAN PLANE

The Lobatchewskian plane can also be so represented, that every ray, α, is represented by a ray cutting at right angles that radius vector from the origin which represents the ray through a fixed centre that the ray α cuts at right angles; and so that all angles about that centre are represented by equal angles about the origin [Fig. 3. △B, red; △O blue].

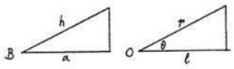

Fig. 3

A right triangle having one of its angles, B, at the centre will be represented by a right triangle having the corresponding angle at the origin. Then we shall have

$$\mathbf{l} \backsim \mathbf{a}$$
$$\mathbf{r} \backsim \mathbf{h}$$
$$\boldsymbol{\theta} = \mathbf{B}$$

$$\mathbf{l} = \mathbf{Fa}$$
$$\mathbf{r} = \mathbf{Fh}$$
$$\mathbf{r} = \mathbf{l}\sec\boldsymbol{\theta}$$
$$\mathrm{Tanh}\,\mathfrak{h} = \mathrm{Tanh}\,\mathfrak{a} \cdot \sec\mathfrak{B}$$

Hence the projection of any point will be determined by the equations

$$\boldsymbol{\theta} = \mathbf{B}$$
$$\mathbf{r} = \mathrm{L}\,\mathrm{Tanh}\,\mathbf{h}$$

where L is the radius of the circle which represents the circle at infinity.

Distances are constructed with the greatest ease. Suppose, for example, that having given two points, C and H, on the map, we wish to know where the ellipse representing a circle about C as a centre and having the radius represented by CH will cut another ray through C. The figure [4] almost explains itself. The line CH is produced to PR, its intersection with the absolute, and the other line is produced to QS, its intersections with the same circle. The quadrangle $PQRS$ is completed so that A is collinear with P and Q and with R and S, while B is collinear with P and S and with Q and R. Then construct I at the inter-

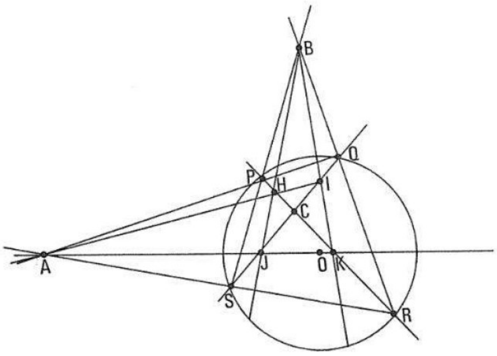

Fig. 4

section of AH and $[QS]$, J at the intersection of BH and $[QS]$, and K at the intersection of AJ and BI. [Then] CH, CI, CJ, CK represent equal distances. By drawing a diameter through C and O, the centre of the circle representing the absolute and laying down four points situated symmetrically to H, I, J, K, on the other side of this diameter, we have eight points on the ellipse representing the circle. There are other obvious modes of constructing equal distances. [Fig. 4 follows Peirse's instructions.]

I do not know any simple geometrical construction for angles, or any which is purely projective. There probably exists such a real projection. Triangles can, however, readily be solved by means of the following

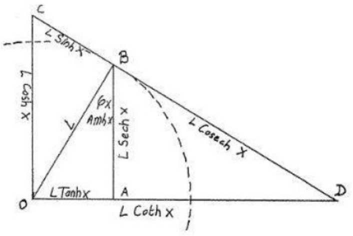

Fig. 5

figure [5]. Let O be the centre of the circle of radius L representing the absolute. Let OA represent the distance x, so that

$$OA = L \operatorname{Tanh} x$$

At A erect a perpendicular to OA cutting the circle of the absolute in B, so that $OB = L$. Then,

$$AB = L \operatorname{Sech} x$$
$$\angle OBA = 2 \arctan e^{x} - \frac{\pi}{2}$$

Through B draw a perpendicular to OB cutting OA produced in D. Then

$$OD = L \operatorname{Coth} x$$
$$BD = L \operatorname{Cosech} x$$

At O raise a perpendicular to OA cutting BD produced in C. Then

$$OC = L \operatorname{Cosh} x$$
$$BC = L \operatorname{Sinh} x.$$

On these principles, angles can be brought to the centre; but with some trouble [see Fig. 6].

additional rotation with the same centre. Then, a composite homothety is equivalent to a simple homothety followed by a rotation. Direct similarities and homotheties are different names for the same transformations (exercise 7.5). Also homotheties with $|k|=1$ and displacements are equivalent.

The *single ratio of three points A*, *B*, and *C* is defined as:

$$(A\ \ B\ \ C) = AB\, AC^{-1}$$

The single ratio is a real number when the three points are aligned, and a complex number in the other case. Under a homothety, the single ratio of any three points remains invariant. Let us prove this. Because any vector is dilated and rotated by a factor *k*, we have:

$$A'B' = OB' - OA' = OB\,k - OA\,k = AB\,k$$

$$A'C' = AC\ k \qquad \Rightarrow \qquad A'C'^{\,-1} = k^{-1}\,AC^{-1}$$

$$(A'\ \ B'\ \ C') = AB\,k\,k^{-1}\,AC^{-1} = AB\,AC^{-1} = (A\ \ B\ \ C)$$

If the single ratio is invariant for a geometric transformation, then it transforms triangles into directly similar triangles and hence also polygons into similar polygons:

$$(A\ \ B\ \ C) = (A'\ \ B'\ \ C') \qquad \Rightarrow \quad AB\,AC^{-1} = A'B'\,A'C'^{\,-1} \quad \Rightarrow AC^{-1}\,A'C' = AB^{-1}\,A'B'$$

Therefore, the homothety always transforms triangles into directly similar triangles as shown in the figure 7.6. It follows immediately that the homothety preserves the angles between lines. It is the simplest case of *conformal* transformations, the geometric transformations which preserve the angles between lines. Since a line may also be transformed into a curve, and for the general case a curve into a curve, the conformal transformations are those which preserve the angle between any pair of curves, that is, the angle between the tangent lines to both curves at the intersection point. A transformation is *directly* or *oppositely conformal* whether it preserves or changes the sense of the angle between two curves (figure 7.7). This condition is equivalent to the conservation of the single ratio of any three points at the limit of accumulation:

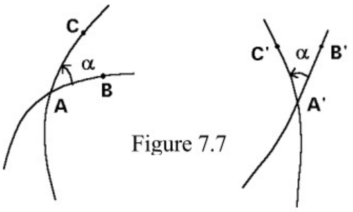

Figure 7.7

$$\lim_{B,C\to A} (A\,B\,C) = \lim_{B',C'\to A'} (A'\,B'\,C') \qquad \text{directly conformal}$$

$$\lim_{B,C\to A} (A\,B\,C) = \lim_{B',C'\to A'} (A'\,B'\,C')^{*} \qquad \text{oppositely conformal}$$

( )

$$N = \frac{1}{2}\left(\frac{P+H}{2}\right) + \frac{1}{2}\left(\frac{Q+R}{2}\right)$$

it follows that (*P*+*H*)/2 and (*Q*+*R*)/2 are opposite extremes of the same diameter. Then the vectors *J*–(*P*+*H*)/2 and *J*–(*Q*+*R*)/2, which are orthogonal:

$$\left(J - \frac{P+H}{2}\right) \cdot \left(J - \frac{Q+R}{2}\right) = 0$$

are the sides of a right angle which intercepts a half circumference of the nine point circle. Therefore, this angle is inscribed and its vertex *J* also lies on the nine-point circle. Also, we may go through the algebraic way to arrive at the same conclusion. Developing the former inner product:

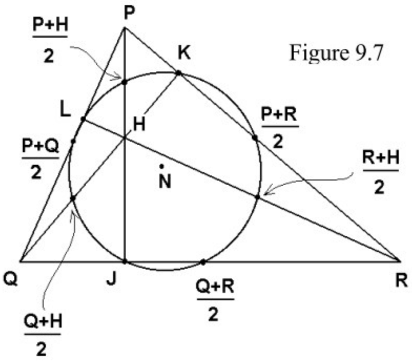

Figure 9.7

$$J^2 - J \cdot \frac{Q+R}{2} - \frac{P+H}{2} \cdot J + \frac{P+H}{2} \cdot \frac{Q+R}{2} = 0$$

Introducing the centre *N* of the nine-point circle, we have:

$$J^2 - 2J \cdot N + 2N \cdot \frac{Q+R}{2} - \left(\frac{Q+R}{2}\right)^2 = 0$$

and after adding and subtracting N^2 we arrive at:

$$(J-N)^2 - \left(\frac{Q+R}{2} - N\right)^2 = 0$$

which shows that the length of *JN* is the radius of the nine-point circle.

From the formulas for the centroid and orthocentre one obtains the centre *N* of the nine-point circle:

$$N = \frac{3G+H}{4} = (P\,QR\,P + Q\,RP\,Q + R\,PQ\,R)(4PQ \wedge QR)^{-1}$$

that is, the point *N* also lies on the Euler's line. The relative distances between the circumcentre *O*, the centroid *G*, the nine-point circle centre *N* and the orthocentre *H* are shown in the figure 9.8.

Figure 9.8

have:

$$A'C'\,A'D'^{-1} = (OC' - OA')\,(OD' - OA')^{-1} = (OC^{-1} - OA^{-1})\,(OD^{-1} - OA^{-1})^{-1}$$

$$= OC^{-1}\,(\,OA - OC\,)\,OA^{-1}\,[\,OD^{-1}\,(\,OA - OD\,)\,OA^{-1}\,]^{-1}$$

$$= OC^{-1}\,CA\,OA^{-1}\,[\,OD^{-1}\,DA\,OA^{-1}\,]^{-1} = OC^{-1}\,CA\,OA^{-1}\,OA\,DA^{-1}\,OD$$

$$= OC^{-1}\,AC\,AD^{-1}\,OD$$

Analogously we have:

$$B'D'\,B'C'^{-1} = OD^{-1}\,BD\,BC^{-1}\,OC$$

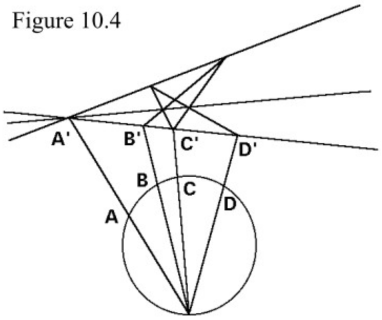
The product of both expressions is the cross ratio:

$$(\,A'\,B'\,C'\,D'\,) = A'C'\,A'D'^{-1}\,B'D'\,B'C'^{-1}$$

$$= OC^{-1}\,AC\,AD^{-1}\,BD\,BC^{-1}\,OC$$

$$= OC^{-1}\,(\,A\,B\,C\,D\,)\,OC = (\,A\,B\,C\,D\,)^*$$

Figure 10.4



So, the cross ratio of four points on a line or a circle, which is real, is preserved, otherwise it becomes conjugated.

Finally let us see that the single ratio is the limit of the cross ratio for one point at infinity:

$$(\,\infty\,B\,C\,D\,) = \lim_{A \to \infty} AC\;AD^{-1}\;BD\;BC^{-1} = BD\;BC^{-1} = (\,B\,D\,C\,)$$

Analogously $(\,A\,\infty\,C\,D\,) = (\,A\,C\,D\,)$, etc.

The homography (Möbius transformation)

The *homography* is defined as the geometric transformation that preserves the complex cross ratio of four points on the plane. In order to specify a homography one must gives only the images A', B' and C' of three points A, B, and C because the fourth image D' is determined by the conservation of their cross ratio:

$$(\,A'\,B'\,C'\,D'\,) = (\,A\,B\,C\,D\,)$$

$$A'C'\,A'D'^{-1}\,B'D'\,B'C'^{-1} = AC\,AD^{-1}\,BD\,BC^{-1}$$

Arranging vectors we write:

$$A'D'^{-1}\,B'D' = A'C'^{-1}\,AC\,AD^{-1}\,BD\,BC^{-1}\,B'C' = A'C'^{-1}\,AC\;\;BC^{-1}\,B'C'\,AD^{-1}\,BD$$

After conjugation we find:

11. CONICS

Conic sections

The *conic sections* (or *conics*) are the intersections of a conic surface with any transversal plane (figure 11.1). The *proper conics* are the curves obtained with a plane not passing through the vertex of the cone. If the plane contains the vertex we have improper conics, which reduce to a pair of straight lines or a point. In general, I shall regard only proper conics, taking into account that the other case can be usually obtained as a limit case.

Let us consider the two spheres inscribed in the cone which are tangent to the plane of the conic. The spheres touch this plane at the points F and F', the *foci* of the conic section. On the other hand, both spheres touch the cone surface at two tangency circles lying in planes perpendicular to the cone axis. The *directrices* of the conic are defined as the intersections of these planes with the plane of the conic.

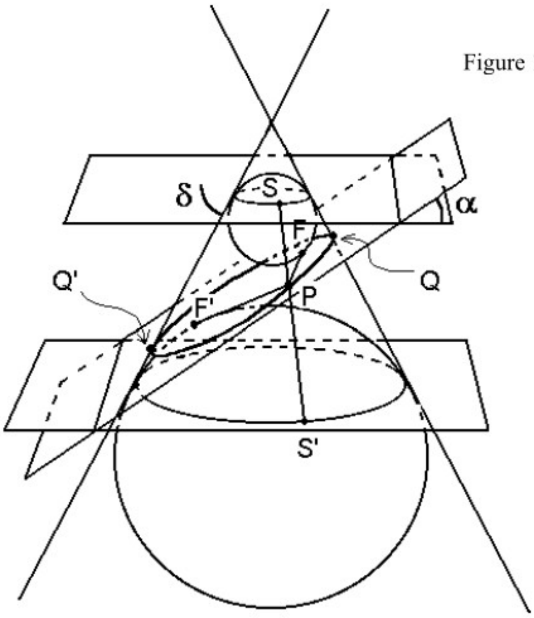


Figure 11.1

Let P be a point on the conic. Since it lies on the plane of the conic, the segment going from P to the focus F is tangent to the sphere. Since it belongs to the cone surface, the generatrix passing through P is also tangent to the sphere. PF and PS are tangent to the same sphere so that their lengths are equal: $|PF| = |PS|$. Also PF' and PS' are tangent to the other sphere so that their lengths are also equal: $|PF'| = |PS'|$. On the other hand the segment SS' of any directrix has constant length, what implies that the addition of distances from any point P on the conic to both foci is constant:

$$|PF|+|PF'|=|PS|+|PS'|=|SS'|=\text{constant}$$

This discussion slightly changes for a plane which intercepts the upper and lower cones. In this case, the distances from *P* to the upper sphere and to the upper branch of the curve must be considered negative[1]. If the plane is parallel to a generatrix of the cone these distances become infinite. This unified point of view for all conics using negative or infinite distances when needed will be the guide of this chapter. I shall not separate equations but only specify cases for distinct conics.

A lateral view of figure 11.1 is given in the figure 11.2. In this figure the point *P* has been drawn in both extremes of the conic (and *S* and *S'* also twice), although we must consider any point on the conic section. As indicated previously $|PF|=|PS|$. But $|PS|$ is proportional to the distance from *P* to the upper plane containing *S* and this distance is also proportional to the distance from *P* to the directrix *r* (figure 11.2):

$$|PF|=|PS|=\frac{\sin\alpha}{\sin\delta}\,\mathrm{d}(P,r)$$

The quotient of the sines of both angles is called the *eccentricity* e of the conic:

$$\mathrm{e}=\frac{\sin\alpha}{\sin\delta}>0$$

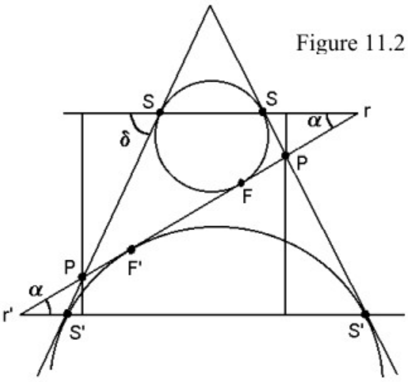

Figure 11.2

Then a conic can be also defined as the geometric locus of the points *P* whose distance from the focus *F* is proportional to the distance from the directrix *r* (figure 11.3).

$$|FP|=\mathrm{e}\,\mathrm{d}(P,r)$$

$|FP|$ is called the *focal radius*. Let *T* be the point of the directrix closest to the focus (figure 11.3). Then the *main axis of symmetry* of the conic is the line which is perpendicular to the directrix and passes through the focus. Under a reflection with respect the main axis of symmetry, the conic is preserved. The oriented distance from any point *P* to the directrix *r* is expressed, using the vector *FT*, as:

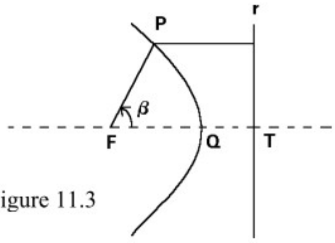

Figure 11.3

---

[1] To consider sensed distances is not a trouble but an advantage. For example, the distance from a point to a line can be also taken as an oriented distance, whose sign indicates the half-plane where the point lies.

$$\mathrm{d}(P,r)=\frac{FT\cdot PT}{|FT|}$$

Defined in this way, the distance from P to r is positive when P is placed on the half-plane that contains the focus of both in which the directrix divides the plane, and negative when P lies on the other half-plane. The equation of the conic becomes:

$$|FP|=\mathrm{e}\,\mathrm{d}(P,r)=\mathrm{e}\frac{FT\cdot PT}{|FT|}$$
$$|FP|\;|FT|=\mathrm{e}\,FT\cdot PT=\mathrm{e}\,FT\cdot(FT-FP)=\mathrm{e}\left(FT^2-FT\cdot FP\right)$$

Let us denote by β the angle between the main axis FT and the focal vector FP:

$$|FP|\;|FT|=\mathrm{e}\left(FT^2-|FT|\;|FP|\cos\beta\right)$$

$$|FP|\;|FT|\,(1+\mathrm{e}\;\cos\beta)=\mathrm{e}\,FT^2$$

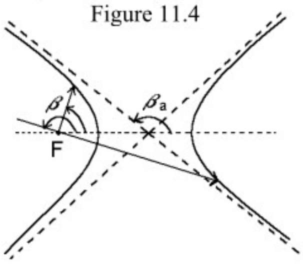
From here one obtains the *polar equation* of a conic:

$$|FP|=\frac{|FT|}{1+\mathrm{e}\;\cos\beta}$$

According to the value of the eccentricity there are three types of proper conics:

1) For $0<\mathrm{e}<1$, the inclination α of the plane of the conic is lower than the inclination δ of the cone generatrix and the denominator is always positive. Then the focal radius is always positive and the points P form a closed curve on the focal half-plane, an *ellipse*.
2) For $\mathrm{e}=1$, $\alpha=\delta$, the plane of the conic is parallel to a cone generatrix. Since the denominator vanishes for $\beta=\pi$, the points P form an open curve called *parabola*. Except for this value of β, the radius is always positive and the curve lies on the focal half-plane.
3) For $\mathrm{e}>1$, $\alpha>\delta$, the plane of the conic intercepts both upper and lower cones. The denominator vanishes twice so that it is an open curve with two branches called *hyperbola* (figure 11.4). The lowest positive angle that makes the denominator zero is the asymptote angle β_a:

Figure 11.4



$$\beta_a=\arccos\left(-\frac{1}{\mathrm{e}}\right)$$

The maximum eccentricity of the hyperbolas as cone sections is obtained with $\alpha=\pi/2$:

$$1 < \mathrm{e} \le \frac{1}{\sin\delta}$$

The focal radius is positive (P lies on the focal branch) for the ranges of β:

$$0 < \beta < \beta_a \qquad \text{and} \qquad 2\pi - \beta_a < \beta < 2\pi$$

and negative (P lies on the non focal branch) for the range:

$$\beta_a < \beta < 2\pi - \beta_a$$

A negative focal radius means that we must take the sense opposite that determined by the angle (figure 11.4). For example, a radius –2 with an angle $7\pi/6$ is equivalent to a radius 2 with an angle of $\pi/6$. So the vertex T' of the non focal branch has an angle π (not zero as it would appear) and a negative focal radius.

Two foci and two directrices

Figure 11.5

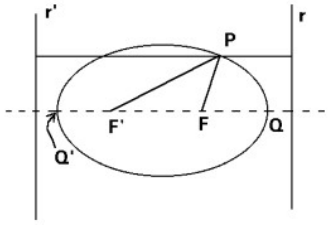


Figure 11.6

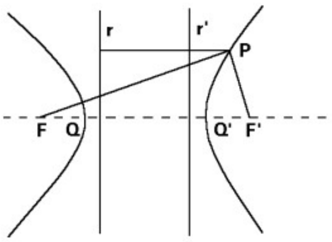

There are usually two spheres touching the cone surface and the conic plane, and hence there are also two foci. For the case of the ellipse, both tangent spheres are located in the same cone. For the case of the hyperbola, each sphere is placed in each cone so that each focus is placed next to each branch. In the case of the parabola, one sphere and the corresponding focus is placed at the infinity. For the improper conics, the tangent spheres have null radius and the foci are coincident with the vertex of the cone, which is the crossing point of both lines.

As the figure 11.1 shows for a proper conic, both directrices r and r' are parallel, and both foci F and F' are located on the axis of symmetry of the conic. Above we have already seen that the addition of oriented distances from both foci to any point P is constant. Let us see the relation with the distance between the directrices. If P is any point on the conic then:

$$|FP| + |F'P| = \mathrm{e}\,\mathrm{d}(P,r) + \mathrm{e}\,\mathrm{d}(P,r') = \mathrm{e}\,\mathrm{d}(r,r')$$

The sum of the oriented distances from any point P to any two parallel lines (the directrices in our case) is constant[2]. Then the addition of both focal radii of any point P

---

[2] Note that this statement is only right for oriented distances but not for positive distances.

on the conic is the product of the eccentricity multiplied by the oriented distance between both directrices. P can be any point, for example Q, the extreme of the conic:

$$|FP|+|F'P|=|FQ|+|F'Q|=|F'Q'|+|F'Q|=|QQ'|$$

whence it follows that the addition of both focal radii is $|QQ'|$, the *major diameter*. Specifying:

1) For the case of the ellipse (figure 11.5), both focal radii are positive and also the major diameter.
2) For the case of the parabola, one directrix is the line at the infinity and one focus is a point at the infinity on the main axis of symmetry. Hence the major diameter has an infinite value.
3) For the case of the hyperbola (figure 11.6), the focal radius of a point on the non focal branch is negative, its absolute value being higher than the other focal radius, which is positive, yielding a negative major diameter.

Vectorial equation

The polar equation of a conic may be written having as parameter the *focal distance* $|FQ|$ instead of the distance from the focus to the directrix $|FT|$:

$$|FP|=\frac{1+\mathrm{e}}{1+\mathrm{e}\ \cos\beta}|FQ|$$

Let Q' be the vertex of the conic closest to the focus F'. The distance from the focus F to Q' is found for $\beta=\pi$:

$$|FQ'|=\frac{1+\mathrm{e}}{1-\mathrm{e}}|FQ|$$

For the ellipse $|FQ'|$ is a positive distance; for the hyperbola it is a negative distance and for the parabola Q' is at infinity. Then the distance between both foci is:

$$|FF'|=|FQ'|-|F'Q'|=|FQ'|-|FQ|=\frac{2\ \mathrm{e}}{1-\mathrm{e}}|FQ|$$

On the other hand the major diameter is:

$$|QQ'|=|FQ|+|FQ'|=\frac{2|FQ|}{1-\mathrm{e}}$$

By dividing both equations, an alternative definition of the eccentricity is obtained:

$$\mathrm{e}=\frac{|FF'|}{|QQ'|}$$

The eccentricity is the ratio of the distance between both foci divided by the major diameter. For the case of ellipse, both distances are positive. For the case of the hyperbola, both distances are negative, so the eccentricity is always positive. When e = 0 both foci are coincident in the centre of a circle. Note that the circle is obtained when we cut the cone with a horizontal plane. In this case, the directrices are the line at the infinity.

The *vectorial equation* of a conic is obtained from the polar equation and contains the radius vector FP. Since FP forms with FQ an angle β (figure 11.3), FP is obtained from the unitary vector of FQ via multiplication by the exponential with argument β and by the modulus of FP yielding:

$$FP = \frac{1+\mathrm{e}}{1+\mathrm{e}\cos\beta} FQ\left(\cos\beta + e_{12}\sin\beta\right)$$

On the other hand, from the directrix property, one easily finds the following equation for a conic:

$$FP^2\, FT^2 = \mathrm{e}^2\,(\, FT^2 - FT \cdot FP\,)^2$$

F, T and e are parameters of the conic, and $P = (x, y)$ is the mobile point. Therefore from this equation we will also obtain a Cartesian equation of second degree. For example, let us calculate the Cartesian equation of an ellipse with eccentricity ½ and focus at the point (3, 4) and vertex at (4,5):

$$\mathrm{e} = 1/2 \qquad F = (\,3, 4\,) \qquad Q = (\,4, 5\,) \qquad P = (\,x, y\,)$$

$$FT = \frac{1+\mathrm{e}}{\mathrm{e}} FQ = 3\,e_1 + 3\,e_2 \qquad T = F + FT = (\,6, 7\,)$$

$$FP = (\,x-3\,)\,e_1 + (\,y-4\,)\,e_2$$

Then the equation of the conic is:

$$[\,(\,x-3\,)^2 + (\,y-4\,)^2\,]\,18 = \frac{1}{4}[\,18 - (\,3\,(x-3) + 3\,(\,y-4\,)\,)\,]^2$$

After simplification:

$$7\,x^2 - 2\,x\,y + 7\,y^2 - 22\,x - 38\,y + 31 = 0$$

The Chasles' theorem

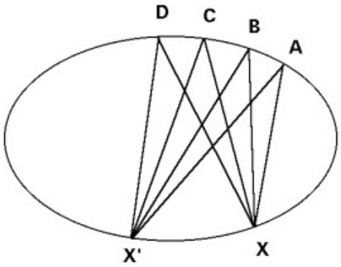

Figure 11.7

According to this theorem[3], the projective cross ratio of any four given points A, B, C and D on a conic with respect to a point X also on this conic is constant independently of the choice of

---

[3] Michel Chasles, *Traité des sections coniques*, Gauthier-Villars, Paris, 1865, p. 3.

("

sector, the modulus of the hyperbolic radius is imaginary. The abscissa x and ordinate y divided by r, the modulus of the radius vector, is also imaginary so the angle is a real quantity plus a right angle and the hyperbolic sine and cosine are exchanged. The values of the angles consistent with the analytic continuation are displayed in the figure 13.1.

Congruence of segments and angles

Two segments (vectors) are *congruent* (have *equal length*) if their determinants are equal, in other words, when one segment can be obtained from the other through an isometry. Segments having equal length always lie on the same sector.

Two hyperbolic angles are said to be *congruent* (or *equal*) if they have the same moduli, that is, if they intercept arcs of hyperbola with the same hyperbolic length.

A triangle is said to be *isosceles* if it has two congruent sides. In colloquial language we talk about "sides with equal length", even "equal sides". Let us see the *isosceles triangle theorem*: the angles adjacent to the base of an isosceles triangle are equal. The proof uses the outer product. The triangle area is the half of the outer product of any two sides, as proved below in the section on the area. Suppose that the sides a and b have the same modulus. Then:

$$|a|\,|c|\,|\sinh\beta| = |b|\,|c|\,|\sinh\alpha| \qquad \Rightarrow \qquad |\beta| = |\alpha|$$

Isometries

In the Euclidean plane, an isometry is a geometric transformation that preserves the modulus of vectors and complex numbers. Now I give a more general definition: a geometric transformation is an *isometry* if it preserves the determinant of every element of the geometric algebra. In fact, the isometries are the inner automorphism of matrices:

$$\mathbf{A'} = \mathbf{B}^{-1}\,\mathbf{A}\,\mathbf{B} \Rightarrow \qquad \det \mathbf{A'} = \det \mathbf{A}$$

When **B** represents a Euclidean vector, the isometry is a reflection in the direction of **B**. If a complex number of argument α is represented by **B**, the transformation is a rotation of angle 2α.

We wish now to obtain the isometries for hyperbolic vectors. The hyperbolic rotation of a hyperbolic vector (figure 13.2) is obtained through the product by an exponential having unity determinant:

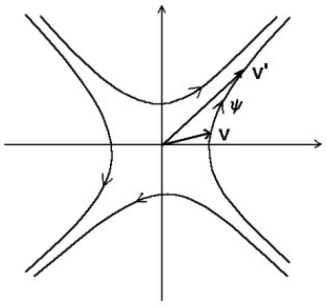

Figure 13.2

$$v'_2 e_2 + v'_{21}\, e_{21} = (v_2 e_2 + v_{21}\, e_{21})(\cosh\psi + \sinh\psi\, e_1)$$

Writing the components, we have:

$$\begin{cases} v'_2 = v_2 \cosh\psi + v_{21}\sinh\psi \\ v'_{21} = v_2 \sinh\psi + v_{21}\cosh\psi \end{cases}$$

which is the Lorentz transformation[3] of the relativity. When a vector is turned through a positive angle ψ, its extreme follows the hyperbola in the direction shown by the arrowheads in the figure 13.2, as is deduced from the components. So, they indicate the geometric positive sense of hyperbolic angles (a not trivial question). Since the points of intersections with the axis corresponds to $\psi = 0$ plus multiples of $\pi\, e_{12}/2$, the signs of the hyperbolic angles are determined: positive in the first and third quadrant, and negative in the second and fourth quadrant.

We can also write the hyperbolic rotation as an inner automorphism of matrices by using the half argument identity for hyperbolic trigonometric functions:

$$\cosh\psi + e_1 \sinh\psi \equiv \left(\cosh\frac{\psi}{2} + e_1 \sinh\frac{\psi}{2} \right)^2$$

and the permutative property:

$$v'_2 e_2 + v'_{21}\, e_{21} = \left(\cosh\frac{\psi}{2} - \sinh\frac{\psi}{2} e_1 \right)(v_2 e_2 + v_{21}\, e_{21})\left(\cosh\frac{\psi}{2} + \sinh\frac{\psi}{2} e_1 \right)$$

If $z = \exp(e_1 \psi/2)$, then the rotation is written as:

$$v' = z^{-1}\, v\, z$$

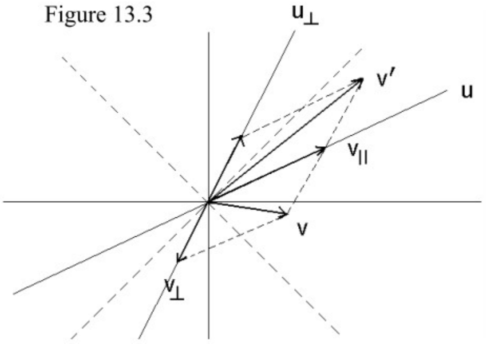
Now it is not needed that z be unitary and can have any modulus. Also, we see that the hyperbolic rotation leaves the hyperbolic numbers invariant.

Analogously to reflections in the Euclidean plane, the hyperbolic reflection of a hyperbolic vector v with respect to a direction given by the vector u is:

$$v' = u^{-1}\, v\, u = u^{-1}\, (\, v_{\|} + v_{\perp})\, u = v_{\|} - v_{\perp}$$

because the proportional vectors commute and those which are orthogonal anticommute (also in the hyperbolic case, because the inner product is zero). Every pair of orthogonal directions (for example $u_{\|}$ and $u_{\perp}$ in figure 13.3) are always seen by us as having symmetry with respect to the quadrant bisectors. Since the determinant is preserved, a vector and its reflection always belong to the same sector, the hyperbolic angle between each vector and the direction of reflection being equal with opposite sign.

Figure 13.3



---

[3] The hyperbolic vector in the space-time is $ct\, e_0 + x\, e_1$ where x is the space coordinate, t the time and c the light celerity. The argument of the hyperbolic rotation ψ is related with the relative velocity V of both frames of reference through $\psi = \text{arg tgh } V/c$.

Finally, note that the extremes of a vector and its transformed vector under a hyperbolic reflection (or any isometry) lie on an equilateral hyperbola.

Theorems about angles

The sum of the oriented angles of a hyperbolic triangle is minus two right circular angles. To prove this theorem, draw a line parallel to a side and apply the Z-theorem (figure 13.4): they will form an angle between opposite directions, which has the value $-\pi\ e_{12}$. The minus sign is caused by the fact that, following the positive orientation of angles, a right angle is subtracted each time an asymptote is trespassed.

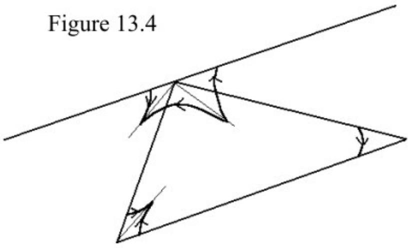


Figure 13.4

Look at the figure 13.5 where an angle inscribed in an equilateral hyperbola is drawn. A diameter divides the inscribed angle into the angles α and β. Then we draw two radius from the origin to both extremes of the angle. All the radius have the same length, so that the upper and lowest triangle are isosceles and have two equal angles. Since the sum of the angles of each hyperbolic triangle is $-\pi\ e_{12}$, the third angle is $-\pi\ e_{12}-2\alpha$ and $-\pi\ e_{12}-2\beta$ respectively. So the supplementary angles are 2α and 2β, and hence the theorem follows: the inscribed angle on a hyperbola $x^2 - y^2 = r^2$ is the half of the central angle (intercepted arc) so that it is constant and independent of the location of its vertex.

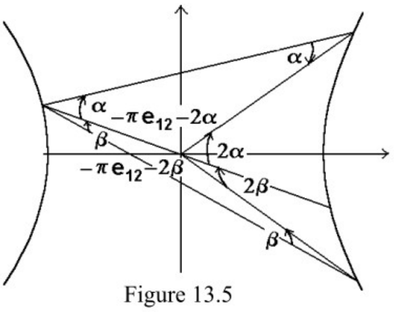

Figure 13.5

For example, take the points (5, 3) and (5, −3) as extremes of an inscribed angle with the vertex placed at the negative branch, for example at (−4, 0) or (−5, −3). Even you can take the vertex at the positive branch, e. g. at (4, 0). Anyway its value is log 2. Now calculate the central angle or intercepted arc (with vertex at the origin) and see that its value is log 4, twice the inscribed angle.

Distance between points

The *distance between two points* on the hyperbolic plane is defined as the modulus of the vector going from one point to the another:

$$d(P,Q) = |\,PQ\,| = \sqrt{(x_Q - x_P)^2 - (y_Q - y_P)^2}$$

In the hyperbolic plane, the distance is a real or imaginary positive number (depending on the sector), which has the following properties:

1) $d(P,Q) = d(Q,P)$
2) If the vectors *PQ*, *QR* and *PR* lie on the positive half sector then they fulfil the triangular inequality:

$$d(P,R) \geq d(P,Q) + d(Q,R)$$

The prove is obtained by means of the inner product:

$$PR^2 = (PQ + QR)^2 = PQ^2 + QR^2 + 2\, PQ \cdot QR$$

$$= PQ^2 + QR^2 + 2\,|\,PQ\,|\,|\,QR\,|\cosh\psi \geq PQ^2 + QR^2 + 2\,|\,PQ\,|\,|\,QR\,|$$

The extraction of the square root yields the triangular inequality:

$$|\,PR\,| \geq |\,PQ\,| + |\,QR\,|$$

So the sum of two sides of a triangle is smaller than the third side whenever they are taken in the positive half sector. For example, let us apply this statement to the triangle with vertices *A* = (5, 3), *B* = (1, 0) and *C* = (10, 1). Taking the modulus of the sides positive, we have:

$$|\,BC\,| = \sqrt{80} \qquad |\,BA\,| = \sqrt{7} \qquad |\,AC\,| = \sqrt{21}$$

$$|\,BC\,| \geq |\,BA\,| + |\,AC\,| \qquad \Rightarrow \qquad \sqrt{80} \geq \sqrt{7} + \sqrt{21}$$

This result must be commented with more detail. Firstly, we see that the straight path has the highest length among the possible paths between two given points. In the Minkowski's space-time this fact causes the *twin paradox*. Since the pseudo-Euclidean length of the path is the proper time for each person, the brother who followed the straight path -going in an inertial frame- has aged more than the brother who followed another path -subjected to accelerations-.

Area on the hyperbolic plane

Now I give a general geometric definition of area valid for both Euclidean and hyperbolic planes. If a parallelogram has orthogonal sides, then the modulus of its *area* is equal to the product of the lengths of the orthogonal sides. In Euclidean geometry a parallelogram with orthogonal sides is called a *rectangle*. In the hyperbolic plane, two sides are orthogonal if their directions are seen by us as symmetric with respect to the direction of the quadrant bisector. So, I have preferred to avoid the word *rectangle* in this case, while the term *parallelogram* is still valid within this context.

Which is the suitable algebraic expression to calculate the area of any parallelogram? Suppose that it is the outer product. If a and b are the sides of the parallelogram then:

$$|A| = |a \wedge b| = |a||b||\sinh\psi(a,b)|$$

Let us see the consistence of this expression. First at all, recall that the angle between orthogonal hyperbolic vectors is a right circular angle:

$$\psi_{\perp} = \pm\frac{\pi}{2}e_{12}$$

so that the area of a parallelogram with orthogonal sides is the product of their lengths as expected:

$$|A| = |a||b|\left|\sinh\left(\pm\frac{\pi}{2}e_{12}\right)\right| = |a||b|\sin\frac{\pi}{2} = |a||b|$$

For any parallelogram not having orthogonal sides, the area is the product of the *base* (one side) for the *altitude* (the projection of the other side onto the direction orthogonal to the base) and this product is only given by the outer product because its anticommutativity removes the proportional projection:

$$|A| = |a \wedge b| = |(a_{\parallel} + a_{\perp}) \wedge b| = |a_{\perp}||b|$$

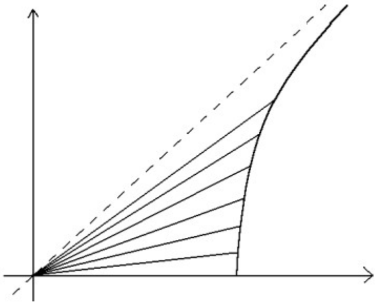

Figure 13.6

The expression for the area in Cartesian components is equal to that for the Euclidean plane. It means that we can calculate areas graphically in the usual way, fact that has allowed till now to define the hyperbolic trigonometric functions from the area scanned by the hyperbola radius in the Euclidean plane, in spite of not being their proper plane. However, as I have explained in the footnote at the page 142, we must perceive the pseudo-Euclidean nature of the area in the hyperbolic plane. The figure 13.6 displays how are the radii perpendicular to the hyperbola because the bisector of the radius and the tangent vector is parallel to the quadrant bisector. Also it may be proved analytically by means of differentiation of the equation $x^2 - y^2 = r^2$:

$$2\,x\,dx - 2\,y\,dy = 0 \quad \Leftrightarrow \quad r \cdot dr = 0$$

showing that the radius vector and its differential are orthogonal for the hyperbola with constant radius. On the other hand, observe that the triangles drawn in the figure 13.6 are isosceles and have two equal angles approaching the right angle value at the limit of null area.

Diameters of the hyperbola and Apollonius' theorem

At the page 129, I postponed an interpretation of the central equation for the hyperbola analogous to the cylindrical angles for the ellipse because it is properly of pseudo-Euclidean nature. Here I develop this interpretation.

If *P* is any point on a hyperbola with major and minor half-axis *OQ* and *OS* (figure 11.17 reproduced below) then its central equation is:

$$OP = \pm \frac{OQ \cosh\chi + OS \dfrac{\sinh\chi}{\sqrt{e^2-1}}}{\sqrt{\cosh^2\chi - \dfrac{\sinh^2\chi}{e^2-1}}}$$

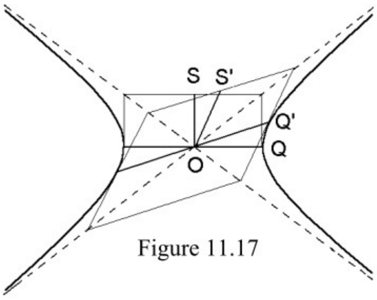

Figure 11.17

Since *OQ* and *OS* are orthogonal, the square of this equation fulfils:

$$\frac{OP^2}{OQ^2}\cosh^2\chi + \frac{OP^2}{OS^2}\sinh^2\chi = 1$$

Both half-axis are related with the eccentricity through:

$$OS^2 = \left(1-e^2\right)OQ^2$$

Note that $OS^2<0$ since it is the square of an ordinate on the hyperbolic plane.

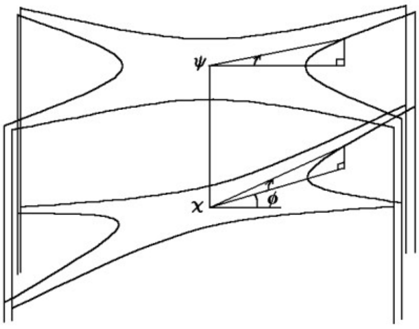
Introducing the hyperbolic angle ψ in the following way:

$$\cosh\psi = \frac{\cosh\chi}{\sqrt{\cosh^2\chi - \dfrac{\sinh^2\chi}{e^2-1}}}$$

now the equation of the hyperbola becomes:

$$OP = \pm\left(OQ\cosh\psi + OS\sinh\psi\right)$$

Figure 13.7



Observe in the figure 13.7 that any hyperbola can be obtained as an intersection of a transverse plane with the equilateral hyperbolic prism. The plane of the acute hyperbola (with $1<e<\sqrt{2}$) forms an angle ϕ with respect to the horizontal, and hence:

$$\cosh\psi = \frac{\cosh\chi\cos\phi}{\sqrt{\cosh^2\chi\cos^2\phi - \sinh^2\chi}}$$

So the eccentricity e of the hyperbola is related with the obliquity ϕ of the transverse plane through the relationship:

$$\cos\phi = \sqrt{\mathrm{e}^2 - 1} \quad \text{with} \quad 1 < \mathrm{e} < \sqrt{2}$$

The Apollonius' conjugate diameters of any hyperbola are the intersections of the transverse plane with a pair of orthogonal axial planes; in other words, two radii are conjugate (figure 11.17) if their projections onto the horizontal plane are turned through the same hyperbolic angle φ:

$$OQ' = OQ\cosh\varphi + OS\sinh\varphi$$

$$OS' = OQ\sinh\varphi + OS\cosh\varphi$$

Our Euclidean eyes see the horizontal projections as symmetric lines with respect to the quadrant bisector. However, they are actually orthogonal because:

$$OQ'^2 - OS'^2 = OQ^2 - OS^2$$

and, therefore, can be taken as a new system of orthogonal coordinates. Even we can draw a new picture with the new diameters on the Cartesian axis.

The central equation of the hyperbola using the rotated axis is:

$$OP = \pm\left(OQ'\cosh(\psi - \varphi) + OS'\sinh(\psi - \varphi)\right)$$

which shows that a hyperbolic rotation of the coordinate axis has been made with respect to the principal diameter of the hyperbola.

The law of sines and cosines

Since the modulus of the area is identical on the Euclidean and hyperbolic planes, a parallelogram is divided by its diagonal in two triangles of equal area. This statement is somewhat subtle since the Euclidean congruence of triangles is not valid in the hyperbolic plane. I shall return to this question later. Now we only need to know that the area of a hyperbolic triangle is the half of the outer product of any two sides.

Following the perimeter of a triangle, let *a*, *b*, and *c* be its sides respectively opposite to the angles α, β and γ. Then the angles formed by the oriented sides are supplementary of the angles of the triangle and:

$$a \wedge b = b \wedge c = c \wedge a \;\Rightarrow\; -|\,a\,|\,|\,b\,|\sinh\gamma = -|\,b\,|\,|\,c\,|\sinh\alpha = -|\,c\,|\,|\,a\,|\sinh\beta$$

$$\frac{|\,a\,|}{\sinh\alpha} = \frac{|\,b\,|}{\sinh\beta} = \frac{|\,c\,|}{\sinh\gamma}$$

which is the *law of sines*.

From $a + b + c = 0$, we have:

$$a^2 = (-b-c)^2 = b^2 + c^2 + 2\, b\cdot c \qquad \Rightarrow \qquad a^2 = b^2 + c^2 - 2\,|\,b\,|\,|\,c\,|\cosh\alpha$$

which is the *law of cosines*. And also:

$$b^2 = a^2 + c^2 - 2\,|\,a\,|\,|\,c\,|\cosh\beta$$

$$c^2 = a^2 + b^2 - 2\,|\,a\,|\,|\,b\,|\cosh\gamma$$

When applying both theorems, we must take care with the sides having imaginary length and the signs of the angles and trigonometric functions.

As an application of the law of sines and cosines, consider the hyperbolic triangle with vertices *A*=(5, 3), *B*=(1, 0), *C*=(10, 1), whose sides belong to the real sector (figure 13.8):

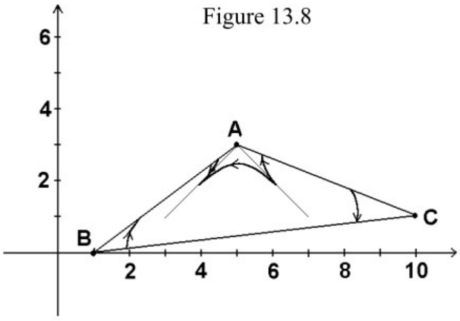


Figure 13.8

$$AB = B - A = -4\,e_2 - 3\,e_{21} \qquad |\,AB\,| = \sqrt{(-4)^2 - (-3)^2} = \sqrt{7}$$

$$BC = C - B = 9\,e_2 + e_{21} \qquad |\,BC\,| = \sqrt{9^2 - 1^2} = \sqrt{80}$$

$$CA = A - C = -5\,e_2 + 2\,e_{21} \qquad |\,CA\,| = \sqrt{(-5)^2 - 2^2} = \sqrt{21}$$

$$BC^2 = CA^2 + AB^2 - 2\,|\,CA\,|\,|\,AB\,|\cosh\alpha \qquad \cosh\alpha = -\frac{26}{7\sqrt{3}}$$

$$CA^2 = AB^2 + BC^2 - 2\,|\,AB\,|\,|\,BC\,|\cosh\beta \qquad \cosh\beta = \frac{33}{4\sqrt{35}}$$

$$AB^2 = BC^2 + CA^2 - 2\,|\,BC\,|\,|\,CA\,|\cosh\gamma \qquad \cosh\gamma = \frac{47}{4\sqrt{105}}$$

From where it follows that:

$$\alpha = -1.3966\ldots - \pi\, e_{12} \qquad \beta = 0.8614\ldots \qquad \gamma = 0.5352\ldots$$

I have obtained their signs from the definition of the angles $\alpha = BAC$, $\beta = CBA$, $\gamma = ACB$ and the geometric plot (figure 13.8). Note that $\alpha + \beta + \gamma = -\pi\, e_{12}$ and they fulfil the law of sines:

$$\frac{|\,BC\,|}{\sinh\alpha} = \frac{|\,CA\,|}{\sinh\beta} = \frac{|\,AB\,|}{\sinh\gamma}$$

because $\sinh\alpha = \sinh(-1.3966+\pi e_{12}) = -\sinh(-1.3966) = \sinh 1.3966$.

Consider now another triangle $A = (2, 4)$, $B = (1,0)$ and $C = (6, 1)$, having sides on real and imaginary sectors (figure 13.9):

$$AB = B - A = -e_2 - 4\, e_{21}$$

$$|\,AB\,| = \sqrt{(-1)^2 - (-4)^2} = \sqrt{15}\; e_{12}$$

$$BC = C - B = 5\, e_2 + e_{21}$$

$$|\,BC\,| = \sqrt{5^2 - 1^2} = \sqrt{24}$$

$$CA = A - C = -4\, e_2 + 3\, e_{21}$$

$$|\,CA\,| = \sqrt{(-4)^2 - 3^2} = \sqrt{7}$$

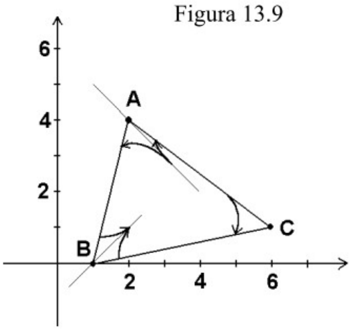

Figura 13.9

$$BC^2 = CA^2 + AB^2 - 2\,|\,CA\,|\,|\,AB\,|\cosh\alpha \qquad \cosh\alpha = \frac{16\, e_{12}}{\sqrt{105}}$$

$$CA^2 = AB^2 + BC^2 - 2\,|\,AB\,|\,|\,BC\,|\cosh\beta \qquad \cosh\beta = \frac{-\,e_{12}}{6\sqrt{10}}$$

$$AB^2 = BC^2 + CA^2 - 2\,|\,BC\,|\,|\,CA\,|\cosh\gamma \qquad \cosh\gamma = \frac{23}{2\sqrt{42}}$$

From the last hyperbolic cosine, which is real, we find the hyperbolic sine for γ, which is a positive angle as shown by the plot:

$$\sinh\gamma = \frac{19}{2\sqrt{42}}$$

which we may use in the law of sines:

$$\frac{\sqrt{24}}{\sinh\alpha} = \frac{\sqrt{7}}{\sinh\beta} = \frac{\sqrt{15}\, e_{12}}{19/2\sqrt{42}} \qquad \Rightarrow \qquad \sinh\alpha = -\frac{19\, e_{12}}{\sqrt{105}} \qquad \sinh\beta = -\frac{19\, e_{12}}{6\sqrt{10}}$$

Recalling that for ψ real:

$$\sinh\left(\psi \pm e_{12}\,\frac{\pi}{2}\right) \equiv \pm e_{12}\cosh\psi \qquad\qquad \cosh\left(\psi \pm e_{12}\,\frac{\pi}{2}\right) \equiv \pm e_{12}\sinh\psi$$

the angles α, β and γ follow:

$$\alpha = -1.2284... - \frac{\pi}{2} e_{12} \qquad \beta = 0.0527... - \frac{\pi}{2} e_{12} \qquad \gamma = 1.1757$$

Observe that the addition of the three angles is $-\pi\ e_{12}$, as expected. According to the definition $\alpha = BAC$, $\beta = CBA$, $\gamma = ACB$, let you see the consistence with the geometric plot. The angle γ has positive sign as shown by the figure 13.9. The bisector of α parallel to the quadrant bisector divides it in two angles, one real and the other complex (with imaginary part $\pi\ e_{12}\ /2$). The algebraic addition of both angles is α.. Taking into account that the second has opposite orientation and must be subtracted and predominates over the first, the negative value of α is explained.

Hyperbolic similarity

Two triangles ABC and $A'B'C'$ are said to be *directly similar*[4] and their vertices and sides denoted with the same letters are *homologous* if:

$$AB\ BC^{-1} = A'B'\ B'C'^{\ -1} \qquad \Rightarrow \qquad AB^{-1}\ A'B' = BC^{-1}\ B'C'$$

One can prove easily that the third quotient of homologous sides also coincides with the other quotients:

$$AB^{-1}\ A'B' = BC^{-1}\ B'C' = CA^{-1}\ C'A' = r$$

The *similarity ratio* r is defined as the quotient of every pair of homologous sides, which is a hyperbolic number. The modulus of the similarity ratio is the size ratio and the argument is the angle of rotation of the triangle $A'B'C'$ with respect to the triangle ABC.

$$r = \frac{|\,A'B'\,|}{|\,AB\,|} \exp\left[\alpha\left(AB, A'B'\right) e_1\right]$$

The definition of similarity is generalised to any pair of polygons in the following way. The polygons $ABC...Z$ and $A'B'C'...Z'$ are said to be directly similar with similarity ratio r and the sides denoted with the same letters to be homologous if:

$$r = AB^{-1}\ A'B' = BC^{-1}\ B'C' = CD^{-1}\ C'D' = ... = YZ^{-1}\ Y'Z' = ZA^{-1}\ Z'A'$$

Here also, the modulus of r is the size ratio of both polygons and the argument is the angle of rotation. The fact that the homologous exterior and interior angles are equal for directly similar polygons is trivial because:

$$B'A'\ B'C'^{\ -1} = BA\ BC^{-1} \qquad \Rightarrow \qquad \text{angle } A'B'C' = \text{angle } ABC$$

$$C'B'\ C'D'^{-1} = CB\ CD^{-1} \qquad \Rightarrow \qquad \text{angle } B'C'D' = \text{angle } BCD \qquad \text{etc.}$$

---

[4] A direct similarity is also called a *similitude* and an opposite similarity sometimes an *antisimilitude*.

The direct similarity is an equivalence relation since it has the reflexive, symmetric and transitive properties. This means that there are classes of equivalence with directly similar figures.

A similitude with $|r|=1$ is a *displacement*, since both polygons have the same size and orientation.

Two triangles *ABC* and *A'B'C'* are *oppositely similar* and the sides denoted with the same letters are *homologous* if:

$$AB\,BC^{-1} = (\,A'B'\,B'C'^{-1}\,)^{*} = B'C'^{-1}\,A'B'$$

where the asterisk denotes the hyperbolic conjugate. The former equality cannot be arranged into quotients of pairs of homologous sides as done before. Because of this, the similarity ratio cannot be defined for the opposite similarity but only the size ratio, which is the quotient of the lengths of any two homologous sides. An opposite similarity is always the composition of a reflection in any line and a direct similarity.

$$AB\,BC^{-1} = v^{-1}\,A'B'\,B'C'^{-1}\,v \quad\Leftrightarrow\quad BC^{-1}\,v^{-1}\,B'C' = AB^{-1}\,v^{-1}\,A'B' \quad\Leftrightarrow$$

$$BC^{-1}\,(\,v^{-1}\,B'C'\,v\,) = AB^{-1}\,(\,v^{-1}\,A'B'^{-1}\,v\,) = r$$

where *r* is the ratio of a direct similarity whose argument is not defined but depends on the direction vector *v* of the reflection axis. Notwithstanding, this expression allows to define the opposite similarity of two polygons. So two polygons *ABC...Z* and *A'B'C'...Z'* are oppositely similar and the sides denoted with the same letters are homologous if for any hyperbolic vector *v* the following equalities are fulfilled:

$$AB^{-1}\,(\,v^{-1}\,A'B'^{-1}\,v\,) = BC^{-1}\,(\,v^{-1}\,B'C'\,v\,) = \dots. = ZA^{-1}\,(\,v^{-1}\,Z'A'\,v\,)$$

that is, if after a reflection one polygon is directly similar to the other. The opposite similarity is not reflexive nor transitive and there are not classes of oppositely similar figures.

An opposite similarity with $|r|=1$ is called a *reversal*, since both polygons have the same size but opposite orientations.

Obviously the plot of similar figures on the hyperbolic plane breaks our Euclidean intuition about figures with the same form. The algebraic definition is very rigorous and clear, but we must change our visual illusions. So I recommend the exercise 13.6.

This chapter is necessarily unfinished because the geometry of the hyperbolic plane can be developed and studied with the same extension and profundity as for the Euclidean plane. Then, it is obvious that many theorems should follow in the same way as Euclidean geometry. As a last example I will define the power of a point with respect to a hyperbola.

Power of a point with respect to a hyperbola with constant radius

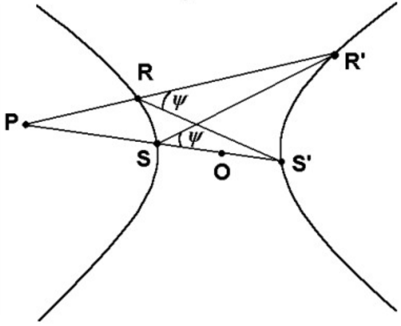
The locus of the points placed at a fixed distance *r* from a given point *O* is an equilateral hyperbola centred at this point with equation:

$$|OP| = r \qquad (x - x_O)^2 - (y - y_O)^2 = r^2$$

The *power of a point* with respect to this hyperbola is the product of both oriented distances from P to the intersections R and R' of a line passing through P with the hyperbola. The power of a point is constant for every line of the pencil of lines of P. In the proof the inscribed angle theorem is used (figure 13.10): the angles $S'RR'$ and $S'SR'$ are equal so the triangles SPR' and RPS' are oppositely similar. Then:

$$PR'\,PS^{-1} = PR^{-1}PS' \;\Rightarrow\; PR\,PR' = PS'\,PS$$

Figure 13.10



Developing the product of distances on the line passing through the centre of the hyperbola we find:

$$PS\,PS' = (PO + OS)(PO + OS') = PO^2 + OS\,OS' = (x_P - x_O)^2 - (y_P - y_O)^2 - r^2$$

that is, the power of a point is obtained by substitution of the coordinates of P on the hyperbola equation.

Exercises

13.1 Let $A = (2, 2)$, $B = (1, 0)$ and $C = (5, 3)$ be the vertices of a hyperbolic triangle. Calculate all the sides and angles and also the area.

13.2 Turn the vector $2\,e_2 + e_{21}$ through an angle $\psi = \log 2$. Do a reflection in the direction $3\,e_2 - e_{21}$. Make also an inversion with radius 3.

13.3 Find the direction and normal vectors of the line $y = 2\,x + 1$ and calculate the perpendicular line passing through the point (3, 1).

13.4 Calculate the power of the point $P = (-7, 3)$ with respect to the hyperbola $x^2 - y^2 = 16$ using the intersections of the lines $y = 3$, $y = -3x - 18$ and that passing through the centre of the hyperbola $y = -3x / 7$. See that in all cases the power of P is equal to the value found by substitution in the Cartesian equation.

13.5 In this chapter I have deduced the law of sines and cosines. Therefore a law of tangents should be expected. Find and prove it.

13.6 Check that the triangle $A = (0, 0)$, $B = (5, 0)$ and $C = (5, 3)$ is directly similar to the triangle $A' = (0, 0)$, $B' = (25, -15)$, $C' = (16, 0)$. Find the similarity ratio and the rotation and dilation of the corresponding homothety. Draw the triangles and you will astonish.

FOURTH PART: PLANE PROJECTIONS OF TRIDIMENSIONAL SPACES

The complete study of the geometric algebra of the tridimensional spaces falls out the scope of this book. However, due to the importance of the Earth charts and of the Lobachevsky's geometry, the first one being more practical and the second one more theoretical, I have written this last section. In order to make the explanations clearer, the tridimensional geometric algebra has been reduced to the minimal concepts, enhancing the plane projections.

The geometric quality of being Euclidean or pseudo-Euclidean is not the signature + or − of a coordinate, but the fact that two coordinates have the same or different signature, in other words, it is a characteristic of a plane. For instance, a plane with signatures + + is equivalent, from a geometric point of view, to another with − − . Therefore, only two kinds of three-dimensional spaces exist: the room space where all the planes are Euclidean (signatures + + + or − − −), and the pseudo-Euclidean space, which has one Euclidean plane and two orthogonal pseudo-Euclidean planes (signatures + − − or + + −).

14. SPHERICAL GEOMETRY IN THE EUCLIDEAN SPACE

The geometric algebra of the Euclidean space

A *vector* of the Euclidean space is an oriented segment in this space with direction and sense, although it can represent other physical magnitudes such as forces, velocities, etc. The set of all the segments (geometric vectors) together with their addition (parallelogram rule) and the product by real numbers (dilation of vectors) has a structure of vector space, symbolised with V_3. Every vector in V_3 is of the form:

$$v = v_1\, e_1 + v_2\, e_2 + v_3\, e_3$$

where e_i are three unitary perpendicular vectors, which form the base of the space. If we define an associative product (*geometric* or *Clifford product*) being a generalisation of that defined for the plane in the first chapter of this book, we will arrive to:

$$e_i^2 = 1 \qquad \text{and} \qquad e_i\, e_j = -e_j\, e_i \ \text{ for } i \neq j$$

In general, the square of a vector is the square of its modulus and perpendicular vectors anticommute whereas proportional vectors commute.

From the base vectors one deduces that the geometric algebra generated by the space V_3 has eight components:

$$Cl(V_3) = Cl_{3,\,0} = \langle 1, e_1, e_2, e_3, e_{23}, e_{31}, e_{12}, e_{123} \rangle$$

Let us see with more detail the product of two vectors:

$$v\, w = (v_1\, e_1 + v_2\, e_2 + v_3\, e_3)(w_1\, e_1 + w_2\, e_2 + w_3\, e_3) = v_1\, w_1 + v_2\, w_2 + v_3\, w_3$$
$$+ (v_2\, w_3 - v_3\, w_2)\, e_{23} + (v_3\, w_1 - v_1\, w_3)\, e_{31} + (v_1\, w_2 - v_2\, w_1)\, e_{12}$$

The product (or quotient) of two vectors is said a *quaternion*[1]. The quaternions are the even subalgebra of $Cl_{3,\,0}$ that generalise the complex numbers to the space. Splitting a quaternion in the real and bivector parts, we obtain the *inner* (or *scalar*) product and the *outer* (or *exterior*) product respectively:

$$v \cdot w = v_1\, w_1 + v_2\, w_2 + v_3\, w_3$$

$$v \wedge w = \left(v_2\, w_3 - v_3\, w_2\right) e_{23} + \left(v_3\, w_1 - v_1\, w_3\right) e_{31} + \left(v_1\, w_2 - v_2\, w_1\right) e_{12}$$

The *bivectors* are oriented plane surfaces and indicate the direction of planes in the space. Who be acquainted with the vector analysis will say that both vectors and bivectors are the same thing. This confusion was originated by Hamilton[2] himself, and continued by the founders of vector analysis, Gibbs and Heaviside. However, vectors and bivectors are different things just as physicists have experienced and know long time ago. The proper vectors are called usually "polar vectors" while the pseudo-vectors that actually are bivectors are usually called "axial vectors". The following magnitudes are vectors: of course a geometric segment, but also a velocity, an electric field, the momentum, etc. On the other hand, the oriented area is, of course, a bivector, but also the angular momentum, the angular velocity and the magnetic field. As a criterion to distinguish both kind of magnitudes one uses the reversal of coordinates, which changes the sense of vectors while leaves bivectors invariant.

The product of two bivectors yields a real number plus a bivector. Both parts can be separated as the symmetric and antisymmetric product. The symmetric product is a real number and its negative value will be denoted here with the symbol • while the antisymmetric product is also a bivector and will be noted here with the symbol × :

$$v \bullet w = -\frac{1}{2}\left(v\, w + w\, v\right) = v_{23}\, w_{23} + v_{31}\, w_{31} + v_{12}\, w_{12}$$

$$v \times w = -\frac{1}{2}\left(v\, w - w\, v\right)$$

$$= \left(v_{31}\, w_{12} - v_{12}\, w_{31}\right) e_{23} + \left(v_{12}\, w_{23} - v_{23}\, w_{12}\right) e_{31} + \left(v_{23}\, w_{31} - v_{31}\, w_{23}\right) e_{12}$$

$$v\, w = -v \bullet w - v \times w$$

Let us see what happens with the outer product of three vectors. According to the extension theory of Grassmann, the product $u \wedge v \wedge w$ is the oriented volume generated by the surface represented by the bivector $u \wedge v$ when it is translated parallelly along the segment w:

---

[1] Hamilton discovered the quaternions in October 16th 1843 and defined them as quotients of two vectors. From this definition he deduced the properties of the product of quaternions. I recommend you the reading of the initial chapters of the *Elements of Quaternions* because of its pedagogic importance.

[2] This confusion is due to the fact that vectors and bivectors are dual spaces of the algebra $Cl_{3,\,0}$. However, this duality does not exist at higher dimensions, although there is also duality among other spaces.

$$u \wedge v \wedge w = \begin{vmatrix} u_x & v_x & w_x \\ u_y & v_y & w_y \\ u_z & v_z & w_z \end{vmatrix} e_{123}$$

Finally, let us see how is the product of three vectors u, v and w. The vector v can be resolved into a component coplanar with u and v and another component perpendicular to the plane u-v:

$$u\, v\, w = u\, v_{\|}\, w + u\, v_{\perp}\, w$$

Now let us analyse the permutative property. In the plane we found $u\, v\, w - w\, v\, u = 0$. In the space the permutative property becomes[3]:

$$u\, v\, w - w\, v\, u = u\, v_{\perp}\, w - w\, v_{\perp}\, u = v_{\perp}\left(-u\, w + w\, u\right)$$

$$= -2\, v_{\perp}\, u \wedge w = -2\, v \wedge u \wedge w = 2\, u \wedge v \wedge w$$

I take the same algebraic hierarchies as in chapter 1: all the abridged products must be operated before the geometric product, convention which is coherent with the fact that in many algebraic situations, the abridged products must be developed in sums of geometric products.

Spherical trigonometry

In this section the relations for the sides and angles of the spherical triangles are deduced. I will take for convenience the sphere having unity radius, although the trigonometric identities are equally valid for a sphere of any radius.

Let us consider any three points A, B and C on the sphere with unity radius centred at the origin (figure 14.1). Then $|A| = |B| = |C| = 1$. The angles formed by each pair of sides will be denoted by α, β and γ, and the sides respectively opposite to these angles will be symbolised by a, b and c respectively. Then a is the arc of the great circle passing through the points B and C, that is, the angle between these vectors:

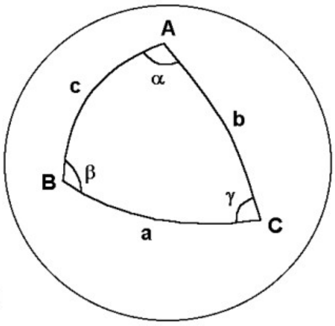


Figure 14.1

$$\sin a = |\, B \wedge C \,|$$

---

[3] From this result it follows that $u \wedge v \wedge w = (u\, v\, w - u\, w\, v + v\, w\, u - v\, u\, w + w\, u\, v - w\, v\, u) / 6$. In other words, the outer product is a fully antisymmetric product. However although being beautiful, it is not so useful for geometric algebra as the permutative property $u \wedge v \wedge w = (u\, v\, w - w\, v\, u)/2$.

Note that in this equality the sine is positive and therefore $a \leq \pi$. So, the spherical trigonometry is deduced for *strict triangles*, those having a, b, $c \leq \pi$.

Also, α is the angle between the sides b and c of the triangle, that is, the angle between the planes passing through the origin, A and B, and the origin, A and C. Since the direction of a plane is given by its bivector, which can be obtained through the outer product, we have:

$$\sin\alpha = \frac{\left|(A\wedge B)\times(A\wedge C)\right|}{|A\wedge B|\,|A\wedge C|}$$

Now we write the products of the numerator using the geometric product:

$$\sin\alpha = \frac{\left|-(A\,B - B\,A)(A\,C - C\,A) + (A\,C - C\,A)(A\,B - B\,A)\right|}{8\,|A\wedge B|\,|A\wedge C|}$$

$$\sin\alpha = \frac{\left|-A\,B\,A\,C + A\,B\,C\,A + B\,A^2\,C - B\,A\,C\,A + A\,C\,A\,B - A\,C\,B\,A - C\,A^2\,B + C\,A\,B\,A\right|}{8\,|A\wedge B|\,|A\wedge C|}$$

We extract the vector A as common factor at the left, but without writing it because $|A| = 1$:

$$\sin\alpha = \frac{\left|-B\,A\,C + B\,C\,A + A\,B\,C - A^{-1}\,B\,A\,C\,A + C\,A\,B - C\,B\,A - A\,C\,B + A^{-1}\,C\,A\,B\,A\right|}{8\,|A\wedge B|\,|A\wedge C|}$$

Applying the permutative property to the suitable pairs of products, we have:

$$\sin\alpha = \frac{\left|6\,A\wedge B\wedge C + 2\,A^{-1}\,A\wedge B\wedge C\,A\right|}{8\,|A\wedge B|\,|A\wedge C|} = \frac{|A\wedge B\wedge C|}{|A\wedge B|\,|A\wedge C|}$$

since the volume $A \wedge B \wedge C$ is a pseudoscalar, which commutes with all the elements of the algebra. Now the *law of sines for spherical triangles* follows:

$$\frac{\sin\alpha}{\sin a} = \frac{\sin\beta}{\sin b} = \frac{\sin\gamma}{\sin c} = \frac{|A\wedge B\wedge C|}{|A\wedge B|\,|B\wedge C|\,|C\wedge A|} \qquad \text{(I)}$$

Let us see the law of cosines. Since $e_{23}^2 = e_{31}^2 = e_{12}^2 = -1$ then:

$$\cos\alpha = \frac{(A\wedge B)\bullet(A\wedge C)}{|A\wedge B|\,|A\wedge C|} = \frac{(A\wedge B)\bullet(A\wedge C)}{\sin c\,\sin b}$$

$$\sin b\,\sin c\,\cos\alpha = -\frac{1}{8}\left[(A\,B - B\,A)(A\,C - C\,A) + (A\,C - C\,A)(A\,B - B\,A)\right]$$

$$= -\frac{1}{8}\left(A\,B\,A\,C - A\,B\,C\,A - B\,A^2\,C + B\,A\,C\,A + A\,C\,A\,B - A\,C\,B\,A - C\,A^2\,B + C\,A\,B\,A\right)$$

Now taking into account that:

$$4\,A\cdot B\;A\cdot C = (A\,B + B\,A)(A\,C + C\,A) = A\,B\,A\,C + A\,B\,C\,A + B\,A^2\,C + B\,A\,C\,A$$

But also:

$$4\,A\cdot B\;A\cdot C = (A\,C + C\,A)(A\,B + B\,A) = A\,C\,A\,B + A\,C\,B\,A + C\,A^2\,B + C\,A\,B\,A$$

and adding the needed terms, we find:

$$\sin b\sin c\cos\alpha = -\frac{1}{8}\left(8\,A\cdot B\;A\cdot C - 2\,A\,B\,C\,A - 2\,B\,A^2\,C - 2\,A\,C\,B\,A - 2\,C\,A^2\,B\right)$$

Extracting common factors and using $A^2 = B^2 = 1$, we may write:

$$\sin b\sin c\cos\alpha = -\frac{1}{8}\left(8\,A\cdot B\;A\cdot C - 2\,A\,(B\,C + C\,B)\,A - 2\,(B\,C + C\,B)\right) = -A\cdot B\;A\cdot C + B\cdot C$$

$$\sin b\sin c\cos\alpha = -\cos c\cos b + \cos a$$

$$\cos a = \cos b\cos c + \sin b\sin c\cos\alpha \qquad \text{(II)}$$

which is the *law of cosines for sides*. The substitution of cos c by means of the law of cosines gives:

$$\cos a = \cos b\,(\cos a\cos b + \sin a\sin b\cos\gamma) + \sin b\sin c\cos\alpha$$

$$\cos a\,(1 - \cos^2 b) = \cos b\sin a\sin b\cos\gamma + \sin b\sin c\cos\alpha$$

and the simplification of sin b:

$$\cos a\sin b = \cos b\sin a\cos\gamma + \sin c\cos\alpha$$

The substitution of sin c = sin a sin γ / sin α yields:

$$\cos a\sin b = \cos b\sin a\cos\gamma + \frac{\sin a\sin\gamma\cos\alpha}{\sin\alpha}$$

Dividing by sin a :

$$\cot a\sin b = \cos b\cos\gamma + \sin\gamma\cot\alpha \qquad \text{(III)}$$

The dual spherical triangle

The perpendicular to the plane containing each side of a spherical triangle cuts the spherical surface in a point. The three points A', B' and C' obtained in this geometric way form the *dual triangle*. The algebraic way to calculate them is the duality operation, which maps bivectors into the perpendicular vectors. The dual of any element is obtained as the product by the pseudoscalar unity $-e_{123}$, which commutes with all the elements of the algebra:

$$A' = -e_{123}\,\frac{B \wedge C}{|B \wedge C|} \qquad B' = -e_{123}\,\frac{C \wedge A}{|C \wedge A|} \qquad C' = -e_{123}\,\frac{A \wedge B}{|A \wedge B|}$$

The inner product of two vectors yields:

$$B' \cdot C' = \frac{(C \wedge A) \bullet (A \wedge B)}{|C \wedge A|\,|A \wedge B|} = -\frac{(A \wedge B) \bullet (A \wedge C)}{|A \wedge B|\,|A \wedge C|} \quad \Leftrightarrow \quad \cos a' = -\cos\alpha$$

which shows that the angle a' and α are supplementary, and so also the other angles:

$$a' = \pi - \alpha \qquad b' = \pi - \beta \qquad c' = \pi - \gamma$$

It is trivial that the dual of the dual triangle is the first triangle, and hence:

$$\alpha' = \pi - a \qquad \beta' = \pi - b \qquad \gamma' = \pi - c$$

We may apply the laws of sines and cosines to the dual triangle. The law of sines is self-dual and may be written in a more symmetric form:

$$\frac{\sin\alpha}{\sin a} = \frac{\sin\beta}{\sin b} = \frac{\sin\gamma}{\sin c} = \frac{|A \wedge B \wedge C|}{|A' \wedge B' \wedge C'|} \qquad \text{(I)}$$

On the other hand, the law of cosines yields a new result when applying duality:

$$-\cos\alpha' = \cos\gamma' \cos\beta' - \sin\beta' \sin\gamma' \cos a'$$

Removing the marks, since this law must be valid for any spherical triangle, we find the *law of cosines for angles*:

$$\cos\alpha = -\cos\gamma \cos\beta + \sin\beta \sin\gamma \cos a \qquad \text{(IV)}$$

Also, applying the equality (III) to the dual triangle we find:

$$\cot\alpha \sin\beta = -\cos\beta \cos c + \sin c \cot a \qquad \text{(V)}$$

The five Bessel's equalities (I to V) allow to solve every spherical triangle knowing any three of its six elements.

Right spherical triangles and Napier’s rule

For the case of a right angle spherical triangle, the five Bessel’s formulas are reduced to a simpler form, and then they may be remembered with the help of the Napier’s pentagon rule (figure 14.2). Draw the angles and the sides of the triangle following the order of the perimeter removing the right angle and writing instead of the legs (the sides adjacent to the right angle) the complementary arcs. Then follow the Pentagon rules:

1) The cosine of every element is equal to the product of the cotangents of the adjacent elements.
2) The cosine of every element is equal to the product of the sines of the nonadjacent elements.

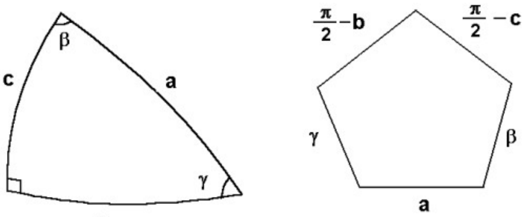

Figure 14.2

For example:

$$\cos a = \sin\left(\frac{\pi}{2} - b\right)\sin\left(\frac{\pi}{2} - c\right) = \cos b \cos c$$

also: $$\cos\left(\frac{\pi}{2} - b\right) = \cot\gamma \cot\left(\frac{\pi}{2} - c\right) \qquad \Rightarrow \qquad \sin b = \cot\gamma \operatorname{tg} c$$

This rule is applied to the right side triangles in the same way: remove the right side and write the complementary of the adjacent angles.

Area of a spherical triangle

A *lune* is a two-sided polygon on the sphere defined by two great circles. The area of a lune is proportional to the angle α between both great circles. For an angle π/2 its area is π, therefore the area of a lune with angle α is 2α. Now let us consider in the sphere shown by figure 14.3 the three lunes having the angles α, β and γ. Then:

$$\begin{cases} s + t = 2\,\alpha \\ s + u' = 2\,\beta \\ s + v = 2\,\gamma \end{cases}$$

where u' is the area of the antipodal triangle of u. Both triangles u and u' have the same angles and area and the system can be rewritten:

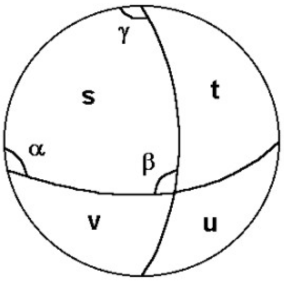

Figure 14.3

$$\begin{cases} s + t = 2\,\alpha \\ s + u = 2\,\beta \\ s + v = 2\,\gamma \end{cases}$$

Adding the three equations, we find:

$$3\,s + t + u + v = 2\left(\alpha + \beta + \gamma\right)$$

The four triangles *s*, *t*, *u* and *v* fill an hemisphere:

$$s + t + u + v = 2\,\pi$$

so the area of the triangle *s* is the *spherical excess*, that is, the addition of the three angles minus π:

$$s = \alpha + \beta + \gamma - \pi$$

Properties of the projections of the spherical surface

No chart of the spherical surface preserving the scale of distances everywhere exists, that is, we cannot depict any map with distances proportional to those measured on the sphere. The *distortion* is the variation of the scale and the angles. Usually there is a line of zero distortion, where the scale is constant.

Since the scale of distances is never preserved for all the points, projections with other interesting properties have been searched in cartography. A projection is said to be *conformal* if it preserves in the map the angles between great circles on the sphere. A projection is said to be *equivalent* if it preserves the area, that is if the figures on the sphere are projected into figures on the map having the same area. A projection is said to be *equidistant* if the scale of distances is preserved, not everywhere but on the line perpendicular to the line of zero distortion, or radially outwards from a point of zero distortion.

The more general concept of projection is any one-to-one mapping of any point (*x*, *y*, *z*) on the sphere into a point (*u*, *v*) on the plane, although the main types of projections are azimuthal, cylindrical and conic. An *azimuthal* projection is a standard projection into a plane, which may be considered touching the sphere. In the tangency point there is zero distortion and the bearings or azimuths from this point are correctly shown. A *cylindrical* projection is a projection into a cylindrical surface around the sphere that will be unrolled. A *conic* projection is a projection into a conical surface tangent to the sphere that will also be unrolled.

Now, I review the main and more used projections beginning with the azimuthal projections.

The central or gnomonic projection

Let us consider the sphere with unity radius (figure 14.4) centred at the origin. Any point on the sphere has the coordinates (*x*, *y*, *z*) fulfilling:

$$x^2+y^2+z^2=1$$

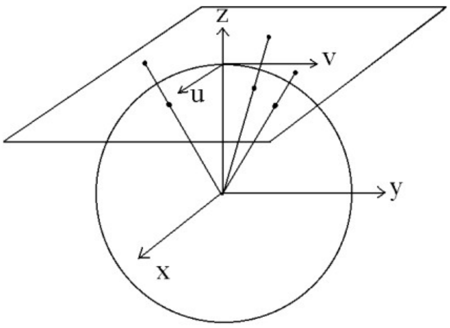

Figure 14.4

Every point on the upper hemisphere is projected into another point on the plane $z = 1$ using as centre of projection the centre of the sphere. Let u and v be the Cartesian coordinates on the projection plane. Taking similar triangles the following relations are found:

$$u=\frac{x}{z} \qquad v=\frac{y}{z}$$

from where we obtain:

$$x=\frac{u}{\sqrt{u^2+v^2+1}} \qquad y=\frac{v}{\sqrt{u^2+v^2+1}} \qquad z=\frac{1}{\sqrt{u^2+v^2+1}}$$

The differential of the arc length is obtained through the differentiation of the above relationships:

$$ds=dx\,e_1+dy\,e_2+dz\,e_3$$

$$ds^2=dx^2+dy^2+dz^2=\frac{\left(1+v^2\right)du^2-2\,u\,v\,du\,dv+\left(1+u^2\right)dv^2}{\left(1+u^2+v^2\right)^2}$$

The geodesics of the sphere are the great circles, which are the intersections with planes passing through its centre. These planes cut the projection plane in straight lines, which are the projections of the geodesics. In other words, any great circle is projected into a line on the projection plane. Taking as equation of the line:

$$v=k\,u+l$$

with k and l constant, the substitution in ds gives:

$$ds=\frac{\sqrt{1+k^2+l^2}}{u^2\left(1+k^2\right)+2\,k\,l\,u+1+l^2}\,du$$

By integration we arrive to the following primitive:

$$s=\operatorname{arctg}\frac{u\left(1+k^2\right)+k\,l}{\sqrt{1+k^2+l^2}}+\text{const}$$

The arc length between two points on this great circle is the difference of this primitive between both points. However it is more advantageous to write it using cosines instead of tangents by means of the trigonometric identity:

$$\cos(s_B - s_A) \equiv \frac{1 + \operatorname{tg} s_A \operatorname{tg} s_B}{\sqrt{1 + \operatorname{tg}^2 s_A}\sqrt{1 + \operatorname{tg}^2 s_B}}$$

After removing *k* and *l* using the equation of the line, we arrive to:

$$\cos(s_B - s_A) = \frac{1 + u_A u_B + v_A v_B}{\sqrt{1 + u_A{}^2 + v_A{}^2}\sqrt{1 + u_B{}^2 + v_B{}^2}}$$

$$= \frac{(u_A e_1 + v_A e_2 + e_3)\cdot(u_B e_1 + v_B e_2 + e_3)}{|u_A e_1 + v_A e_2 + e_3| \; |u_B e_1 + v_B e_2 + e_3|}$$

a trivial result because the arc length is the angle between the position vectors of both points, and also of the proportional vectors going to the projection plane. However, the interest of this result is its analogy with the result found for the hyperboloidal surface.

From this value of the cosine, we may obtain the sine of the arc:

$$\sin(s_B - s_A) = \sqrt{1 - \cos^2(s_B - s_A)} = \frac{\sqrt{(u_A v_B - u_B v_A)^2 + (u_A - v_A)^2 + (u_B - v_B)^2}}{\sqrt{1 + u_A{}^2 + v_A{}^2}\sqrt{1 + u_B{}^2 + v_B{}^2}}$$

$$= \frac{|(u_A e_1 + v_A e_2 + e_3)\wedge(u_B e_1 + v_B e_2 + e_3)|}{|u_A e_1 + v_A e_2 + e_3| \; |u_B e_1 + v_B e_2 + e_3|}$$

which is also a trivial result, since the sine of the angle is proportional to the modulus of the outer product.

Let us see the area function. The differential of the area is easily obtained taking into account that it is a bivector and using the outer product of the differentials of the coordinates:

$$dA = \sqrt{(dx \wedge dy)^2 + (dy \wedge dz)^2 + (dz \wedge dx)^2} = \frac{du \wedge dv}{\left(1 + u^2 + v^2\right)^{3/2}}$$

This result shows that the central projection is not *equivalent* and the distortion increases with the distance to the origin.

Let us consider a plane passing through the centre of the sphere, which cuts its surface in the great circle determined by the equation system:

$$\begin{cases} x^2 + y^2 + z^2 = 1 \\ a\,x + b\,y + z = 0 \quad a, b \quad \text{real} \end{cases}$$

Then the angle between two great circles is the angle between both central planes:

$$\cos\alpha = \frac{(a\, e_{23} + b\, e_{31} + e_{12}) \bullet (a'\, e_{23} + b'\, e_{31} + e_{12})}{|\, a\, e_{23} + b\, e_{31} + e_{12} \,|\; |\, a'\, e_{23} + b'\, e_{31} + e_{12} \,|} = \frac{a\, a' + b\, b' + 1}{\sqrt{a^2 + b^2 + 1}\,\sqrt{a'^2 + b'^2 + 1}}$$

The sides of a spherical triangle are great circles; therefore the central projection of a spherical triangle is a triangle whose sides are straight lines.

Stereographic projection

In the stereographic projection the point of view is placed on the spherical surface. As before, every point (x, y, z) on the sphere with unity radius centred at the origin fulfils the equation:

$$x^2 + y^2 + z^2 = 1$$

We project the spherical surface into the plane $z = 0$ locating the centre of projection at the pole $(0, 0, -1)$ (figure 14.5). The upper hemisphere is projected inside the circle of unity radius while the lowest hemisphere is projected outside. If u and v are the Cartesian coordinates on the projection plane, we have by similar triangles:

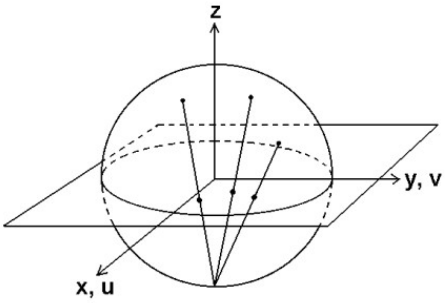

Figure 14.5

$$\frac{x}{u} = z + 1 \qquad \frac{y}{v} = z + 1$$

Using the equation of the sphere one arrives to:

$$x = \frac{2\,u}{1 + u^2 + v^2} \qquad y = \frac{2\,v}{1 + u^2 + v^2} \qquad z = \frac{2}{1 + u^2 + v^2} - 1$$

from where the differential of the arc length is obtained:

$$ds^2 = dx^2 + dy^2 + dz^2 = \frac{4\left(du^2 + dv^2\right)}{\left(1 + u^2 + v^2\right)^2}$$

Now we see that this projection is not equidistant and the distortion increases with the distance to the origin. The factor 4 indicates that the lengths at the origin of coordinates on the plane are the half of the lengths on the sphere. Taking instead of the plane $z = 0$, the plane $z = 1$ this factor becomes 1. Then, we can state correctly the scale of the chart (for example, a polar chart).

The geodesic lines (great circles) are intersection of the sphere surface with planes passing through the origin, which have the equation:

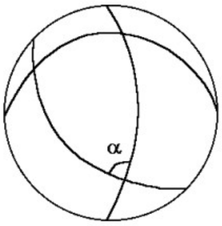
$$z = a\, x + b\, y$$

The substitution by the stereographic coordinates yields:

$$(u+a)^2+(v+b)^2=a^2+b^2+1$$

which is the equation of a circle centred at $(-a, -b)$ with radius $r=\sqrt{a^2+b^2+1}$. Observe that this radius is the hypotenuse of a right angle triangle having as legs the distance to the origin and the unity. That is, the great circles on the sphere are shown in the stereographic projection as circles that intersect the circle $x^2+y^2=1$ in extremes of diameters (figure 14.6). Usually only the projection of the upper hemisphere is used, so that the great circles are represented as circle arcs inside the circle $x^2+y^2\le 1$. The angle α between two of these circles, as explained in the page 89, is obtained from their radii r and r' and centres O and O' through:

Figure 14.6



$$\cos\alpha=\frac{r^2+r'^2-(O-O')^2}{2\,r\,r'}=\frac{a\,a'+b\,b'+1}{\sqrt{a^2+b^2+1}\sqrt{a'^2+b'^2+1}}$$

Just this is the angle between the planes $a\,x+b\,y-z=0$ and $a'\,x+b'\,y-z=0$, that is, the angle between the two great circles represented by the projected circles. Therefore, the stereographic projection is a conformal projection of the spherical surface.

If we calculate the differential of area we find:

$$dA=\frac{4\,du\wedge dv}{\left(1+u^2+v^2\right)^2}$$

Now we see that this projection is not equivalent since distortion of areas increases with the distance from the origin (as commented above, the factor 4 becomes 1 projecting into the plane $z=1$).

Orthographic projection

The orthographic projection of the sphere is a parallel projection (the point of view is placed at the infinity). If we make a projection parallel to the z-axis upon the plane $z=0$, the Cartesian coordinates on the map are identical to x, y and we have:

$$z=\sqrt{1-x^2-y^2} \qquad dz=-\frac{x\,dx+y\,dy}{\sqrt{1-x^2-y^2}}$$

$$ds^2=dx^2+dy^2+dz^2=\frac{dx^2+dy^2+2\,x\,y\,dx\,dy}{1-x^2-y^2}$$

$$dA = \sqrt{\frac{1 + x^2 + y^2}{1 - x^2 - y^2}}\, dx \wedge dy$$

Introducing the distance r to the origin of coordinates and the angle φ with respect to the x-axis, we have:

$$x = r\cos\varphi \qquad y = r\sin\varphi$$

$$ds^2 = \frac{dr^2 + r^2 d\varphi^2 + 2\, r\, dr\, d\varphi}{1 - r^2}$$

An example of orthographic projection is the Earth image that appears in many TV news.

Spherical coordinates and cylindrical equidistant (Plate Carrée) projection

For a sphere with unity radius, the spherical coordinates[4] are related with the Cartesian coordinates by means of:

$$x = \sin\theta\cos\varphi$$

$$y = \sin\theta\sin\varphi$$

$$z = \cos\theta$$

Then the differential of arc length is:

$$ds = (\cos\theta\cos\varphi\, d\theta - \sin\theta\sin\varphi\, d\varphi)\, e_1 + (\cos\theta\sin\varphi\, d\theta + \sin\theta\cos\varphi\, d\varphi)\, e_2 - \sin\theta\, d\theta\, e_3$$

Introducing the unitary vectors e_θ and e_φ as:

$$e_\theta = \cos\theta\cos\varphi\, e_1 + \cos\theta\sin\varphi\, e_2 - \sin\theta\, e_3$$

$$e_\varphi = -\sin\varphi\, e_1 + \cos\varphi\, e_2$$

the differential of arc length in spherical coordinates becomes:

$$ds = d\theta\, e_\theta + \sin\theta\, d\varphi\, e_\varphi$$

$$ds^2 = d\theta^2 + \sin^2\theta\, d\varphi^2$$

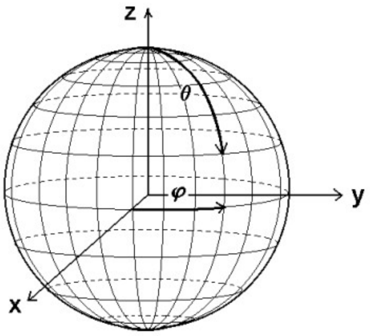


Figure 14.7

---

[4] For geographical coordinates, θ is the colatitude and φ the longitude.

Note that e_θ and e_φ are orthogonal vectors, since their inner product is zero. At $\theta = 0$, *ds* depends only on $d\theta$ and there is a pole. Then θ is the arc length from the pole to the given point (figure 14.7), while φ is the arc length over the equator ($\theta = \pi/2$, $\sin\theta = 1$). The meridians ($\varphi =$ constant) are geodesics, but the parallels ($\theta =$ constant) are not. Exceptionally, the equator is also a geodesic.

In the Plate Carrée projection $u = \varphi$ and $v = \pi/2 - \theta$ (latitude) so that the meridians and parallels are shown in a squared graticule. This projection is equidistant for any meridian whereas the distortion in the parallels increases, as well as for every cylindrical projection, as we separate from the equator. Let us see the area:

$$dA = \sin\theta \; d\theta \wedge d\varphi = \cos v \; du \wedge dv$$

The ratio of the real area with respect to the represented area on the chart is equal to the cosine of the latitude and therefore the projection is not equivalent.

Mercator's projection

The Mercator's projection[5] is defined as the cylindrical conformal projection. If we wish to preserve the angles between curves, we must enlarge the meridians by the same amount as the parallels are enlarged in a cylindrical projection, that is, by the factor 1/sin θ (the secant of the geographical latitude):

$$dv = \frac{-d\theta}{\sin\theta} \qquad \Rightarrow \qquad v = -\log \operatorname{tg}\frac{\theta}{2}$$

The differential of arc length is:

$$ds^2 = d\theta^2 + \sin^2\theta \, d\varphi^2 = \sin^2\theta \left(du^2 + dv^2\right) = \frac{4\exp(2v)}{\left(\exp(2v)+1\right)^2}\left(du^2 + dv^2\right)$$

$$ds = \frac{2\exp(v)}{\exp(2v)+1}\sqrt{du^2 + dv^2}$$

where the distances are increased in an amount independent of the direction and proportional to the inverse of the sine of θ. The differential of area is:

$$dA = \sin\theta \; d\theta \wedge d\varphi = \frac{4\exp(2v)}{\left(\exp(2v)+1\right)^2} du \wedge dv$$

---

[5] The difference between the U.T.M. (Universal Transverse Mercator) projection and the Mercator planisphere is not geometric but geographic: in the U.T.M. the cylinder of projection is tangent to a meridian instead of the equator. All the Earth has been divided in zones of 6º of longitude, where the cylinder of projection is tangent to the central meridian (3º, 9º, 15º ...).

Peters' projection

The Peters' projection is the cylindrical equivalent projection. If we wish to preserve area, we must shorten the meridians in the same amount as the parallels are enlarged in the cylindrical projection, what yields:

$$dv = -\sin\theta\, d\theta \qquad \Rightarrow \qquad v = \cos\theta$$

$$ds^2 = d\theta^2 + \sin^2\theta\, d\varphi^2 = \left(1 - v^2\right) du^2 + \frac{dv^2}{1 - v^2}$$

$$dA = \sin\theta\, d\theta \wedge d\varphi = du \wedge dv$$

which displays clearly the equivalence of the projection. Observe that $v = \cos\theta$ means the sphere is projected following planes perpendicular to the cylinder of projection (figure 14.8).

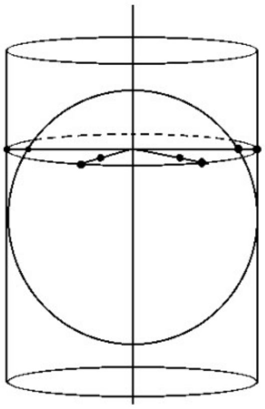

Figure 14.8

Conic projections

These projections are made into a cone surface tangent to the sphere (figure 14.9). Because the cone surface unrolled is a plane circular sector, they are often used to display middle latitudes, while the azimuthal projections are mainly used for poles. In a conic projection a small circle (a parallel) is shown as a circle with zero distortion. The characteristic parameter of a conic projection is the constant of the cone $n = \cos\theta_0$, being θ_0 the angle of inclination of the generatrix of the cone and also the angle from the axis of the cone to any point of tangency with the sphere. Since the graticule of the conic projections is radial, to use the radius r and the angle χ is more convenient:

$$dr = f(\theta)\, d\theta \qquad d\chi = n\, d\varphi$$

The differentials of arc length and area for a conic projection are:

$$ds^2 = d\theta^2 + \sin^2\theta\, d\varphi^2 = \frac{dr^2}{[f(\theta)]^2} + \frac{\sin^2\theta}{n^2}\, d\chi^2$$

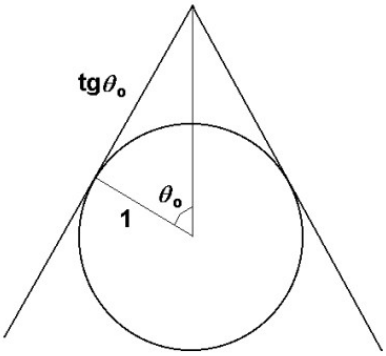
$$dA = \sin\theta\, d\theta \wedge d\varphi = \frac{\sin\theta}{n\, f(\theta)}\, dr \wedge d\chi$$

Let us see as before the three special cases: equidistant, conformal and equivalent projections. The differential of area for polar coordinates r, χ is $dA = r\, dr \wedge d\chi$. If the projection is equivalent, we must identify both dA to find :

$$\frac{d}{d\theta}\left[\frac{\sin\theta}{n\,f(\theta)}\right]=f(\theta) \qquad \Rightarrow \qquad f(\theta)=\frac{1}{\sqrt{n}}\cos\frac{\theta}{2} \quad \text{and} \quad r=\frac{2}{\sqrt{n}}\sin\frac{\theta}{2}$$

$$ds^2=\frac{n}{1-\frac{n\,r^2}{4}}dr^2+\frac{1-\frac{r^2\,n}{4}}{n}r^2d\chi^2$$

Figure 14.9



If the projection is equidistant, the meridians have zero distortion so $d\theta=dr/n$ and:

$$ds^2=\frac{1}{n^2}\left(dr^2+\sin^2\left(\frac{r}{n}\right)d\chi^2\right)$$

If the projection is conformal then $ds^2\propto dr^2+r^2d\chi^2$ so:

$$ds^2=\frac{\sin^2\theta}{n^2r^2}\left(dr^2+r^2\,d\chi^2\right)$$

Solving the differential equation:

$$d\theta=\frac{\sin\theta}{n\,r}dr$$

with the boundary condition $\operatorname{tg}\theta_0=r_0$ as shown by the figure 14.9 we find the Lambert's conformal projection:

$$r=\operatorname{tg}\theta_0\left(\frac{\operatorname{tg}\frac{\theta}{2}}{\operatorname{tg}\frac{\theta_0}{2}}\right)^n$$

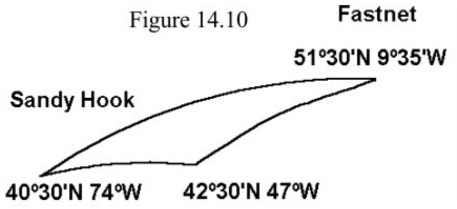
Exercises

14.1 We have seen the gnomonic projection of great circles being always straight lines. Then, why does the shadow of a gnomon of a sundial follow a hyperbola on a plane surface instead of a line during a day? Why does this hyperbola become a straight line the March 21 and September 23?

14.2 Three points on the sphere are projected by means of the stereographic projection into a circle of unity radius with the coordinates A = (–0.5, 0.5), B = (0, –2/3) and C = (2/3, 0). Calculate the sides, angles and area of the triangle which they form.

14.3 Built at Belfast, the Titanic begun its first and last travel in Southampton the April 10th 1912. After visiting Cherbourg the Titanic weighed anchor in the Cork harbour with bearing New York the 11th April. Calculate the length of the shortest trajectory from Fastnet (Ireland) at 51º30'N 9º35'W to Sandy Hook (New York) at 40º30'N 74ºW. From January 15th to July 15th the ships had to follow the orthodrome (great circle) from Fastnet to the point 42º30'N 47ºW and from this point to Sandy Hook passing at twenty miles from the floating lighthouse of Nantucket. Calculate the length of the route the Titanic should have followed. Take as an averaged radius of the Earth 6366 km. The Titanic sank the 15th April at the position 41º46'N 50º14'W. Is this point on the obliged track?

Figure 14.10



14.4 The figure 14.11 is a photograph of the Hale-Bopp comet. The orientation of the camera is unknown, but the W of Cassiopeia constellation appears in the photograph. The declination *D* of a star is the angular distance from the celestial equator to the star (measured on the great circle passing through the celestial pole and the star). The right ascension *A* is the arc of celestial equator measured eastward from the vernal equinox (one of the intersections of the celestial equator with the ecliptic, also called Aries point) to the foot of the great circle passing through the star and the pole. The right ascension and declination of the stars are constant while those of the comets, planets, the Sun and the Moon are variable. The data of Cassiopeia constellation are:

star	Magnitude	*A*	*D*
α Cassiopeia (Schedir)	2.2	0h 40min 6.4s = 10.0267º	56º 29' 57" N
β Cassiopeia (Caph)	2.3	0h 8min 48.1s = 2.2004º	59º 6' 40" N
γ Cassiopeia (Tsih)	2.4	0h 56min 16.9s = 14.0704º	60º 40' 44" N
δ Cassiopeia (Ruchbah)	2.7	1h 25min 21.2s = 21.3383º	60º 11' 57" N

In your system of coordinates, take the *x*-axis as the Aries point and the *z*-axis as the north pole. Then $D = \pi/2-\theta$ and $A=\varphi$.

a) Calculate the focal distance of the photograph, that is, the distance from the point of view to the plane of the photograph. Knowing that the negative was universal (24×36 mm), calculate the focal distance of the camera.
b) Calculate the orientation (right ascension and declination) of the photographic camera.
c) Calculate the coordinates of the Hale-Bopp comet.

Spherical geometry

5.1 Spherical distance

This chapter is devoted to *spherical geometry*; that is, to geometry on the surface of the sphere

$$\mathcal{S} = \{\mathbf{x} \in \mathbb{R}^3 : ||\mathbf{x}|| = 1\}.$$

Later in this chapter we shall use spherical trigonometry to derive Euler's formula for polyhedral surfaces, and this will lead (eventually) to a discussion of the symmetry groups of regular polyhedra.

We take for granted the fact that one can measure the length of a smooth curve, and the area of a (reasonably simple) set, on $\mathcal{S}$. A *great circle*, of length 2π, is the intersection of $\mathcal{S}$ and a plane that passes through the origin. Every other circle on $\mathcal{S}$ is a plane section of $\mathcal{S}$ of length less than 2π. If σ is an arc of a great circle, then the length of σ is the angle (in radians) subtended by σ at 0. Given any two points **a** and **b** on $\mathcal{S}$ there is a unique great circle, say C, that contains them (and C lies in the plane through **0**, **a** and **b**). Also, **a** and **b** divide C into two arcs which have different lengths unless $\mathbf{b} = -\mathbf{a}$.

Definition 5.1.1 Let **a** and **b** be two points on $\mathcal{S}$. Then the *spherical distance* $\delta(\mathbf{a}, \mathbf{b})$ between **a** and **b** is the length of the shorter of the two arcs of the (unique) great circle through **a** and **b**. Clearly,

$$\delta(\mathbf{a}, \mathbf{b}) = \cos^{-1}(\mathbf{a} \cdot \mathbf{b}), \tag{5.1.1}$$

where $\cos^{-1}(\mathbf{a} \cdot \mathbf{b})$ is chosen in the range $[0, \pi]$. □

As an application, consider the Earth to be a perfect sphere of radius R whose centre lies at the origin **0** in $\mathbb{R}^3$. We may suppose that the **i**-axis meets the surface of the earth at the point with zero latitude and longitude, and that the positive **k**-axis passes through the north pole. Thus the point on the Earth's surface with latitude α (positive in the northern hemisphere, and negative in the southern hemisphere), and longitude β is given by the vector

$$R\big(\cos\alpha\cos\beta\,\mathbf{i}+\cos\alpha\sin\beta\,\mathbf{j}+\sin\alpha\,\mathbf{k}\big)$$

(the reader should draw a diagram). Suppose, now that $\mathbf{x}_1$ and $\mathbf{x}_2$ are two points on the Earth's surface, and write these as

$$\begin{aligned}\mathbf{x}_1 &= R\big(\cos\alpha_1\cos\beta_1\,\mathbf{i}+\cos\alpha_1\sin\beta_1\,\mathbf{j}+\sin\alpha_1\,\mathbf{k}\big),\\ \mathbf{x}_2 &= R\big(\cos\alpha_2\cos\beta_2\,\mathbf{i}+\cos\alpha_2\sin\beta_2\,\mathbf{j}+\sin\alpha_2\,\mathbf{k}\big).\end{aligned}$$

Then, from (5.1.1),

$$\delta(\mathbf{x}_1,\mathbf{x}_2)=R\cos^{-1}\big[\cos\alpha_1\cos\alpha_2\cos(\beta_1-\beta_2)+\sin\alpha_1\sin\alpha_2\big]. \qquad (5.1.2)$$

This formula gives us the distance (measured on the surface of the Earth) between the two points with latitude α_i and longitude β_i, $i=1,2$.

Exercise 5.1

1. Verify that any point with latitude α is a spherical distance $R(\pi/2-\alpha)$ from the north pole.
2. Assume that the Earth is a sphere of radius 4000 miles. Show that the spherical distance between London (latitude 51° north, longitude 0°) and Sydney (latitude 34° south, longitude 151° east) is approximately 10 500 miles.
3. Suppose that an aircraft flies on the shortest route from London (latitude 51° north, longitude 0°) to Los Angeles (latitude 34° north, longitude 151° east). How close does the aircraft get to the north pole?
4. Let $\mathbf{x}$ and $\mathbf{y}$ be two points on the sphere. Show that the normal to the plane determined by the great circle through $\mathbf{x}$ and $\mathbf{y}$ intersects the sphere at the points $\pm\mathbf{z}$, where $\mathbf{z}=(\mathbf{x}\times\mathbf{y})/||\mathbf{x}\times\mathbf{y}||$. Suppose that $\mathbf{w}$ lies on the same side of the plane as $\mathbf{z}$. Show that $\cos\delta(\mathbf{w},\mathbf{z})=[\mathbf{w},\mathbf{x},\mathbf{y}]$.

5.2 Spherical trigonometry

We begin our discussion of spherical trigonometry with the the spherical version of Pythagoras' theorem. Consider a triangle on $\mathcal{S}$, by which we mean three points $\mathbf{a}$, $\mathbf{b}$ and $\mathbf{c}$ of $\mathcal{S}$ which do not lie on a great circle, where the sides of the triangle are the arcs of great circles that join these points in pairs. We assume that the angle in the triangle at $\mathbf{c}$ is $\pi/2$, and we may position this triangle so

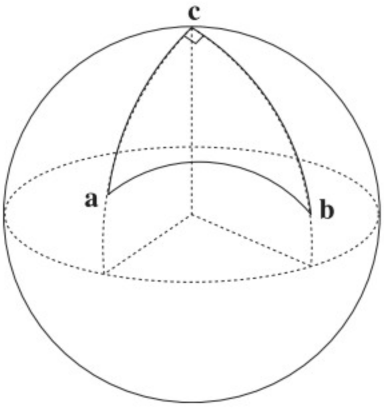

Figure 5.2.1

that $\mathbf{c} = \mathbf{k}$, $\mathbf{a}$ is in the $(\mathbf{i}, \mathbf{k})$-plane, and that $\mathbf{b}$ is in the $(\mathbf{j}, \mathbf{k})$-plane (if necessary we may interchange the labels on **a** and **b**). With this, we have

$$\mathbf{c} = \mathbf{k}, \quad \mathbf{a} = \cos\alpha_1\,\mathbf{i} + \sin\alpha_1\,\mathbf{k}, \quad \mathbf{b} = \cos\alpha_2\,\mathbf{j} + \sin\alpha_2\,\mathbf{k} \qquad (5.2.1)$$

for some α_1 and α_2 (see Figure 5.2.1) so that $(\mathbf{a}\cdot\mathbf{b}) = (\mathbf{a}\cdot\mathbf{c})(\mathbf{b}\cdot\mathbf{c})$. If we now apply (5.1.1) we immediately obtain the following result.

Pythagoras' theorem *Let* **a**, **b** *and* **c** *be the vertices of a spherical triangle on* $\mathcal{S}$*, with the sides making an angle of* $\pi/2$ *at* **c**. *Then*

$$\cos\delta(\mathbf{a}, \mathbf{b}) = \cos\delta(\mathbf{a}, \mathbf{c})\cos\delta(\mathbf{b}, \mathbf{c}). \qquad (5.2.2)$$

Consider (informally) an 'infinitesimal' right-angled triangle. As this triangle is nearly flat we would expect (5.2.2) to look roughly like the usual Euclidean version $a^2 + b^2 = c^2$ of Pythagoras' theorem. This is indeed the case because for small θ, $\cos\theta$ is approximately $1 - \theta^2/2$.

Next, we consider a spherical triangle (as illustrated in Figure 5.2.1) with vertices **a**, **b** and **c**. As is customary in Euclidean geometry, we let the angles at **a**, **b** and **c** be α, β and γ, respectively, and we denote the lengths of the sides by a, b and c; thus $a = \delta(\mathbf{b}, \mathbf{c})$, $b = \delta(\mathbf{c}, \mathbf{a})$ and $c = \delta(\mathbf{a}, \mathbf{b})$. We now prove the following identity; note that the right-hand side here involves *two sides* and *one angle*.

Theorem 5.2.1 *In any spherical triangle with vertices* **a**, **b** *and* **c** *we have*

$$[\mathbf{a}, \mathbf{b}, \mathbf{c}] = \sin a\ \sin b\ \sin\gamma. \qquad (5.2.3)$$

Proof We may choose our axes so that $\mathbf{c} = \mathbf{k}$, and that **a** lies in the $(\mathbf{i}, \mathbf{k})$-plane. As $\delta(\mathbf{a}, \mathbf{c}) = b$, we see that $\mathbf{a} = (\sin b, 0, \cos b)$. Similarly, **b** has latitude

$\pi/2 - a$ and longitude γ; thus

$$\mathbf{b} = (\sin a\ \cos\gamma,\ \sin a\ \sin\gamma,\ \cos a),$$

and (5.2.3) follows directly from these expressions. □

We end this section with the sine rule, and the cosine rule, for spherical geometry.

The sine and cosine rules *In a spherical triangle with vertices* **a**, **b** *and* **c**, *we have the sine rule:*

$$\frac{\sin\alpha}{\sin a} = \frac{\sin\beta}{\sin b} = \frac{\sin\gamma}{\sin c},$$

and the cosine rule: $\cos c = \cos a\ \cos b + \sin a\ \sin b\ \cos\gamma$.

Proof The sine rule follows immediately from (5.2.3) and the fact that $[\mathbf{a}, \mathbf{b}, \mathbf{c}] = [\mathbf{c}, \mathbf{a}, \mathbf{b}] = [\mathbf{b}, \mathbf{c}, \mathbf{a}]$. To prove the cosine rule we may choose **a**, **b** and **c** as in the proof of Theorem 5.2.1. Then

$$\cos c = \cos\ \delta(\mathbf{a}, \mathbf{b}) = \mathbf{a}\cdot\mathbf{b} = \cos a\ \cos b + \sin a\ \sin b\ \cos\gamma,$$

as required. □

Exercise 5.2

1. Derive Pythagoras' Theorem from the cosine rule.
2. Show that if an equilateral spherical triangle has sides of length a and interior angles α, then $\cos(a/2)\ \sin(\alpha/2) = 1/2$. Deduce that $\alpha > \pi/3$ (so that the angle sum of the triangle exceeds π).
3. Calculate the perimeter of a spherical triangle all of whose angles are $\pi/2$.

5.3 Area on the sphere

Let us now find the formula for the area of a spherical triangle on $\mathcal{S}$. We denote the spherical area (that is, the area on $\mathcal{S}$) of a set E by $\mu(E)$, and as the surface area of a sphere of radius r is $4\pi r^2$, we see that $\mu(\mathcal{S}) = 4\pi$. Two (distinct) great circles meet at diametrically opposite points, and they divide the sphere into four regions, called *lunes*. The angle of a lune is the angle (in the lune) at which the circles meet, and it is clear that *the area of a lune of angle* α *is* 2α, for it is obviously proportional to α, and equal to 4π when $\alpha = 2\pi$.

Unlike Euclidean geometry, the area of a spherical triangle is completely determined by its angles (there are no similarity maps in spherical geometry), and the following formula was first found by A. Girard in 1625.

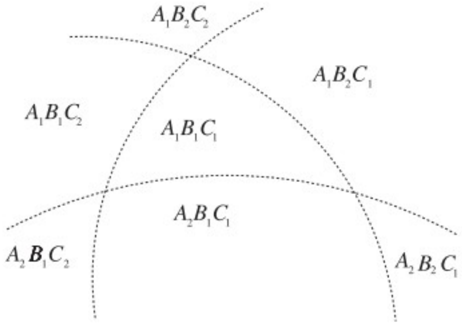

Figure 5.3.1

Theorem 5.3.1 *Let T be a spherical triangle with angles α, β and γ. Then $\mu(T) = \alpha + \beta + \gamma - \pi$.*

Proof The triangle T is formed from sides that lie on three great circles which we denote by $\mathcal{A}$, $\mathcal{B}$ and $\mathcal{C}$. The great circle $\mathcal{A}$ subdivides the sphere into two hemispheres which we denote by A_1 and A_2. We define B_1, B_2, C_1 and C_2 similarly, and these may be chosen so that $T = A_1 \cap B_1 \cap C_1$, with T having angles α, β and γ at its vertices on $\mathcal{B} \cap \mathcal{C}$, $\mathcal{C} \cap \mathcal{A}$ and $\mathcal{A} \cap \mathcal{B}$, respectively. Now $\mathcal{A}$, $\mathcal{B}$ and $\mathcal{C}$ divide the sphere into the eight triangles $A_i \cap B_j \cap C_k$, where $i, j, k = 1, 2$, and which, for brevity, we write as $A_i B_j C_k$. The triangle T $(= A_1 B_1 C_1)$) and its six neighbours are illustrated (symbolically) in Figure 5.3.1; the only triangle that does not appear in this illustration is $A_2 B_2 C_2$.

Now (for example) $A_1 B_1 C_1$ and $A_2 B_1 C_1$ together comprise a lune of angle α determined by the great circles $\mathcal{B}$ and $\mathcal{C}$. Thus we find that

$$\begin{aligned}
\mu(A_1 B_1 C_1) + \mu(A_2 B_1 C_1) &= 2\alpha; \\
\mu(A_1 B_1 C_1) + \mu(A_1 B_2 C_1) &= 2\beta; \\
\mu(A_1 B_1 C_1) + \mu(A_1 B_1 C_2) &= 2\gamma; \\
\mu(A_2 B_2 C_2) + \mu(A_1 B_2 C_2) &= 2\alpha; \\
\mu(A_2 B_2 C_2) + \mu(A_2 B_1 C_2) &= 2\beta; \\
\mu(A_2 B_2 C_2) + \mu(A_2 B_2 C_1) &= 2\gamma.
\end{aligned}$$

Adding each side of these six equations, and noting that

$$\mu(A_1 B_1 C_1) = \mu(A_2 B_2 C_2), \qquad \sum_{i,j,k=1}^{2} \mu(A_i B_j C_k) = 4\pi,$$

we see that $\mu(A_1 B_1 C_1) + \pi = \alpha + \beta + \gamma$ as required. □

The formula for the area of a triangle extends readily to the area of a spherical polygon.

Theorem 5.3.2 *Let P be a polygon on the sphere (with each of its n sides being an arc of a great circle), and let the interior angles of the polygon be $\theta_1, \dots, \theta_n$. Then the area $\mu(P)$ of the polygon is given by*

$$\mu(P) = \theta_1 + \cdots + \theta_n - (n-2)\pi. \tag{5.3.1}$$

The proof of (5.3.1) in the case of a *convex polygon* on the sphere is easy. Suppose that a polygon P has the property that there is some point $\mathbf{x}$ in P that can be joined to each vertex $\mathbf{v}_j$ by an arc of a great circle, with these arcs being non-intersecting (except at $\mathbf{x}$) and lying in P. Then these arcs divide P into n triangles, and applying Theorem 5.3.1 to each, and summing the results, we obtain (5.3.1). The proof of (5.3.1) for a non-convex polygon will be given in the next section. □

Exercise 5.3

1. Calculate the area of a spherical triangle all of whose angles are $\pi/2$, and also the area of a spherical triangle all of whose angles are $3\pi/2$.
2. For which values of θ is it possible to construct an equilateral spherical triangle with each angle equal to θ?
3. Prove the famous result of Archimedes that the area of the part of $\mathcal{S}$ that lies between the two parallel planes given, say, by $x_3 = a$ and $x_3 = b$, is the same as the area of the part of the circumscribing cylinder (given by $x_1^2 + x_2^2 = 1$) that lies between these two planes. Hence find the area of the 'polar cap' $\{\mathbf{x} \in \mathcal{S} : \delta(\mathbf{x}, \mathbf{k}) < r\}$.

5.4 Euler's formula

A spherical triangle T is a region of $\mathcal{S}$ bounded by three arcs σ_1, σ_2 and σ_3 of great circles. The arcs σ_j are the *edges* of T, and the three points $\sigma_i \cap \sigma_j$ are the *vertices* of T. A *triangulation* of the sphere $\mathcal{S}$ is a partitioning of $\mathcal{S}$ into a finite number of non-overlapping spherical triangles T_j such that the intersection of any two of the T_j is either empty, or a common edge, or a common vertex, of the two triangles. The *edges* of the triangulation are the edges of all of the T_j; the *vertices* of the triangulation are all of the vertices of the T_j.

The simplest example of a triangulation on the sphere (say, the surface of the Earth) is found by drawing the equator and n lines of longitude. In this case the triangulation contains $2n$ triangles, $n + 2$ vertices (n on the equator, and one at each pole), and $3n$ edges. If we denote the numbers of triangles (which we now call *faces*), edges and vertices by F, E and V, respectively, we find that $F - E + V = 2$; thus the expression $F - E + V$ *does not depend on the choice of* n. It is even more remarkable that the formula $F - E + V = 2$ holds for *all* triangulations of the sphere. This famous result is due to the Swiss mathematician Leonard Euler (1707–83) who was one of the most productive mathematicians of all time.

Euler's theorem *Suppose that a triangulation of* $\mathcal{S}$ *has* F *triangles,* E *edges and* V *vertices. Then* $F - E + V = 2$.

We shall give Legendre's beautiful proof that is based on the area of a spherical triangle.

Proof The area of a spherical triangle Δ with angles θ_1, θ_2 and θ_3 is $\theta_1 + \theta_2 + \theta_3 - \pi$. Suppose that there are F triangles, E edges and V vertices in a triangulation of the sphere. Then, summing over all angles in all triangles, the total angle sum is $2\pi V$ (for all of the angles occur at a vertex without overlap, and the angle sum at any one of these V vertices is exactly 2π). Also, the sum of the areas of the triangles is the area of the sphere; thus $2\pi V - F\pi = 4\pi$, or $2V = F + 4$. Now (by counting the edges of each triangle, and noting that this counts each edge twice), we obtain $3F = 2E$; thus

$$F - E + V = F - 3F/2 + (F + 4)/2 = 2.$$

□

There are various important extensions of Euler's theorem which we shall now discuss briefly and informally. A *spherical polygon* is a region bounded by a finite number of arcs of great circles in such a way that the arcs form a 'closed' curve on $\mathcal{S}$ that divides $\mathcal{S}$ into exactly two regions. A spherical polygon P is *convex* if any two points in P can be joined by an arc (of a great circle) that lies entirely within P. Now partition $\mathcal{S}$ into a finite number of non-overlapping convex spherical polygons (which now need not be spherical triangles), and suppose that there are F polygons (or faces), E edges (each edge counted only once), and V vertices (each vertex counted only once); then, again, $F - E + V = 2$. To prove this consider one face of the triangulation, and suppose that this is bounded by a polygonal closed curve that comprises m edges and m vertices, say $\mathbf{v}_j$. We take any point $\mathbf{x}$ in the face and join this to each $\mathbf{v}_j$ by a segment of a great circle, thus producing a triangulation of this face that includes, among its edges and vertices, all of the original edges and vertices of the face in the original partition. The contribution of this face (without its boundary) to the count $F - E + V$ from the new triangulation is 1, for it contributes m triangles, m edges and one vertex (at $\mathbf{x}$). As its contribution to $F - E + V$ in the original partition of $\mathcal{S}$ is also 1 (it contributes one to F and zero to E and V), it makes no difference to the count of $F - E + V$ whether we subdivide the face into triangles or not. If we carry out this subdivision for all faces, and then use Euler's theorem, we find that $F - E + V = 2$.

Next, suppose that we partition the sphere into convex polygons and that we then deform the partition continuously in such a way that the numbers F, E and V do not change during the deformation; then (obviously) after the deformation we still have $F - E + V = 2$. In particular, this will still be true when the edges are not necessarily arcs of great circles (or even arcs of any circles) providing that the given 'curvilinear partition' can be 'deformed' into a partition of the prescribed type in such a way that the numbers of faces, edges and vertices remains constant during the 'deformation'. Of course, all this is obvious; the difficulty (if one is to be rigorous) lies in the deformations.

Finally, we can extend this idea and now allow deformations of the sphere itself (together with any given partition of it). For example, as we can deform the sphere to a cube, the formula $F - E + V = 2$ will still hold for a cube. Indeed, if we partition the cube in the natural way into its six square faces, we see that $F = 6$, $E = 12$ and $V = 8$, so $F - E + V = 2$. If we wish, we can now divide each square face into two triangles by drawing one diagonal across each face, and then regard these diagonals together with the 'natural' edges of the cube as the edges of a new triangulation. This triangulation has twelve triangles, eighteen edges and eight vertices and again, $12 - 18 + 8 = 2$. Collectively, these ideas are described by saying that Euler's formula is a *topological invariant*, but we shall not discuss this any further.

Roughly speaking, a *polyhedron* is a 'closed' surface (that is, a surface with no bounding edges) made up by 'joining' polygons together along edges (of the same length), with the resulting surface being capable of being deformed into a sphere. We can also define a *convex polyhedron* to be the (non-empty) intersection of a finite number of half-spaces (a *half-space* is one 'side' of a plane); for example, a cube is easily seen to be the intersection of exactly six half-spaces. A convex polyhedron can be easily deformed into a sphere (by choosing a sphere which contains the polyhedron, and whose centre lies inside the polyhedron, and then projecting the polyhedron radially from the centre onto the sphere); thus, if a convex polyhedron has F faces, E edges and V vertices, then $F - E + V = 2$.

We complete this informal discussion by considering Euler's formula for a plane polygon. Suppose that a closed polygonal curve C (lying in the plane) divides the plane into two regions. Exactly one of these regions will be bounded, and we denote this by P. Suppose now that we triangulate P in the manner considered above. It seems clear that we can deform the polygon P until it lies on the 'southern hemisphere' of $\mathcal{S}$, in such a way that the boundary curve of P lies in the 'equator'. Then there will be, say, m vertices and m edges lying on the equator (for each edge ends at a vertex which is the starting point of the next edge). Let us now include the 'northern hemisphere' N, say, as one of the polygons on the sphere, with the m edges and m vertices being the edges and vertices of N regarded as a the polygon. Then we have constructed a partioning of $\mathcal{S}$ and, for this partition, $F - E + V = 2$. As we have simply added one face to the original picture, it follows that for the triangulation of the plane polygon P, we must have $F - E + V = 1$.

We end this section by completing the proof of Theorem 5.3.2.

The proof of Theorem 5.3.2 Let P be any polygon on the sphere. We extend each side of P to the great circle that contains it, and in this way we subdivide the sphere into a finite number of convex polygons. As each of these polygons either lies within P or outside of P, this shows that *we can subdivide any spherical polygon into a finite number of convex polygons*, and hence also *into a finite number of spherical triangles*.

Now take any polygon P on $\mathcal{S}$, and divide it into triangles T_j as described above. Suppose that the triangulation of P into these triangles T_j has F triangles, E edges and V vertices; then by Euler's formula (as described in the previous paragraph), $F - E + V = 1$. In order to describe the next step of the proof, let us denote the original polygonal curve by C, and its 'interior' (which we have just divided into triangles) by P_0. Suppose now that E_0 of the edges of this new triangulation lie on some side of C, so that $E - E_0$ edges lie in P_0. As each of the F triangles T_j has three sides, we see that $3F = E_0 + 2(E - E_0)$; thus $3F + E_0 = 2E$. We now compute areas. We suppose that the original polygon has n vertices with internal angles $\theta_1, \dots, \theta_n$ at these vertices. These vertices lie on C. Now E_0 of the V vertices in the new triangulation lie on C, and of these, n occur as original vertices of P (on C), while the remaining $E_0 - n$ occur as 'new' vertices lying on C (and interior to an original side of P). The angle sum at each of these $E_0 - n$ vertices is π. The remaining $V - E_0$ vertices are in P_0, and the angle sum at each of these vertices is 2π. Thus

$$\begin{aligned}\mu(P) &= \sum_{j=1}^{F} \mu(T_j)\\ &= (\theta_1 + \cdots + \theta_n) + (E_0 - n)\pi + (V - E_0)2\pi - \pi F\\ &= (\theta_1 + \cdots + \theta_n) - n\pi + (2V - F - E_0)\pi\\ &= (\theta_1 + \cdots + \theta_n) - (n-2)\pi,\end{aligned}$$

because $F - E + V = 1$ and $3F + E_0 = 2E$. □

Exercise 5.4

1. Verify Euler's formula for a 'pyramid' that has an n-gon as a base.
2. What is Euler's formula for a plane polygon from which two polygonal 'holes' have been removed?

5.5 Regular polyhedra

A *regular polyhedron* is a polyhdron that is made by joining together a finite number of congruent, regular polygons, each with p sides, and with exactly q polygons meeting at each vertex, and we say that this a regular polyhedron of *type* (p, q). The *faces* of the polyhedron are the regular p-gons, the *edges* are the segments where two faces are joined, and the *vertices* are the points at the ends of the edges. Such solids, which have a high degree of symmetry, are also known as *Platonic solids* (after Plato who associated them with earth, water, fire, air and the cosmos).

It is clear that if we are to construct a regular polyhedron of type (p, q), then we must be able to places q of the polygons together, in the plane and without overlapping, each having one vertex at the origin. Indeed, the sum of their angles at the origin must be strictly less than 2π, so that p and q must satisfy $q(\pi - 2\pi/p) < 2\pi$. Now this inequality is equivalent to

$$(p-2)(q-2) < 4 \tag{5.5.1}$$

and the only solutions (p, q) of this that are consistent with the obvious geometric constraints $p \geq 3$ and $q \geq 3$ are (3, 3), (3, 4), (3, 5), (4, 3) and (5, 3). In particular, there are at most five such polyhedra (up to scaling).

Now consider a regular polyhedron of type (p, q) and suppose that this has F faces, E edges and V. Then, by Euler's formula, $F - E + V = 2$. As each edge is the edge of exactly two faces, and each face has p edges, we see that $2E = pF$ (we simply count each 'side' of each edge in two different ways). Similarly, as each edge has two 'ends', and each vertex is the endpoint of q 'ends', we see that $2E = qV$. We now have three simultaneous equations, namely $F - E + V = 2$, $pF = 2E$ and $qV = 2E$, and if we solve these for F, E and V in terms of p and q, we find that

$$F = \frac{4q}{2p + 2q - pq}, \quad E = \frac{2pq}{2p + 2q - pq}, \quad V = \frac{4p}{2p + 2q - pq}, \tag{5.5.2}$$

Notice, from (5.5.1), that $2p + 2q - pq > 0$. If we now substitute the five distinct possibilities for (p, q) in the formulae in (5.5.2) we obtain the following

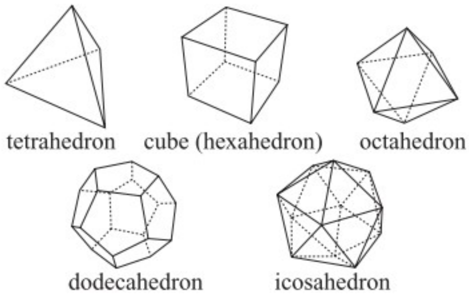

Figure 5.5.1

complete list of regular polyhedra:

polyhedron	*faces*	*edges*	*vertices*
tetrahedron	4	6	4
cube	6	12	8
octahedron	8	12	6
icosahedron	20	30	12
dodecahedron	12	30	20

Of course, this does not show that these solids do actually exist but they do (see Figure 5.5.1), and we shall accept this for the moment.

Finally, we remark that to obtain the Platonic solids it is not enough to merely assume that the faces of the polyhedron are congruent regular polygons. For example, we can attach five equilateral triangles together to form a pyramid with a regular pentagonal base and then join two of these pyramids together across their base; the resulting polyhedron has congruent faces that are equilateral triangles, but it is not a Platonic solid.

Exercise 5.5

1. Establish the formulae (5.5.2). These arise from three simultaneous equations; those who know about matrices should write these equations in matrix form and solve them by finding the inverse matrix. What is the determinant of the matrix?
2. The deficiency of a polyhedron is $2\pi V - \Theta$, where Θ is the sum of all the interior angles of all of its faces. Show that each of the five Platonic solids has deficiency 4π.
3. Show that the mid-points of the faces of a cube form the vertices of a regular octahedron.

4. Let A, B, C and D be the vertices of a regular tetrahedron. Show that the midpoints of the sides AB, BC, CD and DA are coplanar, and form the vertices of a square.

5.6 General polyhedra

In this section we shall examine several results that are closely related to Euler's formula. We have seen that the condition $F - E + V = 2$ is a *necessary* condition for the existence of a polyhedron (that can be deformed into a sphere) with F faces, E edges and V vertices. However, this is not the only necessary condition. Suppose that we 'cut' each edge of the polyhedron at its midpoint and then count the segments that are formed by this cutting. As each edge produces two segments, this count is clearly $2E$. On the other hand, every vertex has at least three segments ending there, and each segment ends at only one vertex; thus the count is at least $3V$. We conclude that $2E \geq 3V$. In a similar way, imagine that we have 'separated' the polyhedron into its faces, and that we now count the edges of all of these faces. Clearly this count is $2E$. On the other hand, each face has at least three sides so the count must be at least $3F$. We deduce that $2E \geq 3F$. Thus

$$F - E + V = 2, \quad 2E \geq 3V, \quad 2E \geq 3F. \tag{5.6.1}$$

are all necessary conditions for the existence of a polyhedron (that can be deformed into a sphere), with F faces, E edges and V vertices. These show that Euler's relation $F - E + V = 2$ is not by itself sufficient for the existence of a polyhedron; for example, there is no polyhedron with $F = 4$, $E = 7$ and $V = 5$ because for these values, $2E < 3V$.

Theorem 5.6.1 *There exists a convex polyhedron with F faces, E edges and V vertices if and only if* (5.6.1) *holds.*

Proof We know that (5.6.1) are necessary conditions for the existence of a polyhedron. To prove their sufficiency; we take positive integers F, E and V satisfying (5.6.1), and we divide the proof into two cases, namely (i) $V \geq F$ and (ii) $V < F$.

(i) Suppose that a convex polyhedron has f faces, e edges and v vertices, and that it has at least one vertex of valency three (that is, exactly three faces meet at the vertex). Then we can truncate the polyhedron at that vertex (that is, we can 'slice' the vertex from the polyhedron) and the resulting polyhedron has $f + 1$ faces, $e + 3$ edges and $v + 2$ vertices. As the resulting polyhedron also has vertices of valency three, we can repeat this operation as often as we wish, say t times, and so obtain a convex polyhedron with $f+t$ faces, $e+3t$ edges and $v+2t$ vertices. If we apply this to the polyhedron that is a pyramid P_m whose base is an m-gon (this has $m+1$ faces, $2m$ edges and $m+1$ vertices), the resulting polyhedron will have $m+1+t$ faces, $2m+3t$ edges and $m+1+2t$ vertices; thus it suffices to show that the equations

$$\begin{aligned} m+1+t &= F, \\ 2m+3t &= E, \\ m+1+2t &= V \end{aligned}$$

have a solution in integers m and t with $m \geq 3$ and $t \geq 0$. These equations are consistent (because $F-E+V=2$), and the solution is $t=V-F$ and $m=2F-V-1$. Finally, $t \geq 0$ by (i), and $m=2F-V-1=(2E-3V)+3 \geq 3$.

(ii) Suppose that a convex polyhedron has f faces, e edges and v vertices, and that one of the faces is triangular. Then we can glue a tetrahedron onto that face, and if the tetrahedron is sufficiently 'flat' the resulting polyhedron will be convex, with a triangular face, and it will have $f+2$ faces, $e+3$ edges and $v+1$ vertices. If we do this t times we obtain a convex polyhedron with $f+2t$ faces, $e+3t$ edges and $v+t$ vertices. If the original polyhedron is the polyhedron P_m used above, the resulting polyhedron will have $m+1+2t$ faces, $2m+3t$ edges and $m+1+t$ vertices, and we now have to solve the equations

$$\begin{aligned} m+1+2t &= F, \\ 2m+3t &= E, \\ m+1+t &= V, \end{aligned}$$

again with $t \geq 0$ and $m \geq 3$. These equations are consistent, with solution $t=F-V$ and $m=2V-F-1$. By (ii), $t>0$, and $m=2V-F-1=(2E-3F)+3 \geq 3$. □

Our next result was known to Euler. Consider a polyhedron with F faces, E edges and V vertices. To examine the geometry in greater detail, let F_n be the number of faces with exactly n edges (so F_3 is the number of triangular faces, and so on), and let V_m be the number of vertices which have exactly m edges ending at that vertex (equivalently, exactly m faces containing that vertex). Clearly,

$$F=F_3+F_4+\cdots, \quad V=V_3+V_4+\cdots. \tag{5.6.2}$$

Theorem 5.6.2

(1) *For any polyhedron,* $3F_3 + 2F_4 + F_5 \geq 12$. *In particular, among all of the faces of a polyhedron, there are at least four faces each of which has at most five edges.*
(2) *For any polyhedron,* $F_3 + V_3 \geq 8$. *In particular, any polyhedron has either a triangular face, or a vertex with exactly three edges meeting at that vertex (or both).*
(3) *The integers* $F_3 + F_5 + F_7 + \cdots$ *and* $V_3 + V_5 + V_7 + \cdots$ *are even.*

Remark There is equality in (1) and (2) in the case of the tetrahedron and the cube, so both inequalities are best possible. Note that (1) implies that one cannot make a polyhedron (however large and complicated) out of a 'random' collection of, say, hexagons. This is not obvious!

Proof As every edge bounds exactly two faces, we have

$$2E = 3F_3 + 4F_4 + 5F_5 + \cdots,$$

and as every edge contains exactly two vertices,

$$2E = 3V_3 + 4V_4 + 5V_5 + \cdots.$$

This proves (3). To prove (2), we note that (summing over $k = 3, 4 \ldots$)

$$\begin{aligned}\sum(4-k)F_k + \sum(4-k)V_k &= 4\sum F_k + 4\sum V_k - \sum kF_k - \sum kV_k \\ &= 4F + 4V - 2E - 2E \\ &= 8.\end{aligned}$$

This shows that

$$F_3 + V_3 = 8 + \sum_{k\geq 5}(k-4)(F_k + V_k) \geq 8, \tag{5.6.3}$$

which is stronger than (2). Finally, Euler's relation in the form

$$6\sum F_k + 6\sum V_k = 12 + \sum kF_k + 2\sum kV_k$$

leads to the identity

$$3F_3 + 2F_4 + F_5 = 12 + \sum_{k\geq 6}(k-6)F_k + \sum_{k\geq 3}(2k-6)V_k \geq 12,$$

and this gives (1). □

We end this chapter with a result, due to Descartes, that is equivalent to Euler's formula. The *deficiency of a vertex* v of a polyhedron P is $2\pi - \sum_j \theta_j$, where the θ_j are the angles at v of the faces that meet at v. The *total deficiency* of P is the sum of the deficiencies of each of its vertices. For example, if P is a cube, then the deficiency of each vertex is $\pi/2$, and so the total deficiency of a cube is 4π. This is no accident.

Descartes' theorem *The total deficiency of any polyhedron is* 4π.

Proof We suppose that a polyhedron has F faces, E edges and V vertices. We have seen that $F = \sum_{m\geq 3} F_m$ and $2E = \sum_{m\geq 3} mF_m$. Thus

$$\begin{aligned} 2(F - E + V) &= 2V - (2E - 2F) \\ &= 2V - \sum_{m\geq 3}(m-2)F_m. \end{aligned}$$

As the sum of the interior angle of an m-gon is $(m-2)\pi$, the total deficiency of the polyhedron is D, where

$$D = 2\pi V - \sum_m (m-2)F_m\pi = 2(F - E + V)\pi.$$

It follows that $D = 4\pi$ *if and only if* $F - E + V = 2$; thus Descartes' theorem is equivalent to Euler's theorem. □

Exercise 5.6

1. Prove (in the notation of the text) that $3V_3 + 2V_4 + V_5 \geq 12$.
2. We have seen that $F_3 + V_3 \geq 8$. Suppose that $F_3 + V_3 = 8$. Use (5.6.3) to show that F_3 and V_3 are even, so that the possible values of (F_3, V_3) are $(0, 8)$, $(2, 6)$, $(4, 4)$, $(6, 2)$ and $(8, 0)$. Show that each of these pairs is attained by some polyhedron.
3. A *deltahedron* is a polyhdedron (that can be deformed into a sphere) whose faces are congruent equilateral triangles. Show that every vertex of a convex deltahedron has valency at most five. Deduce that for any convex deltahedron, (F, E, V) must be of the form $(2k, 3k, k+2)$, where $k = 2, 3, \ldots, 10$. In fact, convex deltahedra exist for all of these k except 9. There exists such a polyhedron with eighteen triangular 'faces', but some of these 'faces' are coplanar.

Quaternions and isometries

6.1 Isometries of Euclidean space

Our first objective is to understand isometries of $\mathbb{R}^3$.

Definition 6.1.1 A map $f : \mathbb{R}^3 \to \mathbb{R}^3$ is an *isometry* if it preserves distances; that is, if for all $\mathbf{x}$ and $\mathbf{y}$, $||f(\mathbf{x}) - f(\mathbf{y})|| = ||\mathbf{x} - \mathbf{y}||$.

Each reflection across a plane is an isometry, and we shall see later that every isometry is a composition of reflections. Consider the plane Π given by $\mathbf{x}{\cdot}\mathbf{n} = d$, where $||\mathbf{n}|| = 1$, and let R be the reflection across Π. As $\mathbf{n}$ is the normal to Π, we see that $R(\mathbf{x}) = \mathbf{x} + 2t\mathbf{n}$, where t is chosen so that the midpoint, $\mathbf{x} + t\mathbf{n}$, of $\mathbf{x}$ and $R(\mathbf{x})$ lies on Π. This last condition gives $d = \mathbf{x}{\cdot}\mathbf{n} + t$, so that

$$R(\mathbf{x}) = \mathbf{x} + 2(d - \mathbf{x}{\cdot}\mathbf{n})\mathbf{n}. \tag{6.1.1}$$

It is geometrically obvious that (a) $R(\mathbf{x}) = \mathbf{x}$ if and only if $\mathbf{x} \in \Pi$, (b) for all $\mathbf{x}$, $R(R(\mathbf{x})) = \mathbf{x}$, and (c) R is an isometry. These properties can be verified algebraically from (6.1.1), as can the next result.

Theorem 6.1.2 *A reflection across a plane* Π *is a linear map if and only if* $0 \in \Pi$.

Now consider two parallel planes, say $\mathbf{x}{\cdot}\mathbf{n} = d_1$ and $\mathbf{x}{\cdot}\mathbf{n} = d_2$, and let R_1 and R_2 denote the reflections in these planes. It is easy to see that $R_1R_2(\mathbf{x}) = \mathbf{x} + 2(d_1 - d_2)\mathbf{n}$, so that *the composition of two reflections in parallel planes is a translation* (and conversely). Clearly, the translation is by $2d\mathbf{n}$, where $\mathbf{n}$ is the common normal of the two planes, and d is their distance apart.

Next, we consider the composition of reflections R_j in two distinct intersecting planes Π_1 and Π_2. The planes intersect in a line L, and each R_j fixes every point of L. In addition, $R_j(\Pi) = \Pi$ for every plane Π that is orthogonal to L. The action of R_2R_1 on Π is a reflection across the line $\Pi \cap \Pi_1$ followed by a reflection across the line $\Pi \cap \Pi_2$; thus we see that *$R_2 R_1$ is a rotation of $\mathbb{R}^3$ about the axis L of an angle equal to twice the angle between the planes* Π_j. This leads us to the following definition of a rotation.

Definition 6.1.3 A *rotation* of $\mathbb{R}^3$ is the composition of reflections across two distinct non-parallel planes. The line of intersection of the planes is the *axis* of the rotation.

Notice that the fact that every rotation has an axis is part of our definition of a rotation. Later we will give an alternative (but equivalent) definition of a rotation in terms of matrices, but then we will need to *prove* that every rotation has an axis. As a rotation of $\mathbb{R}^2$ has one fixed point and no axis, the proof cannot be entirely trivial (in fact, it depends on the fact that every real cubic polynomial has a real root). Each rotation of an odd-dimensional space has an axis, but a rotation of an even-dimensional space need not have an axis (because, as we shall see later, every real polynomial of odd degree has a real root, whereas a real polynomial of even degree need not have any real roots). As each reflection is an isometry, so is any composition of reflections. The converse is also true, and in the following stronger form.

Theorem 6.1.4 *Every isometry of $\mathbb{R}^3$ is the composition of at most four reflections. In particular, every isometry is a bijection of $\mathbb{R}^3$ onto itself. Every isometry that fixes $\mathbf{0}$ is the composition of at most three reflections in planes that contain $\mathbf{0}$.*

A reflection R across a plane is a permutation of $\mathbb{R}^3$ whose square is the identity map. Thus, in some sense, Theorem 6.1.4 is analogous to the result that a permutation of a finite set can be expressed as a product of transpositions. The common feature of these two results (and other results too) is that a given map f is being expressed as a composition of simpler maps f_j for which $f_j^2 = I$. Our proof of Theorem 6.1.4 is based on the following three simple results.

Lemma 6.1.5 *Suppose that f is an isometry with $f(\mathbf{0}) = \mathbf{0}$. Then for all $\mathbf{x}$ and $\mathbf{y}$, $||f(\mathbf{x})|| = ||\mathbf{x}||$ and $f(\mathbf{x}){\cdot}f(\mathbf{y}) = \mathbf{x}{\cdot}\mathbf{y}$ (that is, f preserves norms and scalar products).*

Proof First, $||f(\mathbf{x})|| = ||f(\mathbf{x}) - f(\mathbf{0})|| = ||\mathbf{x} - \mathbf{0}|| = ||\mathbf{x}||$, so that f preserves norms. Next,

$$\begin{aligned} ||f(\mathbf{x})||^2 + ||f(\mathbf{y})||^2 - 2\big(f(\mathbf{x}){\cdot}f(\mathbf{y})\big) &= ||f(\mathbf{x}) - f(\mathbf{y})||^2 \\ &= ||\mathbf{x} - \mathbf{y}||^2 \\ &= ||\mathbf{x}||^2 + ||\mathbf{y}||^2 - 2(\mathbf{x}{\cdot}\mathbf{y}), \end{aligned}$$

so that f also preserves scalar products. □

Lemma 6.1.6 *If an isometry f fixes* $\mathbf{0}$, $\mathbf{i}$, $\mathbf{j}$ *and* $\mathbf{k}$ *then* $f = I$.

Proof Let $f(\mathbf{x}) = \mathbf{y}$. Then $||\mathbf{y} - \mathbf{i}|| = ||f(\mathbf{x}) - f(\mathbf{i})|| = ||\mathbf{x} - \mathbf{i}||$, and as $||\mathbf{y}|| = ||\mathbf{x}||$, we have $\mathbf{y}{\cdot}\mathbf{i} = \mathbf{x}{\cdot}\mathbf{i}$. The same holds for $\mathbf{j}$ and $\mathbf{k}$, so that $\mathbf{y} - \mathbf{x}$ is orthogonal to $\mathbf{i}$, $\mathbf{j}$ and $\mathbf{k}$. Thus $\mathbf{y} = \mathbf{x}$. □

Lemma 6.1.7 *Suppose that* $||\mathbf{a}|| = ||\mathbf{b}|| \neq 0$. *Then there is a reflection R across a plane Π through* $\mathbf{0}$ *such that* $R(\mathbf{a}) = \mathbf{b}$ *and* $R(\mathbf{b}) = \mathbf{a}$.

Proof We may suppose that $\mathbf{a} \neq \mathbf{b}$, since if $\mathbf{a} = \mathbf{b}$ we can take any plane Π through $\mathbf{0}$ and $\mathbf{a}$. Our geometric intuition tells us that Π should be $\mathbf{x}{\cdot}\mathbf{n} = 0$, where $\mathbf{n} = (\mathbf{a} - \mathbf{b})/(||\mathbf{a} - \mathbf{b}||$, so let R be the reflection in this plane. Then $R(\mathbf{x}) = \mathbf{x} - 2(\mathbf{x}{\cdot}\mathbf{n})\mathbf{n}$, and a computation shows that $R(\mathbf{a}) = \mathbf{b}$. Note the use of the identity $2\mathbf{a}{\cdot}(\mathbf{a} - \mathbf{b}) = ||\mathbf{a} - \mathbf{b}||^2$ in this computation. □

The proof of Theorem 6.1.4 Let f be any isometry of $\mathbb{R}^3$. If $f(\mathbf{0}) \neq \mathbf{0}$ then then there is a reflection R_1 that interchanges $\mathbf{0}$ and $f(\mathbf{0})$. If f fixes $\mathbf{0}$, we let $R_1 = I$. Thus $R_1 f$ is an isometry that fixes $\mathbf{0}$, and we let $f_1 = R_1 f$. As $||f_1(\mathbf{k})|| = ||\mathbf{k}||$ there is a reflection R_2 in some plane through the origin that interchanges $f_1(\mathbf{k})$ and $\mathbf{k}$; thus $R_2 f_1$ is an isometry that fixes $\mathbf{0}$ and $\mathbf{k}$. Let $f_2 = R_2 f_1$, and note that by Lemma 6.1.5, $f(\mathbf{i})$ and $f(\mathbf{j})$ are orthogonal unit vectors in the plane $\mathbf{x}{\cdot}\mathbf{k} = 0$. There is a reflection R_3 in some vertical plane through the origin that maps $f(\mathbf{j})$ to $\mathbf{j}$ (and fixes $\mathbf{0}$ and $\mathbf{k}$) so that now, $R_3 f_2$ fixes $\mathbf{0}$, $\mathbf{j}$ and $\mathbf{k}$. Let $f_3 = R_3 f_2$; then f_3 maps $\mathbf{i}$ to $\pm\mathbf{i}$. If f_3 fixes $\mathbf{i}$, let $R_4 = I$. If not, let R_4 be the reflection in $\mathbf{x}{\cdot}\mathbf{i} = 0$. Then Lemma 6.1.6 implies that $R_4 f_3 = I$, so that $f = R_1 R_2 R_3 R_4$. □

A slight modification of the proof just given yields the next result.

Theorem 6.1.8 *The most general isometry f is of the form* $f(\mathbf{x}) = A(\mathbf{x}) + f(\mathbf{0})$, *where A is a linear map.*

Proof Suppose that f is an isometry. Then $A(\mathbf{x}) = f(\mathbf{x}) - f(\mathbf{0})$ is an isometry that fixes $\mathbf{0}$, and the proof of Theorem 6.1.4 shows that g is a composition of (at most three) reflections in planes through $\mathbf{0}$. As each such reflection is a linear map, so is A. □

It is clear that the composition of two isometries is an isometry, and the composition of functions is always associative. Trivially, the identity map is an isometry. If we write an isometry f as a composition, say $R_1 \cdots R_p$, of reflections R_j, then $f^{-1} = R_p \cdots R_1$ and this is an isometry. This proves the next result.

Theorem 6.1.9 *The set of isometries of* $\mathbb{R}^3$ *is a group with respect to composition.*

Although it may seem obvious that the inverse of an isometry f is an isometry, one has to prove (somewhere) that f^{-1} exists, and also that it is defined on $\mathbb{R}^3$.

We have seen that every isometry can be expressed as the composition of at most four reflections, and we want to give an example of an isometry that cannot be expressed as a composition of fewer than four reflections. We need some preliminary remarks. The reflection R given in (6.1.1) can be written as $R = T\tilde{R}$, where $\tilde{R}$ is the reflection in the plane $\mathbf{x}{\cdot}\mathbf{n} = 0$, and $T(\mathbf{x}) = \mathbf{x} + 2d\mathbf{n}$. Thus every reflection is a reflection in a plane through $\mathbf{0}$ followed by a translation. Suppose we have (with the obvious notation) $R_1(\mathbf{x}) = \tilde{R}_1(\mathbf{x}) + \mathbf{a}_1$, and similarly for R_2. Then, as $\tilde{R}_1$ is linear, we have

$$R_1R_2(\mathbf{x}) = \tilde{R}_1\big(\tilde{R}_2(\mathbf{x}) + \mathbf{a_2}\big) + \mathbf{a}_1 = \tilde{R}_1\tilde{R}_2(\mathbf{x}) + \tilde{R}_1(\mathbf{a_2}) + \mathbf{a}_1.$$

A similar argument applies to any composition of reflections; thus *given reflections $R_1, \dots, R_n$ there are reflections $\tilde{R}_1, \dots, \tilde{R}_n$ across planes through the origin, and a vector* $\mathbf{b}$*, such that* $R_1 \cdots R_n(\mathbf{x}) = \tilde{R}_1 \cdots \tilde{R}_n(\mathbf{x}) + \mathbf{b}$. We can now give our example.

Example 6.1.10 Let f be the isometry defined as the rotation of angle π about the $\mathbf{k}$-axis followed by the translation $\mathbf{x} \mapsto \mathbf{x} + \mathbf{k}$; thus f is a 'screw motion' which is given explicitly by $(x_1, x_2, x_3) \mapsto (-x_1, -x_2, x_3 + 1)$. Let A_1 and A_2 be the reflections in the planes $\mathbf{x}{\cdot}\mathbf{i} = 0$ and $\mathbf{x}{\cdot}\mathbf{j} = 0$, respectively; then $f(\mathbf{x}) = A_1A_2(\mathbf{x}) + \mathbf{k}$. Now suppose that f can be written as a composition of p reflections and, as above, write $f(\mathbf{x}) = \tilde{R}_1 \cdots \tilde{R}_p(\mathbf{x}) + \mathbf{b}$, where each $\tilde{R}_j$ is a reflection in a plane through $\mathbf{0}$. As $\mathbf{b} = f(\mathbf{0}) = \mathbf{k}$, we find that $A_2A_1 = \tilde{R}_1 \cdots \tilde{R}_p$. We shall prove below that if Q is any reflection in a plane though the origin then, for all vectors $\mathbf{x}$, $\mathbf{y}$ and $\mathbf{z}$, $[Q(\mathbf{x}), Q(\mathbf{y}), Q(\mathbf{z})] = -[\mathbf{x}, \mathbf{y}, \mathbf{z}]$ (this is because Q reverses the orientation of the vectors). Repeated applications of this rule applied to A_1A_2 and to $\tilde{R}_1 \cdots \tilde{R}_p$ give $(-1)^2 = (-1)^p$ so that p is even. It is clear that f is not the composition of exactly two reflections (for then f would be a translation, or would have a line of fixed points); thus f cannot be expressed as the composition of fewer than four reflections. □

The next result (which we have used in Example 6.1.10) shows how scalar and vector products behave under a reflection in a plane through the origin. In particular, such a reflection reverses the orientation of any three vectors, and this fact was used in Example 6.1.10.

Theorem 6.1.11 *Let R be the reflection in a plane Π that contains the origin. Then for all vectors* $\mathbf{x}$, $\mathbf{y}$ *and* $\mathbf{z}$,

$$R(\mathbf{x})\cdot R(\mathbf{y}) = \mathbf{x}\cdot\mathbf{y}, \tag{6.1.2}$$

$$R(\mathbf{x}) \times R(\mathbf{y}) = -R(\mathbf{x}\times\mathbf{y}), \tag{6.1.3}$$

$$[R(\mathbf{x}), R(\mathbf{y}), R(\mathbf{z})] = -[\mathbf{x}, \mathbf{y}, \mathbf{z}]. \tag{6.1.4}$$

Proof We may assume that Π is given by $\mathbf{x}\cdot\mathbf{n} = 0$, where $||\mathbf{n}|| = 1$, so that $R(\mathbf{x}) = \mathbf{x} - 2(\mathbf{x}\cdot\mathbf{n})\mathbf{n}$, and (6.1.2) follows immediately. Next, (6.1.3) follows from two applications of the formula (4.5.1) for the vector triple product, for

$$\begin{aligned} R(\mathbf{x}) \times R(\mathbf{y}) &= (\mathbf{x}\times\mathbf{y}) - 2(\mathbf{x}\cdot\mathbf{n})(\mathbf{n}\times\mathbf{y}) - 2(\mathbf{y}\cdot\mathbf{n})(\mathbf{x}\times\mathbf{n}) \\ &= (\mathbf{x}\times\mathbf{y}) - 2\mathbf{n}\times\big[(\mathbf{x}\cdot\mathbf{n})\mathbf{y} - (\mathbf{y}\cdot\mathbf{n})\mathbf{x}\big] \\ &= (\mathbf{x}\times\mathbf{y}) - 2\mathbf{n}\times\big[\mathbf{n}\times(\mathbf{y}\times\mathbf{x})\big] \\ &= (\mathbf{x}\times\mathbf{y}) - 2\big[\big(\mathbf{n}\cdot(\mathbf{y}\times\mathbf{x})\big)\mathbf{n} - (\mathbf{y}\times\mathbf{x})\big] \\ &= -R(\mathbf{x}\times\mathbf{y}). \end{aligned}$$

This proves (6.1.3). Finally, (6.1.4) holds because

$$\begin{aligned} [R(\mathbf{x}), R(\mathbf{y}), R(\mathbf{z})] &= R(\mathbf{x})\cdot\big(R(\mathbf{y})\times R(\mathbf{z})\big) \\ &= -R(\mathbf{x})\cdot\big(R(\mathbf{y}\times\mathbf{z})\big) \\ &= -\mathbf{x}\cdot(\mathbf{y}\times\mathbf{z}) \\ &= -[\mathbf{x}, \mathbf{y}, \mathbf{z}]. \end{aligned}$$

□

It is now clear how scalar and vector products behave under rotations that fix the origin; *if A is a rotation about the origin, then*

$$A(\mathbf{x})\cdot A(\mathbf{y}) = \mathbf{x}\cdot\mathbf{y}, \quad A(\mathbf{x})\times A(\mathbf{y}) = A(\mathbf{x}\times\mathbf{y}), \tag{6.1.5}$$

and

$$[A(\mathbf{x}), A(\mathbf{y}), A(\mathbf{z})] = [\mathbf{x}, \mathbf{y}, \mathbf{z}].$$

Note that rotations about the origin preserve the orientation of vectors, and this leads to our final result (which is proved without reference to matrices).

Theorem 6.1.12 *The set of rotations of $\mathbb{R}^3$ that fix $\mathbf{0}$ is a group with respect to composition.*

Proof We need only show that the composition of two rotations is again a rotation, for the rest of the requirements for a group are easily verified. Let

$R_3 = R_2R_1$, where R_1 and R_2 are rotations that fix $\mathbf{0}$. As we have remarked above, each rotation, and therefore R_3 also, preserves the orientation of vectors, and this shows that if we express R_3 as a composition of, say, p reflections in planes through the origin, then p is even. However, by Theorem 6.1.4, R_3 can be expressed as a composition of at most three reflections; thus we must be able to express R_3 as a composition of exactly two reflections, and hence R_3 is a rotation. □

Let f be an isometry, say $f(\mathbf{x}) = \mathbf{x}_0 + A(\mathbf{x})$, where A is the identity map I, or a composition of k reflections in planes through the origin, where k is one, two or three. We say that A is a *direct* isometry if $A = I$ or $k = 2$; otherwise we say that f is *indirect*. Direct isometries preserve orientation; indirect isometries reverse orientation.

Definition 6.1.13 A *screw-motion* in $\mathbb{R}^3$ is a rotation about some line in $\mathbb{R}^3$, followed by a translation in the direction of that that line.

We include the possibilities that the rotation is trivial (so the screw-motion is a translation) and that the translation is trivial (so that the screw-motion is a rotation). It is clear that every screw-motion is a direct isometry of $\mathbb{R}^3$; it is less clear that the converse is true.

Theorem 6.1.14 *Every direct isometry of $\mathbb{R}^3$ is a screw-motion.*

Proof As every translation is a screw-motion, we may confine our attention to a direct isometry f that is of the form $f(\mathbf{x}) = \mathbf{x}_0 + A(\mathbf{x})$, where A is a rotation (so $k = 2$). We choose a vector, say $\mathbf{a}$, lying along the axis of A. If $\mathbf{x}_0$ is a scalar multiple of $\mathbf{a}$, there is nothing to prove, but, in general, this will not be so.

A rotation of the same angle as A, but whose axis is a line in the direction $\mathbf{a}$, and passing through a point $\mathbf{w}$, is given by $\mathbf{x} \mapsto \mathbf{w} + A(\mathbf{x} - \mathbf{w})$; thus we need to be able to show that f can be written in the form $f(\mathbf{x}) = \mathbf{w} + A(\mathbf{x} - \mathbf{w}) + \lambda\mathbf{a}$ for some vector $\mathbf{w}$ and some real λ. Equivalently, because A is linear (so that $A(\mathbf{x} - \mathbf{w}) = A(\mathbf{x}) - A(\mathbf{w})$), we need to be able to find $\mathbf{w}$ and λ such that $\mathbf{x}_0 = \mathbf{w} - A(\mathbf{w}) + \lambda\mathbf{a}$. Now write $\mathbf{x}_0$ in the form $\mathbf{x}_1 + \mu\mathbf{a}$, where $\mathbf{x}_1 \perp \mathbf{a}$; then we need $\mathbf{w}$ and λ to satisfy $\mathbf{w} - A(\mathbf{w}) + \lambda\mathbf{a} = \mathbf{x}_1 + \mu\mathbf{a}$. We take $\lambda = \mu$, and then seek a solution $\mathbf{w}$ of $\mathbf{w} - A(\mathbf{w}) = \mathbf{x}_1$. If W is the plane given by $\mathbf{x}{\cdot}\mathbf{a} = 0$, it is apparent (by elementary geometry, or by using complex numbers) that there is some $\mathbf{w}$ in W such that $\mathbf{w} - A(\mathbf{w}) = \mathbf{x}_1$ and the proof is complete. □

Finally, we consider the following natural problem. Given rotations R_1 and R_2, how can we find the axis and angle of rotation of the rotation R_2R_1? One way is to let Π_0 be the plane containing the axes (which we may assume are distinct) of R_1 and R_2, and let α_0 be the reflection across Π_0. Then choose planes

Π_1 and Π_2 (both containing $\mathbf{0}$) so that if α_1 and α_2 denote reflections across these planes, then $R_2 = \alpha_2\alpha_0$ and $R_1 = \alpha_0\alpha_1$. Then $R_2R_1 = \alpha_2\alpha_0\alpha_0\alpha_1 = \alpha_2\alpha_1$. Further, if we examine the intersection of these planes with the unit sphere, then the calculations of angles and distances involved are a matter of spherical (rather than Euclidean) geometry. We also give an algebraic solution to this problem in terms of quaternions (in Section 6.3), and in terms of matrices (in Chapter 11).

Exercise 6.1

1. Find the formula for the reflection in the plane $x_2 = 0$ followed by the reflection in the plane $x_3 = 0$. Find the fixed points of this transformation, and identify it geometrically.
2. Given unit vectors **a** and **b**, let $R_{\mathbf{a}}$ be the reflection across the plane $\mathbf{x}{\cdot}\mathbf{a}$, and similarly for $R_{\mathbf{b}}$. Show that $R_{\mathbf{a}}R_{\mathbf{b}} = R_{\mathbf{b}}R_{\mathbf{a}}$ if and only if $\mathbf{a} \perp \mathbf{b}$.
3. Let $R_{\mathbf{a}}$ and $R_{\mathbf{b}}$ be the reflections in $\mathbf{x}{\cdot}\mathbf{a} = 0$ and $\mathbf{x}{\cdot}\mathbf{b} = 0$, respectively, where $||\mathbf{a}|| = 1$ and $||\mathbf{b}|| = 1$. Find a formula for the composition $R_{\mathbf{a}}(R_{\mathbf{b}}(\mathbf{x}))$. This composition of reflections is a rotation whose axis is the line of intersection of the two planes. Explain why this axis is the set of scalar multiples of $\mathbf{a} \times \mathbf{b}$, and verify analytically that both $R_{\mathbf{a}}$ and $R_{\mathbf{b}}$ fix every scalar multiple of $\mathbf{a} \times \mathbf{b}$.
4. Let L_1, L_2 and L_3 be three lines in the complex plane $\mathbb{C}$, each containing the origin, and let R_j be the reflection (of $\mathbb{C}$ into itself) across L_j. Show that $R_1R_2R_3$ is a reflection across some line in $\mathbb{C}$. Show, however, that if the L_j do not have a common point then $R_1R_2R_3$ need not be a reflection.
5. Suppose that $R_1, \dots, R_p, S_1, \dots, S_q$ are all reflections across planes that contain $\mathbf{0}$. Show that if $R_1 \cdots R_p = S_1 \cdots S_q$ then $(-1)^p = (-1)^q$. Compare this result with the definition of the signature of a permutation.

6.2 Quaternions

In 1843 Hamilton introduced quaternions as a way to generalize the algebra of complex numbers to higher dimensions. We shall use them to represent reflections and rotations in $\mathbb{R}^3$ algebraically. There are various equivalent ways of describing quaternions but fundamentally they are points in Euclidean four-dimensional space $\mathbb{R}^4$. Before we consider the various representations of quaternions it is convenient to introduce the idea of a Cartesian product of two sets. Given any two sets A and B, the Cartesian product set, which we denote by $A \times B$, is the set of all ordered pairs (a, b), where $a \in A$ and $b \in B$. In as far as there is a natural identification of the objects

$$(w, x, y, z), \quad \big((w, x), (y, z)\big), \quad \big(w, (x, y, z)\big),$$

in $\mathbb{R}^4$, $\mathbb{R}^2 \times \mathbb{R}^2$ and $\mathbb{R} \times \mathbb{R}^3$, respectively, we can identify each of these spaces with the others. Formally, a complex number is an ordered pair of real numbers so that $\mathbb{C} = \mathbb{R}^2$ (this really is equality here, and no identification is necessary), so we can add $\mathbb{C} \times \mathbb{C}$ to this list. Notice that a point in $\mathbb{R} \times \mathbb{R}^3$ is an ordered pair $(a, \mathbf{x})$, where $a \in \mathbb{R}$ and $\mathbf{x} \in \mathbb{R}^3$, and we can write this as $a + x_1\mathbf{i} + x_2\mathbf{j} + x_3\mathbf{k}$.

Definition 6.2.1 A *quaternion* is an expression $a + b\mathbf{i} + c\mathbf{j} + d\mathbf{k}$, where a, b, c and d are real numbers. The set of quaternions is denoted by $\mathbb{H}$.

We now define an addition and a multiplication on the set $\mathbb{H}$ of quaternions, and it is sufficient to do this (and to carry out any subsequent calculations) in any of the models given above since a statement about one model can be converted on demand into a statement about another model. The addition of quaternions is just the natural vector addition in $\mathbb{R}^4$, namely

$$(x_1, x_2, x_3, x_4) + (y_1, y_2, y_3, y_4) = (x_1 + y_1, x_2 + y_2, x_3 + y_3, x_4 + y_4),$$

and clearly $\mathbb{R}^4$ is an abelian group with respect to addition. In terms of the representation in $\mathbb{R} \times \mathbb{R}^3$ this becomes $(a, \mathbf{x}) + (b, \mathbf{y}) = (a + b, \mathbf{x} + \mathbf{y})$, and in terms of $\mathbb{C} \times \mathbb{C}$ it is $(z_1, z_2) + (w_1, w_2) = (z_1 + w_1, z_2 + w_2)$.

The multiplication of quaternions is rather special. We recall how in Section 3.1 we motivated the multiplication of complex numbers by considering the formal product

$$(x + iy)(u + iv) = ux + i(xv + yu) + yvi^2,$$

and then imposing the condition that $i^2 = -1$ to return us to something of the form $p + iq$. We shall now adopt a similar strategy for quaternions. We write the general quaternion as $a + b\mathbf{i} + c\mathbf{j} + d\mathbf{k}$ and then, using the distributive laws, we take a formal product of two such expressions. We now need to specify what we mean by the products of any two of $\mathbf{i}$, $\mathbf{j}$ and $\mathbf{k}$, and these are specified as follows:

(1) $\mathbf{i}^2 = \mathbf{j}^2 = \mathbf{k}^2 = -1$, and
(2) $\mathbf{ij} = \mathbf{k} = -\mathbf{ji}, \quad \mathbf{jk} = \mathbf{i} = -\mathbf{kj}, \quad \mathbf{ki} = \mathbf{j} = -\mathbf{ik}$.

Notice that the product of one of these vectors with itself is a *scalar*; otherwise the product is a vector. Note also how (2) mimics the vector product of these vectors, and (1) mimics the formula $i^2 = -1$. We shall also assume that any real number commutes with each of the vectors $\mathbf{i}$, $\mathbf{j}$ and $\mathbf{k}$; for example, $3\mathbf{j} = \mathbf{j}3$. Of course, we could rewrite this whole discussion formally in terms of four-tuples of real numbers, but to do so would not contribute to an understanding of the underlying ideas. Indeed, the following example is probably more useful:

$$\begin{aligned}(2+3\mathbf{i}-4\mathbf{k})(\mathbf{i}-2\mathbf{j}) &= 2(\mathbf{i}-2\mathbf{j})+3\mathbf{i}(\mathbf{i}-2\mathbf{j})-4\mathbf{k}(\mathbf{i}-2\mathbf{j})\\ &= 2\mathbf{i}-4\mathbf{j}+3\mathbf{i}^2-6\mathbf{ij}-4\mathbf{ki}+8\mathbf{kj}\\ &= 2\mathbf{i}-4\mathbf{j}-3-6\mathbf{k}-4\mathbf{j}-8\mathbf{i}\\ &= -3-6\mathbf{i}-8\mathbf{j}-6\mathbf{k}.\end{aligned}$$

We note that the set of quaternions is closed under multiplication, but that multiplication is *not* commutative (for example, $\mathbf{ij} \neq \mathbf{ji}$); the reader should constantly be aware of this fact. It is an elementary (though tedious) matter to check that the associative law holds for multiplication, and that the distributive laws also hold. If we rewrite the definition of multiplication in terms of quaternions in the form $(a, \mathbf{x})$ we see a striking link with the vector algebra on $\mathbb{R}^3$; this is given in the next result.

Theorem 6.2.2 *The product of quaternions is given by the formula*

$$(a,\mathbf{x})(b,\mathbf{y}) = \big(ab-\mathbf{x}\cdot\mathbf{y},\, a\mathbf{y}+b\mathbf{x}+(\mathbf{x}\times\mathbf{y})\big), \tag{6.2.1}$$

where $\mathbf{x}\cdot\mathbf{y}$ *and* $\mathbf{x}\times\mathbf{y}$ *are the scalar and vectors products, respectively.*

The proof is by pure computation and we omit the details, but the reader should certainly verify this when $a = b = 0$. Note that multiplication by the 'real number' $(a, \mathbf{0})$ gives $(a,\mathbf{0})(b,\mathbf{y}) = (ab, a\mathbf{y}) = (b,\mathbf{y})(a,\mathbf{0})$. This shows that the quaternion $(1, \mathbf{0})$ acts as the identity element with respect to multiplication. Theorem 6.2.2 is of special interest when the two quaternions are pure quaternions, which we now define (these play the role of the purely imaginary numbers in $\mathbb{C}$).

Definition 6.2.3 A *pure quaternion* is a quaternion of the form $(0, \mathbf{x})$ where $\mathbf{x} \in \mathbb{R}^3$. The set of pure quaternions is denoted by $\mathbb{H}_0$.

When applied to pure quaternions, Theorem 6.2.2 yields the important formula

$$(0,\mathbf{x})(0,\mathbf{y}) = \big(-\mathbf{x}\cdot\mathbf{y},\, \mathbf{x}\times\mathbf{y}\big) \tag{6.2.2}$$

in which the quaternion product is expressed only in terms of the scalar and vector products. This shows that if q is the pure quaternion $(0, \mathbf{x})$, and $||\mathbf{x}|| = 1$, then $q^2 = (-1, \mathbf{0})$, and this extends the identities $\mathbf{i}^2 = \mathbf{j}^2 = \mathbf{k}^2 = -1$ to *all* pure quaternions of unit length. It also shows that some quaternions, for example -1, have *infinitely many square roots*.

Let us return to the notation given in Definition 6.1.1 so that we now write $a + \mathbf{x}$ instead of $(a, \mathbf{x})$. The conjugate of a quaternion is defined by analogy with the conjugate of a complex number.

Definition 6.2.4 The *conjugate* of the quaternion $a + \mathbf{x}$ is $a - \mathbf{x}$. We denote the conjugate of a quaternion q by $\bar{q}$.

Theorem 6.2.5 *For quaternions p and q, we have $\overline{(pq)} = \bar{q}\,\bar{p}$.*

This follows directly from Theorem 6.2.2, but note that the order of terms here is important. Finally, we note an important identity: if $q = a + \mathbf{x}$ then, from (6.2.1),

$$q\bar{q} = (a + \mathbf{x})(a - \mathbf{x}) = a^2 + ||\mathbf{x}||^2.$$

Of course,

$$(a^2 + ||\mathbf{x}||^2)^{1/2} = \sqrt{a^2 + x_1^2 + x_2^2 + x_3^2},$$

and as this is the distance between the origin and the point $a + \mathbf{x}$ viewed as a point of $\mathbb{R}^4$, we write this as $||a + \mathbf{x}||$. This is the *norm* of the quaternion, and it obeys the important rule that for any quaternions p and q,

$$||pq|| = ||p||\,||q||.$$

The proof is easy for, using the associative law and Theorem 6.2.5,

$$||pq||^2 = (pq)\overline{(pq)} = p\,q\,\bar{q}\,\bar{p} = p\,||q||^2\,\bar{p} = ||q||^2\,p\bar{p} = ||q||^2\,||p||^2 \tag{6.2.3}$$

as required. □

Finally, we have just seen that if q is not the zero quaternion, and if $q' = ||q||^{-2}\bar{q}$, then $qq' = 1 = q'q$. Thus each non-zero quaternion has a multiplicative inverse, and we have proved the following result.

Theorem 6.2.6 *The set of non-zero quaternions is a non-abelian group with respect to the multiplication defined above.*

In conclusion, the set $\mathbb{H}$ of quaternions, with the addition and multiplication defined above, satisfies all of the axioms for a field *except* that multiplication is not commutative. Accordingly, the quaternions are sometimes referred to as a *skew field*.

Exercise 6.2

1. Simplify the sequence of quaternions $\mathbf{i}$, $\mathbf{ij}$, $\mathbf{ijk}$, $\mathbf{ijki}$, $\mathbf{ijkij}$, ...
2. Let $q = a + \mathbf{x}$. Express a and $\mathbf{x}$ in terms of q and $\bar{q}$.
3. Let q be a pure quaternion. Compute q^2, and hence show that $q^{-1} = -||q||^{-2}q$.

4. Show that $\{1, -1, \mathbf{i}, -\mathbf{i}, \mathbf{j}, -\mathbf{j}, \mathbf{k}, -\mathbf{k}\}$ is a group under multiplication.
5. Prove (6.2.1).
6. Prove Theorem 6.2.5.
7. Show that a quaternion q is a pure quaternion if and only if q^2 is real and not positive.
8. Let p and q be pure quaternions. Show that (in the obvious sense) pq is the vector product $p \times q$ if and only if $p \perp q$ (in $\mathbb{R}^3$). In the same sense, show that $pq = qp$ if and only if $p \times q = 0$.

6.3 Reflections and rotations

The formula (6.1.1) for a reflection across a plane is simple; however the formula for a rotation, obtained by combining two reflections, is not. In this section we shall see how quaternions provide an alternative algebraic way to express reflections and rotations. Quaternions are points of $\mathbb{R}^4$, but we shall pay special attention to the space $\mathbb{H}_0$ of pure quaternions which we identify with $\mathbb{R}^3$.

Consider the map $\theta : \mathbb{H} \to \mathbb{H}$ given by $\theta(y) = -qyq^{-1}$, where q is a non-zero pure quaternion. It is clear that θ is a linear map; that is, $\theta(\lambda_1 y_1 + \lambda_2 y_2) = \lambda_1\theta(y_1) + \lambda_2\theta(y_2)$ and, trivially, $\theta(0) = 0$ and $\theta(q) = -q$. These facts suggest that θ might be related to the reflection across the plane with normal q, and we shall now show that this is so.

Theorem 6.3.2 *The map $\theta : \mathbb{H} \to \mathbb{H}$ given by $\theta(y) = -qyq^{-1}$, where q is a non-zero pure quaternion, maps the set $\mathbb{H}_0$ of pure quaternions into itself. Further, when $\mathbb{H}_0$ is identified with $\mathbb{R}^3$, and q with $\mathbf{q}$, θ is the reflection across the plane $\mathbf{x}\cdot\mathbf{q} = 0$. If $\mathbf{q}$ is a pure quaternion of unit length, then $\theta(y) = qyq$.*

Proof We begin by looking at the fixed points of θ in $\mathbb{H}_0$. A general quaternion y is fixed by θ if and only if $-qy = yq$, and if we write $q = (0, \mathbf{q})$ and $y = (0, \mathbf{y})$, and use (6.2.2), we see that a pure quaternion $\mathbf{y}$ is fixed by θ if and only if $\mathbf{y}\cdot\mathbf{q} = 0$. Now let Π be the plane in $\mathbb{R}^3$ given by $\mathbf{x}\cdot\mathbf{q} = 0$; then θ fixes each point of Π. Now take any pure quaternion $\mathbf{y}$. We can write $\mathbf{y} = \mathbf{p} + \lambda\mathbf{q}$, where λ is real and $\mathbf{p} \in \Pi$. Thus, as θ is linear,

$$\theta(\mathbf{y}) = \theta(\mathbf{p}) + \lambda\theta(\mathbf{q}) = \mathbf{p} - \lambda\mathbf{q}.$$

This shows that $\theta(\mathbf{y})$ is a pure quaternion, and also that it is the reflection of $\mathbf{y}$ in Π. Finally, if $\mathbf{q}$ is a pure quaternion of unit length, then $q^2 = -1$ so that $q^{-1} = -q$ and $\theta(y) = qyq$. □

Before moving on to discuss rotations, we give a simple example.

Example 6.3.3 The reflection across the plane $\mathbf{x}\cdot\mathbf{k} = 0$ is given by $(x_1, x_2, x_3) \mapsto (x_1, x_2, -x_3)$ or, in terms of quaternions, $\mathbf{x} \mapsto \mathbf{kxk}$. We also note (in preparation for what follows) that as $\mathbf{k}^{-1} = -\mathbf{k}$, the map $\mathbf{x} \mapsto \mathbf{kxk}^{-1}$ is given by $(x_1, x_2, x_3) \mapsto (-x_1, -x_2, x_3)$, and this is a rotation of angle π about the **k**-axis. □

We now use quaternions to describe rotations that fix the origin. Consider the rotation R obtained by the reflection across the plane with normal unit **p** followed by the reflection across the plane with unit normal **q**. According to Theorem 6.3.2,

$$R(\mathbf{x}) = q(p\mathbf{x}p)q = (qp)\mathbf{x}(pq), \tag{6.3.1}$$

where $p = (0, \mathbf{p})$ and $q = (0, \mathbf{q})$. This observation yields the following result.

Theorem 6.3.4 *Let $r = (\cos\frac{1}{2}\theta, \sin\frac{1}{2}\theta\,\mathbf{n})$, where **n** is a unit vector. Then r is a unit quaternion, and the map $\mathbf{x} \mapsto r\mathbf{x}r^{-1} = r\mathbf{x}\bar{r}$ is a clockwise rotation by an angle θ about the axis in the direction **n**.*

Proof Choose unit vectors **p** and **q** such that $\mathbf{p}\cdot\mathbf{q} = \cos\frac{1}{2}\theta$ and $\mathbf{p} \times \mathbf{q} = \sin\frac{1}{2}\theta\,\mathbf{n}$. Then the rotation described (geometrically) in the theorem is reflection in $\mathbf{x}\cdot\mathbf{p} = 0$ followed by reflection in $\mathbf{x}\cdot\mathbf{q} = 0$; thus it is given by R in (6.3.1). Now a simple calculation using (6.2.2) shows that $qp = -r$ and $pq = -\bar{r}$. Thus $R(\mathbf{x}) = (-r)\mathbf{x}(-\bar{r}) = r\mathbf{x}\bar{r}$. Finally, as $||r|| = 1$ we see that $\bar{r} = r^{-1}$. □

Theorem 6.3.4 provides a way to find the geometric description of the composition of two given rotations. Let R_r and R_s be the rotations associated with the quaternions

$$r = \cos\tfrac{1}{2}\theta + \sin\tfrac{1}{2}\theta\,\mathbf{n}, \quad s = \cos\tfrac{1}{2}\varphi + \sin\tfrac{1}{2}\varphi\,\mathbf{m}.$$

Then the composition $R_s R_r$ is the map $\mathbf{x} \mapsto s(r\mathbf{x}\bar{r})\bar{s} = (sr)\mathbf{x}(\overline{sr})$, and as sr is also a unit quaternion (which is necessarily of the form $\cos\frac{1}{2}\psi + \sin\frac{1}{2}\psi\,\mathbf{h}$ for some unit vector **h**), we see that $R_s R_r = R_{sr}$. By computing sr as a quaternion product, we can find the axis and angle of rotation of the composition $R_s R_r$. We urge the reader to experiment with some simple examples to see this idea in action.

Exercise 6.3

1. Let r be a unit quaternion ($||\mathbf{r}|| = 1$). Show that we can write $r = \cos\theta + \sin\theta\,\mathbf{p}$, where **p** is a unit pure quaternion.

2. Use Theorem 6.2.2 to show that if p and q are pure quaternions ($p = \mathbf{p}$ and $q = \mathbf{q}$), and if $\mathbf{p} \perp \mathbf{q}$, then $-qpq^{-1} = p$.
3. Use quaternions to find the image of $\mathbf{x}$ under a rotation about the $\mathbf{k}$-axis of angle $\pi/6$. Now verify your result by elementary geometry.
4. Let Π be the plane given by $\mathbf{x}{\cdot}\mathbf{n} = 0$, where $\mathbf{n} = (1, -1, 0)$, and let R be the reflection across Π. Write $\mathbf{x} = (a, b, c)$ and $\mathbf{y} = R(\mathbf{x})$. Verify, both using elementary geometry and quaternion algebra, that $\mathbf{y} = (b, a, c)$.

Hyperbolic geometry

15.1 The hyperbolic plane

In the earlier chapters we have discussed both Euclidean geometry and spherical (non-Euclidean) geometry, and in this last chapter we discuss a second type of non-Euclidean geometry, namely hyperbolic geometry. Gauss introduced the term *non-Euclidean geometry* to describe a geometry which does *not* satisfy Euclid's axiom of parallels, namely that if a point P is not on a line L, then there is exactly one line through P that does not meet L. In spherical geometry, the 'lines' are the great circles, and in this case any two lines meet. Hyperbolic geometry is a geometry in which there are infinitely many lines through the point P that do not meet the line L, and it was developed independently by Gauss (in Germany), Bolyai (in Hungary) and Lobatschewsky (in Russia) around 1820.

We begin by describing the points and lines of hyperbolic geometry without any reference to distance. We shall take the hyperbolic plane to be the upper half-plane $\mathcal{H} = \{x + iy : y > 0\}$ in $\mathbb{C}$. Notice that the real axis $\mathbb{R}$ is not part of $\mathcal{H}$. A *hyperbolic line* (that is, a line in the hyperbolic geometry) is a semicircle in $\mathcal{H}$ whose centre lies on $\mathbb{R}$; such semi-circles are orthogonal to $\mathbb{R}$. However, as our concept of circles includes 'straight lines' (see Chapter 14), we must also regard those straight lines that are orthogonal to $\mathbb{R}$ as hyperbolic lines. Figure 15.1.1 illustrates the hyperbolic lines in $\mathcal{H}$, and we remark that the two 'different' types of line are only different because we are viewing them from a Euclidean perspective.

We notice immediately that Euclid's Parallel Axiom fails; indeed, the two semi-circles have a common point P that does not lie on the line L; moreover, it is easy to see that there are infinitely many hyperbolic lines through P and not meeting L. It is clear, however, that *any two hyperbolic lines meet in at most one point*, and that *there is is a unique hyperbolic line through any two distinct points in $\mathcal{H}$.*

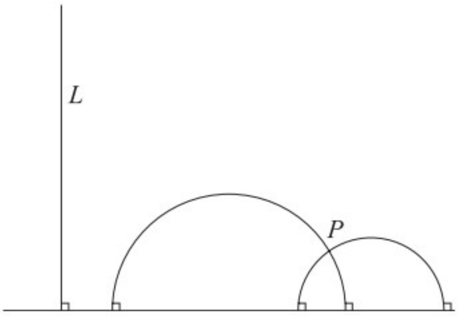

Figure 15.1.1

Now let

$$\Gamma = \left\{ z \mapsto \frac{az+b}{cz+d} : a, b, c, d \in \mathbb{R},\ ad - bc > 0 \right\}.$$

First, we leave the reader to check that Γ is a group. Next, we note that if g is in Γ then it maps $\mathcal{H}$ into itself. Indeed, if we write $g(z) = (az + b)/(cz + d)$, and $z = x + iy$, then

$$\begin{aligned} \operatorname{Im}[g(x+iy)] &= \frac{(az+b)\overline{(cz+d)}}{(cz+d)\overline{(cz+d)}} \\ &= \frac{(ad-bc)\,y}{|cz+d|^2} > 0. \end{aligned} \tag{15.1.1}$$

Exactly the same reason shows that g also maps the lower half-plane (given by $y < 0$) into itself; thus g must also map the circle $\mathbb{R} \cup \{\infty\}$ into itself. As Γ is a group, the same holds for g^{-1}; thus

$$g\bigl(\mathbb{R} \cup \{\infty\}\bigr) = \mathbb{R} \cup \{\infty\} = g^{-1}\bigl(\mathbb{R} \cup \{\infty\}\bigr).$$

This implies that the coefficients a, b, c and d in g may be chosen to be real (note that we cannot assert that they *are* real, for they are only determined to within a complex scalar multiple). The case $c = 0$ is easy, so we may assume that $c \neq 0$. Then, by scaling the coefficients by the factor $1/c$, we can choose these coefficients so that, in effect, $c = 1$. Then, as $g(\infty) = a$, and $g^{-1}(\infty) = -d$, we see that a and d are real. Finally, if $a = 0$ then $-b = ad - bc > 0$ so that b is real. If, however, $a \neq 0$, then $-b/a = g^{-1}(0)$ so that b is again real. To summarize: if $g(z) = (az + b)/(cz + d)$, and $g \in \Gamma$, then we may assume that a, b, c and d are real. This implies that, for each z,

$$\overline{g(z)} = \overline{\left(\frac{az+b}{cz+d}\right)} = \frac{\bar{a}\bar{z}+\bar{b}}{\bar{c}\bar{z}+\bar{d}} = \frac{a\bar{z}+b}{c\bar{z}+d} = g(\bar{z}). \tag{15.1.2}$$

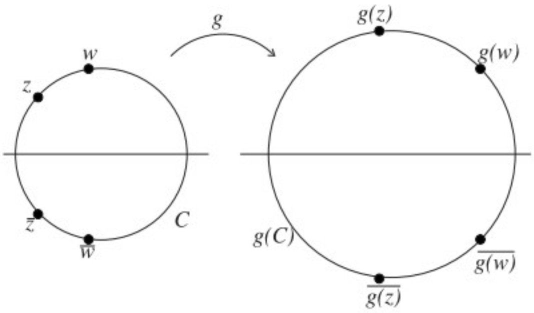

Figure 15.1.2

Let us now see how g in Γ acts on hyperbolic lines. Let z and w be distinct points of $\mathcal{H}$, and let us consider the hyperbolic line L through z and w. Now L is part of the (unique) Euclidean circle C that passes through z, w, $\bar{z}$ and $\bar{w}$, so that $g(C)$ passes through $g(z)$, $g(w)$, $g(\bar{z})$ and $g(\bar{w})$. However, (15.2.1) now implies that $g(C)$ passes through $g(z)$, $\overline{g(z)}$, $g(w)$ and $\overline{g(w)}$, so that $g(C)$ is orthogonal to $\mathbb{R}$ (see Figure 15.1.2). It follows that $g(L) = \mathcal{H} \cap g(C)$, and this proves the following result.

Theorem 15.1.1 *If $g \in \Gamma$ and L is a hyperbolic line, then $g(L)$ is a hyperbolic line.*

Theorem 15.1.1 suggests that the elements of Γ might be regarded as the rigid motions of hyperbolic geometry. This suggestion is strengthened by the fact (which will not be proved here) that any bijective map of $\mathbb{C}_\infty$ onto itself that maps circles to circles is a Möbius map of z or of $\bar{z}$; this is a type of converse of Theorem 13.3.2. Further, any Möbius map that preserves $\mathcal{H}$ must be in Γ (Exercise 15.1.1). In the next section we shall introduce a distance in $\mathcal{H}$, and we shall then see that the elements of Γ are indeed the isometries of $\mathcal{H}$.

There is a second model of the hyperbolic plane which is useful, and often preferable to the model $\mathcal{H}$. In this model the hyperbolic plane is the unit disc $\mathbb{D}$, namely $\{z : |z| < 1\}$ (see Figure 15.1.3). The Möbius map $g(z) = (z - i)/(z + i)$ maps $\mathcal{H}$ onto $\mathbb{D}$ (because $\mathcal{H}$ is given by $|z - i| < |z + i|$), and so we may take the hyperbolic lines in the model $\mathbb{D}$ to be the images under g of the hyperbolic lines in $\mathcal{H}$. Thus the hyperbolic lines in $\mathbb{D}$ are the arcs of circles in $\mathbb{D}$ whose endpoints lie on the cirle $|z| = 1$ and which are orthogonal to this circle at their endpoints. The two models $\mathcal{H}$ and $\mathbb{D}$ may be used interchangeably, and any result about one may be transferred to the other by any Möbius map that maps $\mathcal{H}$ to $\mathbb{D}$, or $\mathbb{D}$ to $\mathcal{H}$.

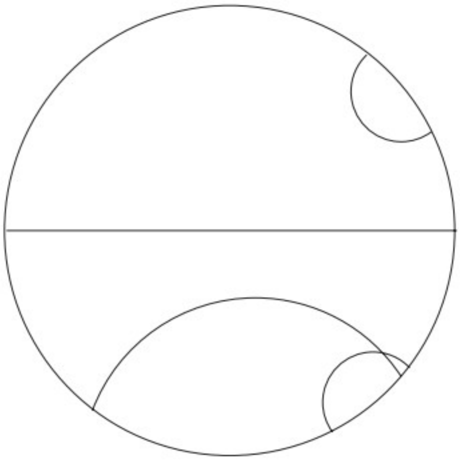

Figure 15.1.3

Exercise 15.1

1. Show that if f is a Möbius map which maps $\mathbb{R} \cup \{\infty\}$ onto itself, then f can be written in the form $f(z) = (az + b)/(cz + d)$, where a, b, c, d are real and $ad - bc \neq 0$. Show further that $f(\mathcal{H}) = \mathcal{H}$ if and only if $ad - bc > 0$.
2. Let z_1 and z_2 be distinct points in the hyperbolic plane. Show that there is a unique hyperbolic line that passes through z_1 and z_2.
3. Suppose that w_1 and w_2 are in $\mathcal{H}$. Show that there is some g in Γ such that $g(w_1) = w_2$. This shows that *the stabilizer of any point in $\mathcal{H}$ is conjugate to the stabilizer of any other point in $\mathcal{H}$.*
4. Verify the steps in the following argument. Let $g(z) = (z - i)/(z + i)$; then g maps $\mathcal{H}$ onto $\mathbb{D}$, where $\mathbb{D} = \{z : |z| < 1\}$. Note that $g(i) = 0$ and $g(-i) = \infty$. Now suppose that f maps $\mathcal{H}$ onto itself and fixes i; then f also fixes $-i$. It follows that gfg^{-1} maps $\mathbb{D}$ onto itself, and fixes 0 and ∞. Thus gfg^{-1} is a Euclidean rotation about the origin, and hence *the group of hyperbolic isometries that fix a given point w is isomorphic to the group of Euclidean rotations that fix the origin.*

15.2 The hyperbolic distance

We shall now introduce a distance in $\mathcal{H}$, and then show that the elements of Γ are isometries for this distance (in fact, they are the only orientation-preserving isometries). There are two ways to define this *hyperbolic distance*, and we shall

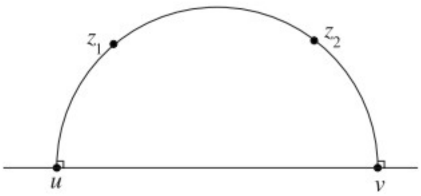

Figure 15.2.1

start with the more elementary way. Consider distinct points z_1 and z_2 in $\mathcal{H}$, and let L be the hyperbolic line through these points. Then L has endpoints u and v, say, chosen so that u, z_1, z_2 and v occur in this order along L (see Figure 15.2.1). We can find a Möbius map g in Γ such that $g(u) = 0$ and $g(v) = \infty$ (see Exercise 15.2.1); then $g(z_1) = ia$ and $g(z_2) = ib$, say, where $0 < a < b$. If we now recall that cross-ratios are invariant under Möbius maps, we have

$$[u, z_1, z_2, v] = [0, ia, ib, \infty] = b/a > 1.$$

This allows us to make the following definition.

Definition 15.2.1 The *hyperbolic distance* between z_1 and z_2 in $\mathcal{H}$ is $\log [u, z_1, z_2, v]$ when $z_1 \neq z_2$, and zero otherwise. We denote this distance by $\rho(z_1, z_2)$. □

Theorem 15.2.2 *The elements of* Γ *preserve the hyperbolic distance between two points in* $\mathcal{H}$.

Proof This is immediate because the hyperbolic distance is defined as a cross-ratio, cross-ratios are invariant under Möbius maps, and each g in Γ is a Möbius map. □

Notice that if, in Definition 15.2.1, we have $z_1 = ia$ and $z_2 = ib$, where $0 < a < b$, then

$$\rho(ia, ib) = \log[0, ia, ib, \infty] = \log b/a$$

(see Definition 13.4.1). This leads to the following more general result.

Theorem 15.2.3 *The hyperbolic distance is additive along hyperbolic lines.*

Proof Suppose that z_1, z_2, z_3 lie on a hyperbolic line L with end-points u and v such that u, z_1, z_2, z_3, v occur in this order along L. We can find some g in Γ such that $g(u) = 0$ and $g(v) = \infty$, and then $g(z_j) = ia_j$, where $0 < a_1 < a_2 < a_3$.

As $\rho(z_i, z_j) = \log a_j/a_i$ when $i < j$ we see that

$$\begin{aligned}\rho(z_1, z_3) &= \log a_3/a_1\\ &= \log a_3/a_2 + \log a_2/a_1\\ &= \rho(z_1, z_2) + \rho(z_2, z_3).\end{aligned}$$

□

We are now in a position to give explicit formulae for the hyperbolic distance (see Exercise 15.2.2).

Theorem 15.2.4 *For z and w in $\mathcal{H}$,*

$$\sinh^2 \frac{1}{2}\rho(z, w) = \frac{|z - w|^2}{4\,\mathrm{Im}[z]\,\mathrm{Im}[w]}, \qquad (15.2.1)$$

$$\cosh^2 \frac{1}{2}\rho(z, w) = \frac{|z - \bar{w}|^2}{4\,\mathrm{Im}[z]\,\mathrm{Im}[w]}. \qquad (15.2.2)$$

Proof First, choose g in Γ (as above) so that $g(z) = ia$ and $g(w) = ib$, where $0 < a < b$. By applying the map $z \mapsto z/a$ (which is in Γ), we may assume that $a = 1$. Then $\rho(z, w) = \rho(i, ib) = \log b$, so that

$$\sinh^2 \frac{1}{2}\rho(z, w) = \sinh^2\big(\log\sqrt{b}\big) = \frac{(b-1)^2}{4b}. \qquad (15.2.3)$$

Next, let

$$F(z, w) = \frac{|z - w|^2}{4\,\mathrm{Im}[z]\,\mathrm{Im}[w]}.$$

Then, from (13.1.2) and (15.1.1), we see that F is invariant under any g in Γ; that is,

$$F\big(g(z), g(w)\big) = F(z, w).$$

Thus

$$F(z, w) = F(i, ib) = \frac{(b-1)^2}{4b}, \qquad (15.2.4)$$

and this together with (15.2.3) gives (15.2.1). The second formula (15.2.2) follows from the fact that, for all z, $\cosh^2 z = 1 + \sinh^2 z$. □

We remark that, as Theorem 15.2.4 suggests, in calculations involving the hyperbolic distance it is almost always advantageous to use the functions sinh or cosh of $\rho(z, w)$ or $\frac{1}{2}\rho(z, w)$; *only rarely is $\rho(z, w)$ used by itself.*

We end with a brief discussion of an alternative (but equivalent) way to define distance. First, we define the *hyperbolic length* of a curve γ in $\mathcal{H}$ to be the line integral

$$\int_\gamma \frac{|dz|}{y},$$

where, as usual $z = x + iy$. Now let L be the hyperbolic line through two points z and w in $\mathcal{H}$, and let σ be the arc of L that lies between z and w. It can be shown that σ has hyperbolic length $\rho(z, w)$ and, moreover, that any other curve joining z to w has a greater hyperbolic length than σ. Thus the hyperbolic line through two points does indeed give the shortest path between these points.

Finally, if g is in Γ, and $g(z) = (az + b)/(cz + d)$, then, from (13.1.2), we see that

$$|g'(z)| = \frac{|ad - bc|}{|cz + d|^2},$$

where $g'(z)$is the usual derivative of g. In conjunction with (15.1.1) this gives

$$\frac{|g'(z)|}{\mathrm{Im}[g(z)]} = \frac{1}{\mathrm{Im}[z]}.$$

This (together with the formula for a change of variable in a line integral) shows that for each g in Γ, and each curve γ, $g(\gamma)$ has the same hyperbolic length as γ.

Exercise 15.2

1. Show that for any u and v in $\mathbb{R} \cup \{\infty\}$ with $u \neq v$, there is a g in Γ with $g(u) = 0$ and $g(v) = \infty$. [Hint: apply $z \mapsto -1/(z - v)$ and then a translation.]
2. The functions sinh and cosh are defined by $\sinh z = (e^z - e^{-z})/2$ and $\cosh z = (e^z + e^{-z})/2$. Show that (a) $\cosh^2 z - \sinh^2 z = 1$, and (b) $\cosh 2z = 2\cosh^2 z - 1 = 1 + 2\sinh^2 z$.
3. Find the hyperbolic distance between the points $1 + iy$ and $-1 + iy$ as a function of y. Show that for a given positive t there is a value of y such that this distance is t.
4. Let L be the Euclidean line given by $\mathrm{Im}[z] = 2$. Show that $2i$ is the point on L that is closest (as measured by the hyperbolic distance) to the point i.

15.3 Hyperbolic circles

Suppose that $w \in \mathcal{H}$, and $r > 0$. The *hyperbolic circle* with *hyperbolic centre* w and *hyperbolic radius* r is the set $\{z \in \mathcal{H} : \rho(z, w) = r\}$.

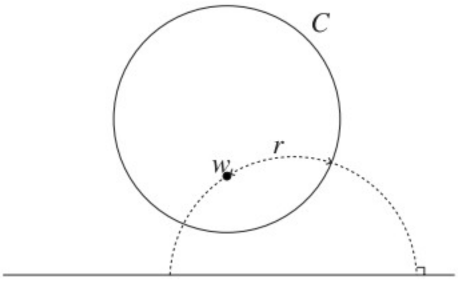

Figure 15.3.1

Theorem 15.3.1 *Each hyperbolic circle is a Euclidean circle in* $\mathcal{H}$.

Proof Let C be the hyperbolic circle with centre w and radius r. There is a map g in Γ with $g(w) = i$ (see Exercise 15.1.2), so that $g(C)$ is the hyperbolic circle with centre i and radius r. Now by Theorem 15.2.4, $z \in g(C)$ if and only if $|z - i|^2/4y = \sinh^2 \frac{1}{2}r$, where $z = x + iy$. This equation simplifies to give $x^2 + (y - \cosh r)^2 = \sinh^2 r$, so that $g(C)$ is a Euclidean circle in $\mathcal{H}$. As g^{-1} maps circles to circles, and $\mathcal{H}$ to itself, we see that $g^{-1}\big(g(C)\big)$, namely C, is a Euclidean circle in $\mathcal{H}$. □

Notice that the hyperbolic centre of a hyperbolic circle is *not* the same as its Euclidean centre (and similarly for the radii); indeed, the hyperbolic circle $g(C)$ in the proof of Theorem 15.3.1 has hyperbolic centre i, and Euclidean centre $i \cosh r$ (and $\cosh r > 1$). A hyperbolic circle with centre w and hyperbolic radius r is illustrated in Figure 15.3.1. Finally, it can be shown that the length of a hyperbolic circle of hyperbolic radius r is $2\pi \sinh r$, and that its hyperbolic area (which we have not defined) is $4\pi \sinh^2(\frac{1}{2}r)$. Notice that the hyperbolic radius of a hyperbolic circle of radius r grows roughly like πe^r; in the Euclidean case, it is $2\pi r$. Finally, we mention (but do not prove) the hyperbolic counterpart of the fact that the area of a spherical triangle is π less than its angle sum.

Theorem 15.3.2 *The area of a hyperbolic triangle with angles* α, β *and* γ *is* $\pi - (\alpha + \beta + \gamma)$. *In particular, this area cannot exceed* π.

Exercise 15.3

1. Find the equation of the hyperbolic circle with centre $2i$ and radius e^2. Suppose that this circle meets the imaginary axis at ia and ib, where $0 < a < 2 < b$. Find a and b, and verify directly that $\rho(ia, 2i) = e^2 = \rho(2i, ib)$.

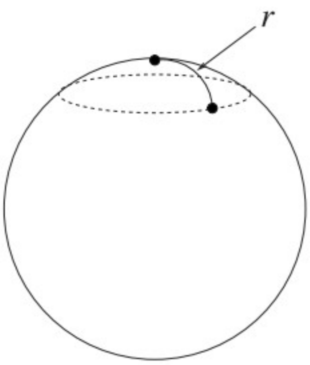

Figure 15.3.2

2. Consider the unit sphere in $\mathbb{R}^3$ as a model of spherical geometry in which distances are measured on the surface of the sphere. What is the circumference of the circle whose centre is at the ‘north pole’ (see Figure 15.3.2) and whose radius is r? Now compare the circumference of a circle of radius r in Euclidean geometry, spherical geometry and hyperbolic geometry.

15.4 Hyperbolic trigonometry

A hyperbolic triangle is a triangle whose sides are arcs of hyperbolic lines. We begin with the hyperbolic version of Pythagoras’ theorem (see Figure 15.4.1).

Theorem 15.4.1 *Suppose that a hyperbolic triangle has sides of hyperbolic lengths a, b and c, and that the two sides of lengths a and b are orthogonal. Then* $\cosh c = \cosh a \; \cosh b$.

In our proof of this result we shall need to use the fact that a Möbius map is *conformal*; that is, it preserves the angles between circles. In particular, this implies that if two circles C and C' are orthogonal, and if g is any Möbius map, then $g(C)$ and $g(C')$ are orthogonal. We shall not give a proof of this (although the proof is not difficult).

Proof Let the vertices of the hyperbolic triangle be v_a, v_b and v_c, where v_a is opposite the side of length a, and so on. There is some g in Γ such that $v_c = i$ and $v_b = ik$, where $k > 1$. As g preserves the orthogonality of circles we see that g maps v_a to some point $s + it$, where $s^2 + t^2 = 1$ (see Figure 15.4.2). As g preserves hyperbolic distances, this means that we may assume that $v_a = s + it$,

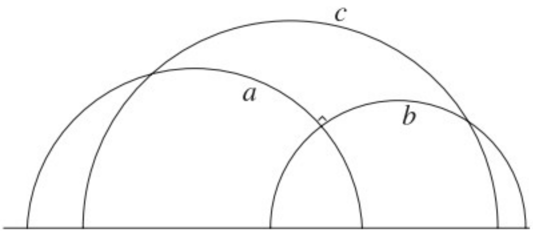

Figure 15.4.1

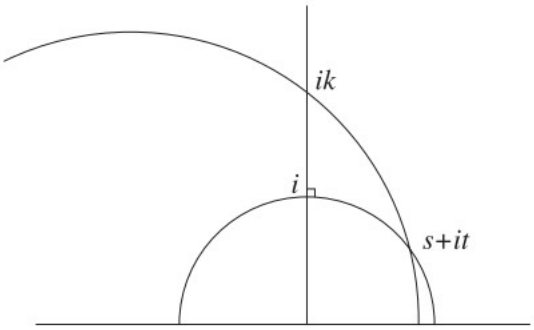

Figure 15.4.2

$v_b = ik$ and $v_c = i$. Now $\rho(i, ik) = a$, $\rho(i, s + it) = b$ and $\rho(ik, s + it) = c$. As

$$\cosh a = \frac{k^2 + 1}{2k}, \quad \cosh b = \frac{1}{t}, \quad \cosh c = \frac{k^2 + 1}{2tk},$$

the given formula follows. □

It is interesting to examine Pythagoras' theorem for small triangles, and for large triangles. As $\cosh z = 1 + z^2/2\,! + z^4/4\,! + \cdots$, we see that when a, b and c are very small, the formula is, up to the second-order terms, $c^2 = a^2 + b^2$. Thus, infinitesimally, the hyperbolic version of Pythagoras' theorem agrees with the Euclidean version. This is because the hyperbolic distance is obtained form the Euclidean distance by applying a 'local scaling factor' of $1/y$ at z. As this scaling factor is essentially constant on an infinitesimal neighbourhood of a point, the 'infinitesimal hyperbolic geometry is just a scaled version of the Euclidean geometry. However, as the scaling factor varies considerably over large distances, the global hyperbolic geometry is very different from the Euclidean geometry. For example, if in Pythagoras' theorem, a, b and c are all very large, then, as $\cosh x$ is approximately $e^x/2$ when x is large, we have (approximately) $4e^c = e^a e^b$ so that $c = a + b - \log 2$. In other words, in a 'large' hyperbolic right-angled triangle, the length of the hypotenuse is almost the sum of the lengths of the other two sides! If this were the case in Euclidean geometry, then the triangle would be very 'flat', but this is not so in hyperbolic geometry.

Finally, we remark that hyperbolic trigonometry is as rich and well understood as Euclidean trigonometry (and spherical trigonometry) is. For example, there is a sine rule, and cosine rules in hyperbolic geometry. In most applications it is the hyperbolic trigonometry that is important, and hyperbolic geometry by itself has relatively few applications.

Exercise 15.4

1. Suppose that a, b and c are the sides of a right-angled hyperbolic triangle with the right-angle opposite the side of length c. Prove that $c \leq a + b$; this is a special case of the triangle inequality.
2. Consider a right-angled hyperbolic triangle with both sides ending at the right angle having length a. Let the height of this triangle be h (the distance from the right angle to the third side). Find h as a function of a. What is the limiting behaviour of h as $a \to +\infty$?

15.5 Hyperbolic three-dimensional space

We end this text with a very brief description of three-dimensional hyperbolic geometry, and a sketch of the proof of Theorem 14.3.2. These are given in this and the next section, and they combine many of the ideas that have been introduced in this text. We take *hyperbolic space* to be the upper-half of $\mathbb{R}^3$, namely

$$\mathcal{H}^3 = \{(x, y, t) \in \mathbb{R}^3 : t > 0\}.$$

It is convenient to identify the point (x, y, t) with the quaternion $x + y\mathbf{i} + t\mathbf{j}$, and also to identify the quaternion $\mathbf{i}$ with the complex number i. Thus we can write (x, y, t) as $z + t\mathbf{j}$, where z is the complex number $x + iy$. Note that in this notation we have the convenient formula

$$z\mathbf{j} = (x + y\mathbf{i})\mathbf{j} = x\mathbf{j} + y\mathbf{k} = x\mathbf{j} - y\mathbf{j}\mathbf{i} = \mathbf{j}\bar{z}. \tag{15.5.1}$$

Suppose now that $g(z) = (az + b)/(cz + d)$, where $ad - bc \neq 0$. We can now let g act on hyperbolic space $\mathcal{H}^3$ by the rule

$$g : z + t\mathbf{j} \mapsto \left[a(z + t\mathbf{j}) + b\right]\left[c(z + t\mathbf{j}) + d\right]^{-1}, \tag{15.5.2}$$

where this computation is to be carried out in the algebra of quaternions. This lengthy (but elementary) exercise shows that

$$g(z + t\mathbf{j}) = \frac{(az + b)(\bar{c}\bar{z} + \bar{d}) + a\bar{c}t^2 + |ad - bc|t\mathbf{j}}{|cz + d|^2 + |c|^2t^2}. \qquad (15.5.3)$$

Notice that as quaternions are not commutative, we have to choose (and then be consistent about) which side we shall write the inverse in (15.5.2). However, in (15.5.3), the denominator is real (and positive), and as every real number commutes with every quaternion, we can write it in the usual form for a fraction without any ambiguity. Notice also that if we put $t = 0$ in (15.5.3), we recapture the correct formula for the action of g on $\mathbb{C}$.

The consequences of (15.5.3) are far-reaching. First, if we consider g to be a translation, say $g(z) = z + b$, then we find that $g(z + t\mathbf{j}) = (z + b) + t\mathbf{j}$; thus g is just the 'horizontal' translation by b. If $g(z) = az$, then we find that

$$g(z + t\mathbf{j}) = az + |a|t\mathbf{j}.$$

If $|a| = 1$, so that g is a rotation of the complex plane, then g acts on $\mathcal{H}^3$ as a rotation about the vertical axis through the origin. If $a > 0$, so that g acts as a 'stretching' from the origin by a factor a in $\mathbb{C}$, then g also acts as a stretching (from the origin, and by the same factor) in $\mathcal{H}^3$. Of course, the more interesting case is when $g(z) = 1/z$; here

$$g(z + t\mathbf{j}) = \frac{\bar{z} + t\mathbf{j}}{|z|^2 + t^2}.$$

We define the lines in $\mathcal{H}$ to be the 'vertical' semi-circles, and the 'vertical' rays (exactly as in the two-dimensional case; see Figure 15.5.1), and we can define the hyperbolic distance between two points again by a cross-ratio (thinking of the vertical plane through the two points as the complex plane), or by integrating $|dx|/x_3$, where $x = (x_1, x_2, x_3)$, over curves. When all this has been done, we arrive at the following beautiful result.

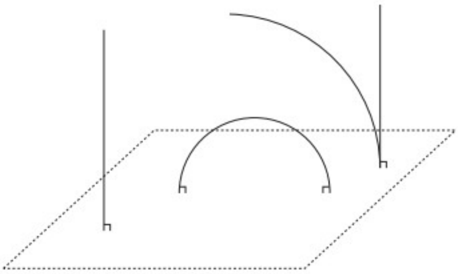

Figure 15.5.1

Theorem 15.5.1 *Every Möbius map acts on hyperbolic space $\mathcal{H}^3$ as a hyperbolic isometry, and every isometry that preserves orientation is a Möbius map.*

15.6 Finite Möbius groups

Finally, we give only the briefest sketch of the ideas behind a proof of Theorem 14.3.2. The aim of this sketch is to give the reader a glimpse of some beautiful interaction between algebra and geometry, and it is far from being complete. First, the Möbius maps (that act on $\mathbb{C}_\infty$) can be extended (either as a composition of reflections and inversions, or in terms of the quaternion algebra) to act on all of $\mathbb{R}^3$. The upper-half $\mathcal{H}^3$ of $\mathbb{R}^3$ with the hyperbolic metric $ds = |dx|/x_3$ is a model of three-dimensional hyperbolic geometry, and the Möbius group is the group of orientation-preserving isometries of this space.

Now let G be a finite Möbius group; then G may be regarded as a finite group of isometries of $\mathcal{H}^3$, so that each point in $\mathcal{H}^3$ has a finite orbit. Take any orbit and let B be the smallest hyperbolic ball that contains the orbit. Analytic arguments show that B is unique, and as the chosen orbit is invariant under G, so is B, and hence (finally) so too is the hyperbolic centre of B. This argument proves that the elements of the finite group G have a common fixed point ζ in $\mathcal{H}^3$. There is now a Möbius map (which acts on all of $\mathbb{R}^3 \cup \{\infty\}$) that converts the upper-half space model of three-dimesional hyperbolic space into the unit ball model (much as there is a Möbius map that takes the upper half-plane to the unit disc). This can be chosen so that ζ is carried to the origin; thus the finite Möbius G is conjugate to a Möbius group G' of hyperbolic isometries that act on the unit ball in $\mathbb{R}^3$ with the extra property that every element of G' fixes 0. It is not difficult to show that every such isometry is a Euclidean rotation of $\mathbb{R}^3$ and the sketch of the proof is complete. □

Consequently there exist linear transformations $\sigma_1, \cdots, \sigma_n$ each of which induces a perspectivity such that $\sigma\sigma_1 \cdots \sigma_n$ leaves invariant every element in S. The projectivity ρ induced by $\sigma_n^{-1} \cdots \sigma_1^{-1}$ is consequently a product of [at most] n perspectivities and satisfies $X^{\rho} = X^{\sigma}$ for every subspace X of S.

Theorem 1: *A projectivity is a collineation if, and only if, it is a product of* [*at most* 3] *projectivities each of which possesses a full line of fixed points.*

PROOF: The sufficiency of our condition is an immediate consequence of Lemma 2. If conversely σ is a collineation, and if L is a line, then we deduce from Proposition 1 the existence of perspectivities σ_1 and σ_2 such that $P^{\sigma} = P^{\sigma_1\sigma_2}$ for every point P on L. Then $\sigma = \rho\sigma_1\sigma_2$ where the projectivity ρ leaves invariant every point on the line L and where the perspectivities σ_i have at least a line of fixed points each.

Theorem 2: *A projectivity of a linear manifold of finite rank is a collineation if, and only if, it is a product of perspectivities.*

This is an immediate consequence of Lemma 2 and Proposition 1.

For linear manifolds of infinite rank we may give to Proposition 1 a similar interpretation by saying that a projectivity is a collineation if, and only if, it may be "approximated" by products of perspectivities. We leave the details to the topologically interested reader.

III.3. The Second Fundamental Theorem of Projective Geometry

We assume in the course of the present section that A is an F-space of finite rank $r(A) = n$. We shall assume that $1 < n$, since otherwise our investigation would not have any content [and some assertions would cease to be valid]. It is, however, not neccessary to assume that $2 < n$, since we are going to investigate collineations which are *defined* by the fact that they are induced by linear transformations.

It will be convenient to term *simplex* a set of $r(A) + 1$ points no $r(A)$ of which are contained in a hyperplane of A. This is equivalent to saying that any $r(A)$ of the $r(A) + 1$ points of a simplex are independent. If, for instance, A is a plane, then a simplex consists of four points no three of which are collinear.

Lemma 1: *If the points P_i [$i = 0, 1, \cdots, r(A)$] form a simplex, then there exists a basis $b_1, \cdots, b_n$ of A such that $P_i = Fb_i$ for $i = 1, \cdots, n$ and*

$$P_0 = F\sum_{j=1}^{n} b_j.$$

Proof: Let b_0 be any element such that $P_0 = Fb_0$. Since the points $P_1, \cdots, P_n$ are independent, and since n is the finite rank of A, we have $A = \sum_{j=1}^{n} P_j$. Consequently there exist elements b_j in P_j such that $b_0 = b_1 + \cdots + b_n$. If b_i were 0, then b_0 and hence P_0 would be part of the hyperplane $\sum_{i \neq j} P_j$ which is impossible. Consequently $P_i = Fb_i$; and from the independence of the points $P_1, \cdots, P_n$ it follows now that $b_1, \cdots, b_n$ is a basis of A.

Proposition 1: *If P_i' and P_i'' are simplices, then there exists a collineation σ such that $P_i'' = P_n'^{\sigma}$ for $i = 0, 1, \cdots, n$.*

Proof: We infer from Lemma 1 the existence of bases $p_1', \cdots, p_n'$ and $p_1'', \cdots, p_n''$ of A such that $P_i' = Fp_i'$, $P_i'' = Fp_i''$ for $i = 1, \cdots, n$ and $P_0' = F\sum_{i=1}^{n} p_i'$, $P_0'' = F\sum_{i=1}^{n} p_i''$. There exists furthermore one and only one linear transformation σ of A such that $p_i'^{\sigma} = p_i''$ for $i = 1, \cdots, n$; and it is clear that the collineation induced by σ meets all the requirements.

Proposition 2: *The identity is the only collineation leaving invariant every point of a simplex if, and only if, F is a commutative field.*

Proof: Denote by P_i some simplex of A. Then there exists, by Lemma 1, a basis $b_1, \cdots, b_n$ of A such that $P_i = Fb_i$ for $i = 1, \cdots, n$ and $P_0 = F\sum_{i=1}^{n} b_i$.

Assume now that the identity is the only collineation which leaves invariant every point P_i of our simplex. Suppose that $f \neq 0$ is a number in F. Then there exists one and only one linear transformation σ of A such that $b_i^{\sigma} = fb_i$ for $i = 1, \cdots, n$. This linear transformation σ induces a collineation which satisfies $P_i^{\sigma} = P_i$ for $i = 0, 1, \cdots, n$. Hence σ induces the identity projectivity. Consider now some element z in F. Then it follows that

$$F(b_1 + zb_2) = [F(b_1 + zb_2)]^{\sigma} = F(fb_1 + zfb_2) = F(b_1 + f^{-1}zfb_2).$$

Because b_1 and b_2 are independent, it follows now that $z = f^{-1}zf$ or $fz = zf$; and this is true for every f and every z. Hence F is commutative.

Assume now conversely that the field F be commutative. Consider some collineation σ which leaves invariant each of the points P_i of our simplex. This collineation σ is induced by a linear transformation which we denote by σ too. From $P_i^{\sigma} = P_i$ for $i = 0, 1, \cdots, n$ we deduce the existence of numbers $f_i \neq 0$ in F such that

$$b_i^\sigma = f_i b_i \text{ for } i = 1, \cdots, n, \quad \left[\sum_{i=1}^{n} b_i\right]^\sigma = f_0 \sum_{i=1}^{n} b_i.$$

But this implies

$$\sum_{i=1}^{n} f_0 b_i = \sum_{i=1}^{n} b_i^\sigma = \sum_{i=1}^{n} f_i b_i;$$

and we infer from the independence of the b_i that $f_0 = f_1 = \cdots = f_n$. If a is any element in A, then

$$a^\sigma = \left[\sum_{i=1}^{n} a_i b_i\right]^\sigma = \sum_{i=1}^{n} a_i f_0 b_i = f_0 \sum_{i=1}^{n} a_i b_i = f_0 a$$

since F is commutative. Hence σ leaves invariant every point in A so that σ is the identity projectivity.

Remark 1: Mapping the point (x_0,x_1,x_2) of the complex plane upon its conjugate complex point $(\bar{x}_0,\bar{x}_1,\bar{x}_2)$ we obtain a semi-linear transformation which leaves invariant every point of the simplex (1,1,1), (1,0,0), (0,1,0), (0,0,1); but which does not leave invariant the point represented by $(i,1,0)$ where $i^2 = -1$. Thus the Proposition 2 ceases to be true, if we omit the restriction to collineations.

Remark 2: If the rank of A is at least 3, then we may consider the group of all projectivities which leave invariant every point of some given simplex. This group may be seen [by application of the First Fundamental Theorem of Projective Geometry of III.1] to be isomorphic to the group of automorphisms of the field F. See III.2, Survey of the groups of a linear manifold.

Remark 3: If F is not commutative, then there exist collineations, not the identity, which leave invariant every point in a given simplex [Proposition 2]. It follows from III.2, Theorem 2 that this collineation is a product of perspectivities. Thus a product of perspectivities may leave invariant every point in a simplex without being the identity.

The Second Fundamental Theorem of Projective Geometry may now be stated as follows:

Every simplex may be mapped upon every other simplex by one and only one collineation if, and only if, the field of coordinates is commutative.

The proof is an immediate consequence of Propositions 1 and 2.

Remark 4: It is possible to extend the results of this section to linear manifolds of infinite rank. If one wants to do this, one has to investigate the effect of a linear transformation on the subspaces of finite rank. Furthermore one has to find a substitute for the concept of simplex which in its present form looses its meaning in the case of infinite rank. We leave this discussion to the interested reader.

APPENDIX II

The Theorem of Pappus

In the Second Fundamental Theorem of Projective Geometry [§ 3] we have met a first instance where the commutativity of the field F [of coordinates] appears important. In the present appendix we give Hilbert's celebrated characterization of commutativity of F by means of geometric configurations.

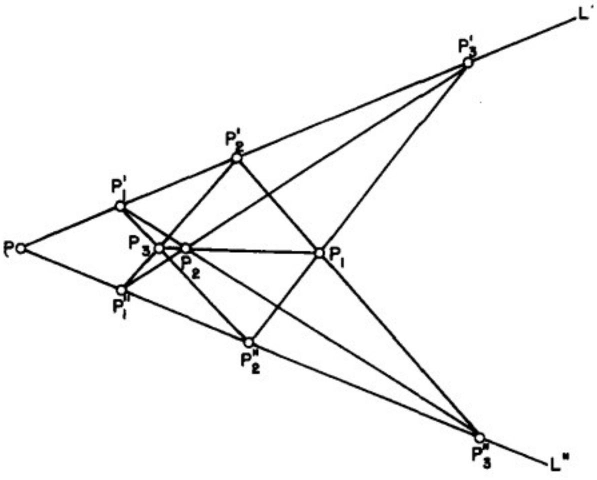

Fig. 4

We are considering configurations of ten coplanar points which are obtained as follows. There are given two distinct lines L' and L'' meeting in a point P and on each of the lines three distinct points P'_i on L' and and P''_i on L'' such that $P \neq P'_i$ and $P \neq P''_i$ for $i = 1,2,3$. One verifies easily that the three intersections

$$P_i = (P'_j + P''_k) \cap (P''_j + P'_k)$$

where i,j,k is a permutation of 1,2,3 are well determined points; and we say that *this configuration* $[P_i,P'_i,P''_i]$ *has the Property of Pappus, if* P_1,P_2,P_3 *are collinear points.*

We select at random an element a such that $P = Fa$. From

$$P \leqslant L' = P_1' + P_2'$$

we infer the existence of elements b and b' in P_1' and P_2' respectively such that $a = b' - b$; and b and b' are different from 0, since P is different from P_i'. Hence $P_1' = Fb$ and $P_2' = F(a + b)$. Since P_3' is on $L' = P + P_1'$, we have $P_3' = F(a + d'b)$ with $d' \neq 0, 1$, if we only note that P_3' is different from P, P_1', P_2'. Likewise we find an element c in A and an element $d'' \neq 0, 1$ in F such that $P_1'' = Fc$, $P_2'' = F(a + c)$, $P_3'' = F(a + d''c)$.

The configuration $[P_i, P_i', P_i'']$ *has the Property of Pappus if, and only if,* $d'd'' = d''d'$.

PROOF: We note first that a,b,c are three independent elements. Thus $F(a + b + c)$ is a point; and it is clear that this point is on the lines $P_2' + P_1'' = F(a + b) + Fc$ and $P_2'' + P_1' = F(a + c) + Fb$. But these lines meet in P_3; and thus it follows that $P_3 = F(a + b + c)$. Similarly one sees that $P_2 = F(a + d'b + d''c)$. Finally we note that

$$(d' - 1)^{-1}d' + (d'' - 1)^{-1} = (d' - 1)^{-1} + (d'' - 1)^{-1}d''$$

and that therefore

$$\begin{aligned}(d' - 1)^{-1}d'(a + b) &+ (d'' - 1)^{-1}(a + d''c)\\ &= (d' - 1)^{-1}(a + d'b) + (d'' - 1)^{-1}d''(a + c)\end{aligned}$$

is the intersection P_1 of the lines $P_2' + P_3'' = F(a + b) + F(a + d''c)$ and $P_2'' + P_3' = F(a + c) + F(a + d'b)$. Since P_2 and P_3 are certainly different points, it follows that our configuration has the Property of Pappus if, and only if, $P_1 \leqslant P_2 + P_3$; and this is equivalent to the property:

There exist numbers h,k in F such that

$$\begin{aligned}(d' - 1)^{-1}d'(a + b) &+ (d''- 1)^{-1}(a + d''c)\\ &= h(a + d'b + d''c) + k(a + b + c).\end{aligned} \tag{1}$$

From the independence of a,b,c it follows that the numbers h,k satisfy equation (1) if, and only if, they satisfy the following equations:

$$\left\{\begin{aligned} h + k &= (d' - 1)^{-1}d' + (d'' - 1)^{-1},\\ hd' + k &= (d' - 1)^{-1}d',\\ hd'' + k &= (d''- 1)^{-1}d''.\end{aligned}\right. \tag{2}$$

Thus the existence of solutions h,k of (2) is necessary and sufficient for the validity of the Property of Pappus.

If there exist numbers h,k which satisfy (2), then subtraction of the first equation (2) from the other two equations (2) gives:

$$h(d' - 1) = - (d'' - 1)^{-1}, \qquad h(d'' - 1) = 1 - (d' - 1)^{-1}d' = - (d' - 1)^{-1}.$$

Consequently

$$-(d''-1)^{-1}(d'-1)^{-1} = h = -(d'-1)^{-1}(d''-1)^{-1}$$

or $(d'-1)(d''-1) = (d''-1)(d'-1)$; and this implies $d'd'' = d''d'$.

If conversely $d'd'' = d''d'$, then one sees easily that

$$h = -(d''-1)^{-1}(d'-1)^{-1}, \qquad k = (d'-1)^{-1}d''(d''-1)^{-1}$$

are solutions of the equations (2). Thus we have shown that $d'd'' = d''d'$ is necessary and sufficient for the validity of the Property of Pappus, as we claimed.

Finally we say that the *Postulate of Pappus* is satisfied by the linear manifold (F,A) [of rank at least 3], if every configuration $[P_i,P_i',P_i'']$ has the Property of Pappus. If a,b,c are three independent elements, and if neither of the numbers d',d'' is 0 or 1, then the points $P_1' = Fb$, $P_2' = F(a+b)$, $P_3' = F(a+d'b)$ and $P_1'' = Fc$, $P_2'' = F(a+c)$, $P_3'' = F(a+d''c)$ lead as before to a configuration of the type considered here. Consequently we have the fundamental result:

The Postulate of Pappus is satisfied by the linear manifold (F,A) of rank not less than 3 if, and only if, the field F is commutative.

III.4. The Projective Geometry of a Line in Space; Cross Ratios

A line [= linear manifold of rank 2] has no geometrical structure, if considered as an isolated or absolute phenomenon, since then it is nothing but a set of points with the number of points on the line as the only invariant [see III.1, Remark 1 and the Projective Structure Theorem]. But the line receives a definite geometrical structure, if imbedded into a linear manifold of higher rank.

If (F,A) is a linear manifold of rank not less than 3, and if L' and L'' are lines in (F,A), then geometrical equivalence of a configuration on L' with one on L'' in the absolute sense is defined by any one-to-one correspondence between the points on L' and those on L'' whereas geometrical equivalence relative to the containing manifold (F,A) is defined by those correspondences which are induced by auto-projectivities of (F,A). Thus there arises the problem of characterizing those correspondences which are induced by projectivities. To do this we have to introduce the concept of cross ratio; and we emphasize that this concept, so central in classical discussions of projective geometry, is needed only for a treatment of the rather special problem under consideration.

DEFINITION 1: *Suppose that P,Q,R,S are four distinct points on the line*

L. Then the number s in F belongs to the cross ratio $\begin{bmatrix} P & Q \\ S & R \end{bmatrix}$ *if, and only if, there exist elements p,q in A such that*

$$P = Fp, \qquad Q = Fq, \qquad R = F(p + q), \qquad S = F(p + sq).$$

The justification for the "square" symbol indicating the cross ratio [which is due to F. Levi] will be found in the symmetry rules that we are going to derive later. The justification for defining the cross ratio not as a number but as set of numbers will be found in the following proposition.

Proposition 1: *The cross ratio of four distinct collinear points is a complete class of conjugate numbers.*

Here we term as usual the numbers h and k in F *conjugate*, if there exists a number $c \neq 0$ in F such that $h = c^{-1}kc$; and we shall designate the totality of numbers conjugate to the number k in F by the symbol $\langle k \rangle$.

PROOF: Consider four distinct collinear points P,Q,R,S. Then

$$P + Q = P + R = P + S = Q + R = Q + S = R + S = L$$

is a line in our linear manifold (F,A). We have to show first that there exists at least one number in the cross ratio $\begin{bmatrix} P & Q \\ S & R \end{bmatrix}$.

To do this consider any element r such that $R = Fr$. Since r belongs to $P \oplus Q$, there exist uniquely determined elements p,q in P and Q respectively such that $r = p + q$; and p and q are different from 0, since R is different from Q and P. Hence $P = Fp$, $Q = Fq$, $R = F(p + q)$. Since p is on $Q + S = P + Q$, there exist elements q' and w in Q and S respectively such that $p = q' + w$; and q' and w are different from 0, since P is different from S and Q. Hence $Q = Fq'$ and $S = Fw$. From $Fq = Q = Fq'$ we deduce the existence of a number $s \neq 0$ such that $q' = - sq$; and now it follows that $S = Fw = F(p + sq)$. Hence s belongs to the cross ratio $\begin{bmatrix} P & Q \\ S & R \end{bmatrix}$; and we note that $s \neq 0,\ 1$.

Suppose now that s is some definite number in the cross ratio. Then there exist elements p,q in A such that

$$P = Fp, \qquad Q = Fq, \qquad R = F(p + q), \qquad S = F(p + sq).$$

Consider now a number s' in F conjugate to s. Then there exists a number $t \neq 0$ in F such that $s = t^{-1}s't$; and we find

$$P = F(tp), \qquad Q = F(tq), \qquad R = F(tp + tq), \qquad S = F(tp + s'(tq))$$

so that s' belongs to the cross ratio $\begin{bmatrix} P & Q \\ S & R \end{bmatrix}$. Assume conversely that s' belongs to the cross ratio. Then there exist elements p',q' in A such that

$$P = Fp', \qquad Q = Fq', \qquad R = F(p' + q'), \qquad S = F(p' + s'q').$$

There exist numbers h,k,m,n in F neither of which is 0 such that

$$p' = hp, \qquad q' = kq, \qquad p' + q' = m(p + q), \qquad p' + s'q' = n(p + sq).$$

Hence $m(p + q) = hp + kq$ and $n(p + sq) = hp + s'kq$. From the independence of p and q we deduce now the validity of $m = h = k$ and $n = h$, $ns = s'k$ or $s' = nsn^{-1}$ so that s' is conjugate to s. Thus the cross ratio $\begin{bmatrix} P & Q \\ S & R \end{bmatrix}$ is the totality of numbers conjugate to s, as we intended to prove.

Remark 1: We have shown incidentally the obvious fact that 0, 1 do not belong to the cross ratio $\begin{bmatrix} P & Q \\ S & R \end{bmatrix}$, if we insist that the points P,Q,R,S are all distinct. If we would permit $S = P$, then our definition would give the value 0 to the cross ratio; and if we permit $S = R$, then our definition would give the value 1 to the cross ratio. These two possibilities we shall consequently allow occasionally. But $S = Q$ cannot be admitted unless we want to give the value ∞ to the cross ratio; and the points P,Q,R have to be considered distinct in any case. By and large it will prove most convenient to insist that P,Q,R,S are four distinct collinear points.

Remark 2: From $P = Fp$, $Q = Fq$, $R = F(p + q)$, $S = F(p + sq)$ we deduce also $S = F(q + s^{-1}p)$, provided $s \neq 0$; and this shows that $\begin{bmatrix} Q & P \\ S & R \end{bmatrix}$ is the totality of inverses of elements in $\begin{bmatrix} P & Q \\ S & R \end{bmatrix}$. This fact we may express in the form

$$\begin{bmatrix} P & Q \\ S & R \end{bmatrix}^{-1} = \begin{bmatrix} Q & P \\ S & R \end{bmatrix};$$

and one verifies similarly that

$$\begin{bmatrix} P & Q \\ S & R \end{bmatrix}^{-1} = \begin{bmatrix} P & Q \\ R & S \end{bmatrix}.$$

Next we note that $1 - t^{-1}st = t^{-1}(1 - s)t$. Thus $1 - s$ ranges with s over a whole class of conjugate numbers; and with every class C of conjugate numbers $1 - C$ is a well defined class of conjugate numbers in F. If we note now that

$$S = F(p + sq), \qquad P = F(-p), \qquad Q = F[(p + sq) + (-p)],$$
$$R = F[(p + sq) + (1 - s)(-p)],$$

then we find that

$$\begin{bmatrix} S & P \\ R & Q \end{bmatrix} = 1 - \begin{bmatrix} P & Q \\ S & R \end{bmatrix}.$$

The values of the cross ratios which we obtain by all the 24 possible permutations of the four points P,Q,R,S are now easily computed. In particular one checks the validity of *the symmetry formulas*

$$\begin{bmatrix} P & Q \\ S & R \end{bmatrix} = \begin{bmatrix} S & R \\ P & Q \end{bmatrix} = \begin{bmatrix} Q & P \\ R & S \end{bmatrix} = \begin{bmatrix} R & S \\ Q & P \end{bmatrix}.$$

REMARK 3: One verifies without difficulty that every class of conjugate numbers in F, not 0 or 1, is the cross ratio of some quadruplet of collinear points.

The following formulas will prove useful in our discussion; and they may also remind the reader of known expressions for cross ratios in classical instances.

Lemma 1: *Suppose that p and q are two independent elements in A.*

(*a*) *If u,v,w are three distinct numbers in F, then*

$$\begin{bmatrix} Fq & F(p+uq) \\ F(p+wq) & F(p+vq) \end{bmatrix} = \langle (v-u)(w-u)^{-1} \rangle.$$

(*b*) *If h,k,m,n are four distinct numbers in F, then*

$$\begin{bmatrix} F(p+hq) & F(p+kq) \\ F(p+nq) & F(p+mq) \end{bmatrix} = \langle (h-n)(k-n)^{-1}(k-m)(h-m)^{-1} \rangle.$$

PROOF: Formula (*a*) one verifies by realising that

$$\begin{aligned} F(p+vq) &= F[(v-u)q + (p+uq)], \\ F(p+wq) &= F[(v-u)q + (v-u)(w-u)^{-1}(p+uq)]. \end{aligned}$$

To prove (*b*) we verify first the following equality.

(*c*) If x,y,z are distinct numbers in F, then

$$F(p+xq) = F[-(p+yq) + (y-x)(z-x)^{-1}(p+zq)].$$

This identity follows from the following identities:

$$\begin{aligned} &(y-x)(z-x)^{-1} - 1 = (y-x-z+x)(z-x)^{-1} = (y-z)(z-x)^{-1}, \\ &(y-x)(z-x)^{-1}z - y = (y-x)(z-x)^{-1}z - z - (y-z) \\ &\quad = [(y-x)(z-x)^{-1} - 1]z - (y-z) \\ &\quad = (y-z)(z-x)^{-1}z - (y-z) = (y-z)(z-x)^{-1}[z-(z-x)] \\ &\quad = (y-z)(z-x)^{-1}x. \end{aligned}$$

From (*c*) one deduces (*b*) by remarking that

$$F(p+mq) = F[-(p+hq) + (h-m)(k-m)^{-1}(p+kq)]$$

and

$$\begin{aligned} F(p+nq) &= F[-(p+hq) + (h-n)(k-n)^{-1}(p+kq)] \\ &= F[-(p+hq) + (h-n)(k-n)^{-1}(k-m)(h-m)^{-1}(h-m)(k-m)^{-1}(p+kq)]. \end{aligned}$$

So far our discussion of cross ratios has been very similar to the classical discussion of this concept, in spite of the fact that the cross ratio is a class of conjugate numbers. We come now to a result which is rather different from classical results. If P,Q,R are three distinct collinear points, and if $\langle s \rangle$ is a class of conjugate numbers in F, then we may always find a point S on the line $P+Q$ such that $\begin{bmatrix} P & Q \\ S & R \end{bmatrix} = \langle s \rangle$, since we can always find elements p,q in A such that $P = Fp$, $Q = Fq$, $R = F(p+q)$, and since we may then choose $S = F(p+sq)$. But the point S is, in general, not uniquely determined by P,Q,R and the cross ratio, as may be seen from the following proposition.

Proposition 2: *The following properties of the four distinct points P,Q,R,S on the line L are equivalent.*

(I) *If X is a point on L such that $\begin{bmatrix} P & Q \\ S & R \end{bmatrix} = \begin{bmatrix} P & Q \\ X & R \end{bmatrix}$, then $S = X$.*

(II) $\begin{bmatrix} P & Q \\ S & R \end{bmatrix}$ *is a one element set.*

(III) $\begin{bmatrix} P & Q \\ S & R \end{bmatrix}$ *is part of the center of F.*

Proof: The equivalence of properties (III) and (II) is evident once one remembers that an element in F belongs to the center of F if, and only if, it commutes with every element in F. To prove the equivalence of (I) and (II) we remark first that there exist elements p,q in A and an element s in F such that

$$P = Fp, \quad Q = Fq, \quad R = F(p+q), \quad S = F(p+sq)\,; \begin{bmatrix} P & Q \\ S & R \end{bmatrix} = \langle s \rangle.$$

Assume now the validity of (I) and consider some element $f \neq 0$ in F. If we let $X = F(p + f^{-1}sfq)$, then

$$\begin{bmatrix} P & Q \\ X & R \end{bmatrix} = \langle s \rangle = \begin{bmatrix} P & Q \\ S & R \end{bmatrix};$$

and it follows from (I) that $F(p + f^{-1}sfq) = X = S = F(p+sq)$; and this implies $f^{-1}sf = s$ because of the independence of the elements p,q. Thus $\langle s \rangle$ is a one element set; and we have shown that (II) is a consequence of (I). If conversely (II) is satisfied, and if X is a point on L such that $\begin{bmatrix} P & Q \\ S & R \end{bmatrix} = \begin{bmatrix} P & Q \\ X & R \end{bmatrix}$, then $X = F(p+xq)$, since X is different from Q. Hence $\langle s \rangle = \langle x \rangle$; and this implies $s = x$ by (II) so that $S = X$. Thus (I) is a consequence of (II); and this completes the proof.

Remark 4: It is an immediate consequence of Proposition 2 that commutativity of the field F is necessary and sufficient for the fact that three collinear points and the cross ratio determine uniquely the fourth point; see Theorem 2 below.

Remark 5: If F does not have characteristic 2, then -1 is a center element different from 0 and 1. It is customary to term the four distinct collinear points P,Q,R,S *a harmonic set,* if $\begin{bmatrix} P & Q \\ S & R \end{bmatrix} = -1$. In this case the four points may be represented in the form:

$$P = Fp, \qquad Q = Fq, \qquad R = F(p+q), \qquad S = F(p-q).$$

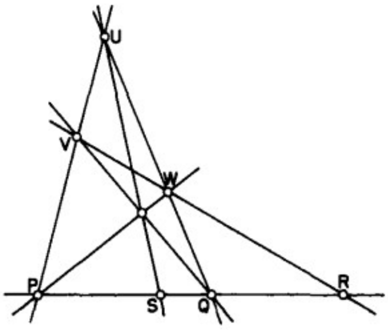

Fig. 5

It is now easy to verify that the following property is necessary and sufficient for the four points P,Q,R,S to form a harmonic set:

If U is a point not on the line $P+Q$, if V and W are points such that

$$\begin{aligned} U+V &= V+P = P+U, \\ U+W &= W+Q = Q+U, \\ V+W &= W+R = R+V, \end{aligned}$$

then the three lines $U+S$, $W+P$, $V+Q$ meet in a point.

Since we do not want to exclude fields of characteristic 2 from our discussion, it will be impossible [and usually unnecessary] to give harmonic sets the preferential treatment so often accorded to them.

Theorem 1: *Suppose that P,Q,R,S and P',Q',R',S' are quadruples of distinct collinear points.*

(*a*) *There exists a projectivity π of the linear manifold (F,A) such that $P^\pi = P'$, $Q^\pi = Q'$, $R^\pi = R'$, $S^\pi = S'$ if, and only if, there exists an automorphism α of the field F such that* $\begin{bmatrix} P & Q \\ S & R \end{bmatrix}^\alpha = \begin{bmatrix} P' & Q' \\ S' & R' \end{bmatrix}$.

(*b*) *There exists a collineation σ of (F,A) such that $P^\sigma = P'$, $Q^\sigma = Q'$, $R^\sigma = R'$, $S^\sigma = S'$ if, and only if,* $\begin{bmatrix} P & Q \\ S & R \end{bmatrix} = \begin{bmatrix} P' & Q' \\ S' & R' \end{bmatrix}$.

Proof: We note first that we may represent the points of the first quadruple in the form:

$$P = Fp, \quad Q = Fq, \quad R = F(p+q), \quad S = F(p+sq), \quad \begin{bmatrix} P & Q \\ S & R \end{bmatrix} = \langle s \rangle.$$

It follows from the First Fundamental Theorem of Projective Geometry

[III.1] that every projectivity π is induced by a semi-linear transformation α. But then

$$P^\pi = Fp^\alpha, \qquad Q^\pi = Fq^\alpha, \qquad R^\pi = F(p^\alpha + q^\alpha), \qquad S^\pi = F(p^\alpha + s^\alpha q^\alpha),$$
$$\begin{bmatrix} P^\pi & Q^\pi \\ S^\pi & R^\pi \end{bmatrix} = \langle s^\alpha \rangle = \langle s \rangle^\alpha = \begin{bmatrix} P & Q \\ S & R \end{bmatrix}^\alpha;$$

and this proves the necessity of our condition.

If there exists an automorphism α such that $\begin{bmatrix} P' & Q' \\ S' & R' \end{bmatrix} = \begin{bmatrix} P & Q \\ S & R \end{bmatrix}^\alpha$, then $\begin{bmatrix} P' & Q' \\ S' & R' \end{bmatrix} = \langle s^\alpha \rangle$. Consequently there exist elements p',q' in A such that

$$P' = Fp',\ Q' = Fq',\ R' = F(p' + q'),\ S' = F(p' + s^\alpha q').$$

Since p,q as well as p',q' are pairs of independent elements, one constructs easily a semi-linear transformation (α,β) of (F,A) such that $p^\beta = p'$, $q^\beta = q'$, $(xy)^\beta = x^\alpha y^\beta$ for x in F and y in A [use the fact that p,q as well as p',q' are part of some basis and that any two bases contain the same number of elements; see Chapter II]. This semi-linear transformation induces a projectivity π which maps P,Q,R,S upon P',Q',R',S' respectively. This completes the proof of (*a*). The proof of (*b*) is quite similar to the proof of (*a*), once one remembers that collineations are induced by linear transformations [$\alpha = 1$ in the above notation].

The preceding theorem shows that cross ratios characterize in a way the projective structure of quadruples of collinear points. Our next objective is the characterization of those mappings which preserve some or all cross ratios. It is a fairly obvious consequence of Theorem 1 that it will suffice to consider permutations of the points on some line which possess at least three fixed points.

Suppose now that σ is a permutation of the points on the line L and that the three distinct points U, V, W are fixed points of σ. Then we show as usual the existence of [independent] elements p,q such that $U = Fp$, $V = Fq$, $W = F(p + q)$. Every point, not V, on L may be represented in one and only one way in the form $F(p + xq)$ for x in F so that the elements p,q define a one-to-one correspondence between the points, not V, on L and the elements in F. Consequently there exists a well determined permutation σ' of the numbers in F such that

$$[F(p + xq)]^\sigma = F(p + x^{\sigma'} q).$$

It is clear that $0 = 0^{\sigma'}$, $1 = 1^{\sigma'}$; and that every permutation σ' of the numbers in F which leaves invariant 0 and 1 comes from a permutation of the points on L with fixed points U, V, W.

Proposition 3: *Assume that p, q are two independent elements in A, that σ is a permutation of the points on the line $Fp + Fq = L$ with fixed points Fp, Fq, $F(p + q)$ and that the corresponding permutation of the numbers in F is denoted by σ too so that*

$$[F(p + xq)]^\sigma = F(p + x^\sigma q) \text{ for every } x \text{ in } F.$$

If z is a number neither 0 nor 1 in the center of F, then the following properties of z and σ are equivalent.

(I) *If P, Q, R, S are four distinct points on L such that $\begin{bmatrix} P & Q \\ S & R \end{bmatrix} = z$, then $\begin{bmatrix} P^\sigma & Q^\sigma \\ S^\sigma & R^\sigma \end{bmatrix} = z$.*

(II) *The permutation σ of F satisfies $z = z^\sigma$ and $x^\sigma + y^\sigma = (x + y)^\sigma$, $(xyx)^\sigma = x^\sigma y^\sigma x^\sigma$ for every x, y in F.*

(III) *σ is an automorphism or anti-automorphism of F which leaves invariant z.*

We note that the center element z is the only element in its class of conjugate elements and that we may consequently identify z with its class $\langle z \rangle$. Furthermore we remind the reader that an *anti-automorphism* of the field F is a permutation of the elements in F which preserves addition, but inverts the order of multiplication $[(xy)^\sigma = y^\sigma x^\sigma]$.

PROOF: Assume first the validity of (I). Then $z^\sigma = z$, since

$$\begin{bmatrix} Fp & Fq \\ F(p + zq) & F(p + q) \end{bmatrix} = z,$$

and since therefore

$$\langle z^\sigma \rangle = \begin{bmatrix} Fp & Fq \\ F(p + z^\sigma q) & F(p + q) \end{bmatrix} = \begin{bmatrix} [Fp]^\sigma & [Fq]^\sigma \\ [F(p + zq)]^\sigma & [F(p + q)]^\sigma \end{bmatrix} = z.$$

Next we deduce from Lemma 1, (a) that we have for every $x \neq 0$ in F

$$\begin{bmatrix} Fq & Fp \\ F(p + xq) & F(p + zxq) \end{bmatrix} = z;$$

and consequently it follows from (I) and Lemma 1, (a) as before that

$$z = \begin{bmatrix} Fq & Fp \\ F(p + x^\sigma q) & F(p + zx)^\sigma q) \end{bmatrix} = \langle (zx)^\sigma (x^\sigma)^{-1} \rangle.$$

But this implies clearly

$$(zx)^\sigma = zx^\sigma \text{ for every } x \text{ in } F. \tag{I.1}$$

[Note that our proof holds for $x \neq 0$ only; but our formula is true for $x = 0$ too, since $0 = 0^\sigma$.]

If u and v are two different numbers in F, then we let $w = z^{-1}(v - u) + u$ which is possible, since $z \neq 0$. Since $z \neq 1$, w is different from u and v. Since z is in the center of F, we deduce from Lemma 1, (*a*) that

$$\begin{bmatrix} Fq & F(p + uq) \\ F(p + wq) & F(p + vq) \end{bmatrix} = \langle (v - u)(w - u)^{-1} \rangle = z.$$

As before we deduce from (i) and Lemma 1, (*a*) [which may be applied, since the permutation σ maps distinct elements upon distinct elements] that

$$z = \begin{bmatrix} Fq & F(p + u^\sigma q) \\ F(p + w^\sigma q) & F(p + v^\sigma q) \end{bmatrix} = \langle (v^\sigma - u^\sigma)(w^\sigma - u^\sigma)^{-1} \rangle.$$

Consequently

$$z(w^\sigma - u^\sigma) = v^\sigma - u^\sigma \qquad \text{or} \qquad zw^\sigma = v^\sigma - u^\sigma + zu^\sigma.$$

From (i,1) and the definition of w we deduce that

$$zw^\sigma = (zw)^\sigma = (v - u + zu)^\sigma;$$

and thus we have shown the validity of

(i.2) $\qquad (v - u + zu)^\sigma = v^\sigma - u^\sigma + zu^\sigma$ for every u,v in F.

[Actually we have verified this formula for $u \neq v$ only; but in case $u = v$, our formula is equivalent with (i.1).]

If x and y are numbers in F, then we may form $u = (z - 1)^{-1}y$, since $z \neq 1$. It follows from (i.2) that

$$(x + y)^\sigma = (x + zu - u)^\sigma = x^\sigma - u^\sigma + zu^\sigma = x^\sigma + (z - 1)u^\sigma.$$

Letting $v = 0$ in (i.2) we obtain $[(z - 1)u]^\sigma = (z - 1)u^\sigma$; and now it follows that

$$x^\sigma + (z - 1)u^\sigma = x^\sigma + [(z - 1)u]^\sigma = x^\sigma + y^\sigma.$$

Thus we have shown:

(i.3) $\qquad (x + y)^\sigma = x^\sigma + y^\sigma$ for every x and y in F.

Next we prove that

(i.4) $\qquad [k(zk - h)^{-1}h]^\sigma = k^\sigma(zk^\sigma - h^\sigma)^{-1}h^\sigma, \qquad$ provided $h \neq zk$.

This formula is trivially true, if k or $h = 0$. Thus we assume that neither h nor k is 0. If $h = k$, then (i.4) is a consequence of $(z - 1)u^\sigma = [(z - 1)u]^\sigma$ which equation is a consequence of (i.1) and (i.3). Thus we assume that $h \neq k$. Now we let $m = (z - 1)k(zk - h)^{-1}h$. If h were equal to m, then we would have $(z-1)k = zk - h$ or $k = h$ which is impossible; and $k \neq m$ is shown likewise. Now we infer from Lemma 1 (*b*) that

$$\begin{bmatrix} F(p+hq) & F(p+kq) \\ Fp & F(p+mq) \end{bmatrix} = \langle hk^{-1}(k-m)(h-m)^{-1} \rangle.$$

But $k^{-1}(k-m) = 1 - k^{-1}m = 1 - (z-1)(zk-h)^{-1}h$

$$= (zk-h)^{-1}[zk - h - (z-1)h] = (zk-h)^{-1}z(k-h)$$

and consequently

$$\begin{aligned} z(h-m) &= z[1-(z-1)k(zk-h)^{-1}]h = z[(zk-h)-(z-1)k](zk-h)^{-1}h \\ &= z[k-h](zk-h)^{-1}h = (zk-h+h-zh)(zk-h)^{-1}h \\ &= h + (1-z)h(zk-h)^{-1}h = h[1+(1-z)(zk-h)^{-1}h] \\ &= h(zk-h)^{-1}[zk-h+(1-z)h] = h(zk-h)^{-1}z(k-h) \\ &= hk^{-1}(k-m) \end{aligned}$$

or

$$\begin{bmatrix} F(p+hq) & F(p+kq) \\ Fp & F(p+mq) \end{bmatrix} = z.$$

Now we apply (I) and Lemma 1, (*b*) to find that

$$h^\sigma(k^\sigma)^{-1}(k^\sigma - m^\sigma)(h^\sigma - m^\sigma)^{-1} = z \quad \text{or} \quad h^\sigma(k^\sigma)^{-1}(k^\sigma - m^\sigma) = z(h^\sigma - m^\sigma).$$

By a direct computation it follows that $m^\sigma = (z-1)k^\sigma(zk^\sigma - h^\sigma)^{-1}h^\sigma$; and now (I.4) is an immediate consequence of the formula $[(z-1)u]^\sigma = (z-1)u^\sigma$ which we have used before and which is contained in (I.1) and (I.3).

(I.5) $\qquad (ab^{-1}a)^\sigma = a^\sigma(b^\sigma)^{-1}a^\sigma$ for $b \neq 0$ and a in F.

We let $k = a$ and $h = zk - b$. Then $h \neq zk$, since $b \neq 0$. Thus we may apply (I.4) and find that [$zk - h = b$ and therefore]

$$\begin{aligned} [ab^{-1}(za-b)]^\sigma &= [k(zk-h)^{-1}h]^\sigma = k^\sigma(zk^\sigma - h^\sigma)^{-1}h^\sigma \\ &= k^\sigma[(zk-h)^\sigma]^{-1}h^\sigma = a^\sigma(b^\sigma)^{-1}(za-b)^\sigma \end{aligned} \qquad \text{by (I.1) and (I.3).}$$

From (I.3) we deduce now $(ab^{-1}za)^\sigma = a^\sigma(b^\sigma)^{-1}(za)^\sigma$; and (I.5) is a consequence of (I.1).

If we let in (I.5) in particular $a = 1$ and remember that $1^\sigma = 1$, then we find that $(b^{-1})^\sigma = (b^\sigma)^{-1}$; and now one deduces from (I.5) the validity of $(aba)^\sigma = a^\sigma b^\sigma a^\sigma$. Thus (II) is a consequence of (I).

Assume now the validity of (II). Considering a and $b = a^{-1}$ we find that $a^\sigma = a^\sigma(a^{-1})^\sigma a^\sigma$ or $(a^{-1})^\sigma = (a^\sigma)^{-1}$. Letting $b = 1$ and remembering $1^\sigma = 1$ we find that $(a^2)^\sigma = (a^\sigma)^2$; and letting $a = x + y$ we deduce from this last formula:

$$\begin{aligned} (a^\sigma)^2 + a^\sigma b^\sigma + b^\sigma a^\sigma + (b^\sigma)^2 &= [(a+b)^\sigma]^2 = [(a+b)^2]^\sigma \\ &= [a^2\, b + ab + a + b^2]^\sigma = (a^2)^\sigma + (ab)^\sigma + (ba)^\sigma + (b^2)^\sigma \\ &= (a^\sigma)^2 + (ab)^\sigma + (ba)^\sigma + (b^\sigma)^2 \end{aligned}$$

or

$$a^\sigma b^\sigma + b^\sigma a^\sigma = (ab)^\sigma + (ba)^\sigma.$$

Next we note that

$$\begin{aligned}(ba)^\sigma &= [(ab)(ab)^{-1}(ba)]^\sigma = [a(b(ab)^{-1}b)a]^\sigma = a^\sigma[b(a)b^{-1}b]^\sigma a^\sigma \\ &= a^\sigma b^\sigma[(ab)^{-1}]^\sigma b^\sigma a^\sigma = a^\sigma b^\sigma[(ab)^\sigma]^{-1}b^\sigma a^\sigma.\end{aligned}$$

Hence

$$a^\sigma b^\sigma + b^\sigma a^\sigma = (ab)^\sigma + (ba)^\sigma = (ab)^\sigma + a^\sigma b^\sigma[(ab)^\sigma]^{-1}b^\sigma a^\sigma$$

and consequently

$$[(ab)^\sigma - a^\sigma b^\sigma][(ab)^\sigma]^{-1}[(ab)^\sigma - b^\sigma a^\sigma] = 0$$

so that we have shown:

(II.1) If a,b are elements in F, then $(ab)^\sigma = \begin{cases} a^\sigma b^\sigma \\ b^\sigma a^\sigma \end{cases}$.

Next we prove:

(II.2) If a,b,c are elements in F, then

(*a*) either $(ab)^\sigma = a^\sigma b^\sigma$ and $(ac)^\sigma = a^\sigma c^\sigma$ or else $(ab)^\sigma = b^\sigma a^\sigma$ and $(ac)^\sigma = c^\sigma a^\sigma$; and

(*b*) either $(ba)^\sigma = b^\sigma a^\sigma$ and $(ca)^\sigma = c^\sigma a^\sigma$ or else $(ba)^\sigma = a^\sigma b^\sigma$ and $(ca)^\sigma = a^\sigma c^\sigma$.

Suppose (*a*) were false. Then we may assume without loss in generality that $(ab)^\sigma \neq a^\sigma b^\sigma$. It follows from (II.1) that $b^\sigma a^\sigma = (ab)^\sigma \neq a^\sigma b^\sigma$; and this implies because of the invalidity of (*a*) that $(ac)^\sigma \neq c^\sigma a^\sigma$. Hence $a^\sigma c^\sigma = (ac)^\sigma$ by (II.1). Likewise

$$\begin{aligned}b^\sigma a^\sigma + a^\sigma c^\sigma &= (ab)^\sigma + (ac)^\sigma = (ab + ac)^\sigma = [a(b + c)]^\sigma \\ &= \begin{cases} a^\sigma(b + c)^\sigma = a^\sigma b^\sigma + a^\sigma c^\sigma \\ (b + c)^\sigma a^\sigma = b^\sigma a^\sigma + c^\sigma a^\sigma \end{cases}\end{aligned}$$

and both these possibilities lead to a contradiction. Hence (*a*) is true; and the validity of (*b*) is shown likewise.

If σ were neither an automorphism nor an anti-automorphism of F, then there would exist elements d,e,f,g in F such that $(de)^\sigma \neq d^\sigma e^\sigma$ and $(fg)^\sigma \neq g^\sigma f^\sigma$. We infer from (II.1) and (II.2) that

$$\begin{aligned}&(de)^\sigma = e^\sigma d^\sigma \text{ and } (dx)^\sigma = x^\sigma d^\sigma,\ (xe)^\sigma = e^\sigma x^\sigma \text{ for every } x \text{ in } F,\\ &(fg)^\sigma = f^\sigma g^\sigma \text{ and } (fy)^\sigma = f^\sigma y^\sigma,\ (yg)^\sigma = y^\sigma g^\sigma \text{ for every } y \text{ in } F.\end{aligned}$$

In particular we have therefore $(dg)^\sigma = d^\sigma g^\sigma = g^\sigma d^\sigma$ and $(fe)^\sigma = e^\sigma f^\sigma = f^\sigma e^\sigma$. From (II.1) we deduce now that

$$\begin{aligned}e^\sigma d^\sigma + (fe)^\sigma + (dg)^\sigma + f^\sigma g^\sigma &= (de)^\sigma + (fe)^\sigma + (dg)^\sigma + (fg)^\sigma \\ &= [(d + f)(e + g)]^\sigma \\ &= \begin{cases} (d + f)^\sigma(e + g)^\sigma = d^\sigma e^\sigma + (fe)^\sigma + (dg)^\sigma + f^\sigma g^\sigma \\ (e + g)^\sigma(d + f)^\sigma = e^\sigma d^\sigma + (fe)^\sigma + (dg)^\sigma + g^\sigma f^\sigma. \end{cases}\end{aligned}$$

But both these possibilities lead to a contradiction. Thus it is impossible that σ is neither an automorphism nor an anti-automorphism. Hence (III) is a consequence of (II).

Assume finally the validity of (III). Then σ certainly satisfies the following conditions:

$$(x+y)^\sigma = x^\sigma + y^\sigma, \qquad (zx)^\sigma = zx^\sigma \text{ for } x,y \text{ in } F,$$

since z is a center element of F such that $z = z^\sigma$. Consider now four distinct points P,Q,R,S on the line L such that $\begin{bmatrix} P & Q \\ S & R \end{bmatrix} = z$. We distinguish two cases.

Case 1: One of the points P,Q,R,S is the point Fq.

In Remark 2 we have shown that the cross ratio does not change its value, if the four points undergo a certain transitive group of permutations. Hence we may assume without loss in generality that

$$P = Fq, \qquad Q = F(p+uq), \qquad R = F(p+vq), \qquad S = F(p+wq).$$

It follows from Lemma 1, (*a*) that

$$(v-u)(w-u)^{-1} = z \qquad \text{or} \qquad v-u = z(w-u).$$

From the properties of σ already stated it follows that

$$v^\sigma - u^\sigma = (v-u)^\sigma = [z(w-u)]^\sigma = z(w-u)^\sigma = z(w^\sigma - u^\sigma)$$

or $(v^\sigma - u^\sigma)(w^\sigma - u^\sigma)^{-1} = z$; and now it follows from Lemma 1, (*a*) that

$$\begin{bmatrix} P^\sigma & Q^\sigma \\ S^\sigma & R^\sigma \end{bmatrix} = \begin{bmatrix} Fq & F(p+u^\sigma q) \\ F(p+w^\sigma q) & F(p+v^\sigma q) \end{bmatrix} = \langle (v^\sigma - u^\sigma)(w^\sigma - u^\sigma)^{-1} \rangle = z.$$

Case 2: None of the points P,Q,R,S is the point Fq.

Then our points have the form $P = F(p+hq)$, $Q = F(p+kq)$, $R = F(p+mq)$, $S = F(p+nq)$; and it follows from Lemma 1, (*b*) that

$$(*) \qquad (h-n)(k-n)^{-1}(k-m)(h-m)^{-1} = z;$$

and that

$$(**) \qquad \begin{bmatrix} P^\sigma & Q^\sigma \\ S^\sigma & R^\sigma \end{bmatrix} = \langle (h^\sigma - n^\sigma)(k^\sigma - n^\sigma)^{-1}(k^\sigma - m^\sigma)(h^\sigma - m^\sigma)^{-1} \rangle.$$

If σ happens to be an automorphism of the field F, then we deduce from (*), (**) and the invariance of z immediately that

$$\begin{bmatrix} P^\sigma & Q^\sigma \\ S^\sigma & R^\sigma \end{bmatrix} = z.$$

Thus we assume finally that σ is an anti-automorphism of F. We note first that

$$(+)\left\{\begin{aligned} &1-[(h-n)(k-n)^{-1}-1][(h-n)(h-m)^{-1}-1]\\ &\quad=(h-n)(k-n)^{-1}+(h-n)(h-m)^{-1}-(h-n)(k-n)^{-1}(h-n)(h-m)^{-1}\\ &\quad=(h-n)[(k-n)^{-1}(h-m)+1-(k-n)^{-1}(h-n)](h-m)^{-1}\\ &\quad=(h-n)(k-n)^{-1}[(h-m)+(k-n)-(h-n)](h-m)^{-1}\\ &\quad=(h-n)(k-n)^{-1}(k-m)(h-m)^{-1}. \end{aligned}\right.$$

Since this expression is by (*) the center element z, and since from $z=1-uv$ we may deduce $z=u^{-1}[1-uv]u=1-vu$, we find that

$$\begin{aligned} z&=(h-n)(k-n)^{-1}(k-m)(h-m)^{-1}\\ &=1-[(h-n)(k-n)^{-1}-1][(h-n)(h-m)^{-1}-1]\\ &=1-[(h-n)(h-m)^{-1}-1][(h-n)(k-n)^{-1}-1]\\ &=1-[(n-h)(m-h)^{-1}-1][(n-h)(n-k)^{-1}-1] \qquad [\text{by } (+)]\\ &=(n-h)(m-h)^{-1}(m-k)(n-k)^{-1}\\ &=(h-n)(h-m)^{-1}(k-m)(k-n)^{-1}\\ &=(h-m)^{-1}(k-m)(k-n)^{-1}(h-n) \end{aligned}$$

since z is in the center and since therefore transformation with $(h-n)$ does not change the value of z. Now it follows from (**) and the invariance of z under σ that

$$\begin{bmatrix} P^\sigma & Q^\sigma \\ S^\sigma & R^\sigma \end{bmatrix} = \langle [(h-m)^{-1}(k-m)(k-n)^{-1}(h-n)]^\sigma \rangle = z;$$

and thus we have shown that (I) is a consequence of (III). This completes the proof.

REMARK 6: When proving that (III) is a consequence of (II), we actually showed the following fact:

A permutation σ of the field F is an automorphism or anti-automorphism of F if, and only if, $1=1^\sigma$, $(x+y)^\sigma=x^\sigma+y^\sigma$, $(xyx)^\sigma=x^\sigma y^\sigma x^\sigma$.

These permutations σ of F shall be termed *semi-automorphisms of F.*

The proof we gave is a reproduction of a proof due to Hua [see L.-K. Hua: On the Automorphism of a Sfield, *Proceedings of the National Acad. of Sciences*, vol. 35 (1949), 386-389]. For a more recent investigation of the general problem of semi-automorphisms the reader is advised to consult N. Jacobson–C. E. Rickart: Jordan Homomorphisms of Rings, *Trans. Amer. Math. Soc.*, vol. 69 (1950), pp. 479–502.

REMARK 7: If one considers in particular the case $z=-1$ [which is impossible if, and only if, F has characteristic 2], then one investigates the permutations of the points of a line which preserve harmonic sets [Remark 5]; and one aims at a generalization of what is known as von

Staudt's Theorem; see in this context Proposition 4 below and G. Ancochea: Le théorème de von Staudt en géométrie projective quaternionienne, *Journal für die reine und angewandte Mathematik*, vol. 184 (1942), pp. 193-198, where further references may be found.

For a convenient enunciation of further results we have to introduce a concept which generalizes the relation between point permutations and number permutations appearing in Proposition 3. Consider a one-to-one correspondence σ mapping the totality of points on the line L upon the totality of points on the line L^σ. Then we term the permutation τ of the numbers in the field F a *σ-admissible permutation of F*, if there exist independent elements p,q in L and independent elements p',q' in L^σ such that

$$(Fp)^\sigma = Fp',\ [F(p+q)]^\sigma = F(p'+q'),\ (Fq)^\sigma = Fq',$$
$$[F(p+xq)]^\sigma = F(p'+x^\tau q') \qquad \text{for every } x \text{ in } F.$$

We note that $0 = 0^\tau$, $1 = 1^\tau$ is an immediate consequence of the preceding equations; and that the field permutation σ appearing in Proposition 3 is admissible with respect to the point permutation σ. It is easy to see that to every one-to-one mapping σ of the points on L upon the points on L^σ there exists at least one σ-admissible permutation of the field F; and that permutations of the field F which leave invariant 0 and 1 lead [in many ways] to one-to-one mappings of the points on one line onto the points on some other line.

Lemma 2: *If σ is a one-to-one correspondence mapping the points on the line L upon the totality of points on the line L^σ, and if the semi-automorphism α of the field F is σ-admissible, then*

$$\begin{bmatrix} P^\sigma & Q^\sigma \\ S^\sigma & R^\sigma \end{bmatrix} = \begin{bmatrix} P & Q \\ S & R \end{bmatrix}^\alpha \text{ for any four points } P,Q,R,S \text{ on } L.$$

Proof: Since σ is α-admissible, there exist elements p,q,p',q' such that

$$L = Fp + Fq, \qquad L^\sigma = Fp' + Fq',$$
$$(Fp)^\sigma = Fp', \qquad [F(p+q)]^\sigma = F(p'+q'), \qquad (Fq)^\sigma = Fq',$$
$$[F(p+xq)]^\sigma = F(p'+x^\alpha q') \text{ for every } x \text{ in } F.$$

From now on we are going to use arguments quite similar to those used already when deriving (I) from (III) in the proof of Proposition 3.

Consider four distinct points P,Q,R,S on L. We distinguish two cases.

Case 1: One of the four points is Fq.

We may assume without loss in generality that

$$P = Fq \text{ and } Q = F(p+uq),\ R = F(p+vq),\ S = F(p+wq).$$

Then u,v,w are three distinct numbers in F; and we deduce from Lemma 1, (*a*) that

$$\begin{bmatrix} P & Q \\ S & R \end{bmatrix} = \langle (v-u)(w-u)^{-1} \rangle, \qquad \begin{bmatrix} P^\sigma & Q^\sigma \\ S^\sigma & R^\sigma \end{bmatrix} = \langle (v^\alpha - u^\alpha)(w^\alpha - u^\alpha)^{-1} \rangle.$$

But α is an automorphism or anti-automorphism of F; and the numbers xy^{-1} and $y^{-1}x = y^{-1}(xy^{-1})y$ are conjugate in F. Hence

$$\langle (v^\alpha - u^\alpha)(w^\alpha - u^\alpha)^{-1} \rangle = \langle [(v - u)(w - u)^{-1}]^\alpha \rangle$$

or

$$\begin{bmatrix} P^\sigma & Q^\sigma \\ S^\sigma & R^\sigma \end{bmatrix} = \begin{bmatrix} P & Q \\ S & R \end{bmatrix}^\alpha$$

Case 2: None of the four points P,Q,R,S equals Fq.

In this case we have $P = F(p + hq)$, $Q = F(p + kq)$, $R = F(p + mq)$, $S = F(p + nq)$ where h,k,m,n are four different numbers in F. It follows from Lemma 1, (*b*) that

$$\begin{bmatrix} P & Q \\ S & R \end{bmatrix} = \langle (h - n)(k - n)^{-1}(k - m)(h - m)^{-1} \rangle,$$

$$\begin{bmatrix} P^\sigma & Q^\sigma \\ S^\sigma & R^\sigma \end{bmatrix} = \langle (h^\alpha - n^\alpha)(k^\alpha - n^\alpha)^{-1}(k^\alpha - m^\alpha)(h^\alpha - m^\alpha)^{-1} \rangle.$$

During the last part of the proof of Proposition 3 we verified an identity:

$$(+) \qquad \begin{aligned} &(h - n)(k - n)^{-1}(k - m)(h - m)^{-1} \\ &\quad = 1 - [(h - n)(k - n)^{-1} - 1][(h - n)(h - m)^{-1} - 1] = t; \end{aligned}$$

and this number t is conjugate in F to

$$\begin{aligned} t' &= 1 - [(h - n)(h - m)^{-1} - 1][(h - n)(k - n)^{-1} - 1] \\ &= 1 - [(n - h)(m - h)^{-1} - 1][(n - h)(n - k)^{-1} - 1] \\ &= (n - h)(m - h)^{-1}(m - k)(n - k)^{-1} \end{aligned}$$

by a second application of the identity $(+)$; and this number t' is conjugate in F to

$$t'' = (m - h)^{-1}(m - k)(n - k)^{-1}(n - h) = (h - m)^{-1}(k - m)(k - n)^{-1}(h - n)$$

which is obtained from t by inversion of the order of the factors. We may state this result as follows:

$$(++) \quad \langle (h - n)(k - n)^{-1}(k - m)(h - m)^{-1} \rangle = \langle (h - m)^{-1}(k - m)(k - n)^{-1}(h - n) \rangle.$$

If α is an automorphism, then we may apply it on the first expression in $(++)$; and if α is an anti-automorphism, then we apply it on the second expression in $(++)$. In this way we see that

$$\begin{bmatrix} P & Q \\ S & R \end{bmatrix}^\alpha = \langle (h^\alpha - n^\alpha)(k^\alpha - n^\alpha)^{-1}(k^\alpha - m^\alpha)(h^\alpha - m^\alpha)^{-1} \rangle = \begin{bmatrix} P^\sigma & Q^\sigma \\ S^\sigma & R^\sigma \end{bmatrix};$$

and this completes the proof of the lemma.

Proposition 4: *Suppose that* σ *is a one-to-one correspondence mapping the points on the line* L *upon the totality of points on the line* L^σ*; and suppose that the center of* F *contains at least three elements. Then* σ *preserves all the* *cross ratios if, and only if, the σ-admissible permutations of the field F are semi-automorphisms which leave invariant every class of conjugate elements in F.*

PROOF: The sufficiency of our condition is an immediate consequence of Lemma 2. Assume conversely that σ preserves all the cross ratios and consider a σ-admissible permutation τ of the elements in the field F. Then there exist pairs of independent elements p,q and p',q' in L and L^{σ} respectively such that

$$(Fp)^{\sigma} = Fp', \quad [F(p+q)]^{\sigma} = F(p'+q'), \quad (Fq)^{\sigma} = Fq',$$
$$[F(p+xq)]^{\sigma} = F(p'+x^{\tau}q') \text{ for every } x \text{ in } F.$$

There exists clearly a linear transformation η of the F-space L^{σ} upon the F-space L such that $(xp'+yq')^{\eta} = xp+yq$ for x,y in F. This linear transformation η induces a one-to-one correspondence σ' of the totality of points on L^{σ} upon the totality of points on L; and it is easy to see [either by application of Lemma 1 or by application of Lemma 2] that σ' preserves cross ratios. Consequently $\sigma\sigma'$ is a cross ratio preserving permutation of the points on the line L; and this permutation has clearly the following further properties:

$$(Fp)^{\sigma\sigma'} = Fp, \quad [F(p+q)]^{\sigma\sigma'} = F(p+q), \quad (Fq)^{\sigma\sigma'} = Fq,$$
$$[F(p+xq)]^{\sigma\sigma'} = F(p+x^{\tau}q) \text{ for } x \text{ in } F.$$

By hypothesis there exists in the center of F a number $z \neq 0, 1$. Since the permutation $\sigma\sigma'$ preserves all cross ratios, it satisfies Proposition 3, (I); and consequently it follows from Proposition 3 that τ is a semi-automorphism. That this semi-automorphism τ leaves invariant every class of conjugate elements in F, is an immediate consequence of the fact that

$$\langle x\rangle = \begin{bmatrix} Fp & Fq \\ F(p+xq) & F(p+q) \end{bmatrix} = \begin{bmatrix} Fp & Fq \\ F(p+x^{\tau}q) & F(p+q) \end{bmatrix} = \langle x^{\tau}\rangle$$

holds for every x in F. This completes the proof.

REMARK 8: If σ is a semi-automorphism of the field F which leaves invariant every class of conjugate elements in F, then σ leaves invariant every element in the center Z of F. If σ is an automorphism of the field F which leaves invariant every element in the center Z of F, and if F is finite over Z, then it is a celebrated theorem that σ is an inner automorphism of F [see, for instance, Artin-Nesbitt-Thrall (1), p. 66, Corollary 7.2D]. But if F is infinite over Z, then there exist automorphisms of F which leave invariant every class of conjugate elements in F and which are *not* inner automorphisms of F. [An example may be found in G. Köthe: Schiefkörper unendlichen Ranges über dem Zentrum, *Math.*

Ann., vol. 105 (1931), pp. 15-39.] If F is finite over Z, and if σ is an anti-automorphism of F, then σ leaves invariant every element in Z whereas the elements x and x^σ, for x in F, always satisfy the same equations over Z. It follows that x and x^σ are conjugate elements in F [see, for instance, Artin-Nesbitt-Thrall (1), p. 67, Theorem 7.2 E]. An example of such an anti-automorphism may be obtained by mapping every real quaternion $x_0 + x_1 i + x_2 j + x_3 k$ upon its "conjugate" $x_0 - x_1 i - x_2 j - x_3 k$. This shows that semi-automorphisms which leave invariant every class of conjugate elements may be inner automorphisms, automorphisms which are not inner and anti-automorphisms which are not automorphisms; and it is clear that cross ratios do not suffice for distinguishing between these various kinds of mappings of the points on a line.

Theorem 2: *The field F is commutative if, and only if, the identity is the only permutation of the points on a line which preserves cross ratios and possesses three fixed points.*

This theorem is a kind of complement to the Second Fundamental Theorem of Projective Geometry [III.3]; and it is also an improvement upon Remark 4.

PROOF: Assume first that the identity is the only permutation of the points on a line which preserves cross ratios and possesses three fixed points. If $g \neq 0$ is a number in F, and if p,q are two independent elements in A, then we may define a permutation σ of the points on the line $L = Fp + Fq$ by the rule:

$$(Fq)^\sigma = Fq, \qquad [F(p + xq)]^\sigma = F(p + g^{-1}xgq) \text{ for } x \text{ in } F.$$

It is clear that σ possesses the three distinct fixed points, Fp, Fq, $F(p + q)$; and it follows from Lemma 2 that σ preserves cross ratios, since the mapping $x \rightarrow g^{-1}xg$ is an inner automorphism of the field F. It follows from our hypothesis that $\sigma = 1$. Hence $p + g^{-1}xgq$ belongs, for every x in F, to $F(p + xq)$. This implies $x = g^{-1}xg$ for every x in F, since p and q are independent elements. Thus g belongs to the center of F. Since we have shown that every element in F belongs to the center of F, we have shown the commutativity of F.

Assume conversely the commutativity of the field F. If F consists of the two elements 0 and 1 only, then lines carry three points only; and the only permutation of the points on a line with three fixed points is naturally the identity. Thus we may assume that F contains at least three elements. Consider now a cross ratio preserving permutation σ of the points on the line L which possesses three fixed points. These fixed points may be assumed to have the form Fp, $F(p + q)$, Fq. Then there exists a σ-admissible permutation τ of the numbers in F such that

$$[F(p + \ )]xq^\sigma = F(p + x^\tau q)$$

for every x in F. It follows from Proposition 4 that τ is a semi-automorphism of F which leaves invariant every class of conjugate elements in F. But F is a commutative field so that $\tau = 1$. Hence $\sigma = 1$, as we wanted to show.

Remark 9: It is easy to see the equivalence of the conditions of Theorem 2 with the following property:

The one-to-one correspondences σ' and σ'' of the totality of points on the line L upon the totality of points on the line L' satisfy $\sigma' = \sigma''$ if, and only if,

(*a*) There exist three distinct points P_i $[i = 1,2,3]$ on L such that $P_i^{\sigma'} = P_i^{\sigma''}$ for $i = 1,2,3$; and

(*b*) $\begin{bmatrix} P^{\sigma'} & Q^{\sigma'} \\ S^{\sigma'} & R^{\sigma'} \end{bmatrix} = \begin{bmatrix} P^{\sigma''} & Q^{\sigma''} \\ S^{\sigma''} & P^{\sigma''} \end{bmatrix}$ for any distinct points P,Q,R,S on L.

Proposition 5: *Suppose that the characteristic of the field F is not 2 [so that $+1 \neq -1$]. Then the following properties of the one-to-one mapping σ of the points on the line L onto the points on the line L^σ are equivalent.*

(I) $\begin{bmatrix} P & Q \\ S & R \end{bmatrix} = \begin{bmatrix} P' & Q' \\ S' & R' \end{bmatrix}$, *if, and only if,* $\begin{bmatrix} P^\sigma & Q^\sigma \\ S^\sigma & R^\sigma \end{bmatrix} = \begin{bmatrix} P'^\sigma & Q'^\sigma \\ S'^\sigma & R'^\sigma \end{bmatrix}$.

(II) *Suppose that P,Q,R,S is a harmonic set. Then P',Q',R',S' is a harmonic set if, and only if,*

$$\begin{bmatrix} P^\sigma & Q^\sigma \\ S^\sigma & R^\sigma \end{bmatrix} = \begin{bmatrix} P'^\sigma & Q'^\sigma \\ S'^\sigma & R'^\sigma \end{bmatrix}$$

(III) *σ-admissible permutations of F are semi-automorphisms.*

Proof: It is trivial that (I) implies (II), since harmonic sets have cross ratio -1. Assume next the validity of (II). Consider any harmonic set P,Q,R,S; and suppose that W is a point on L^σ such that

$$\begin{bmatrix} P^\sigma & Q^\sigma \\ S^\sigma & R^\sigma \end{bmatrix} = \begin{bmatrix} P^\sigma & Q^\sigma \\ W & R^\sigma \end{bmatrix}$$

Then there exists one and only one point V on the line L such that $W = V^\sigma$; and it follows from (II) that P,Q,R,V is also a harmonic set. It follows from Proposition 2 that $V = S$; and this implies $W = S^\sigma$. Applying Proposition 2 again it follows now that the cross ratio $\begin{bmatrix} P^\sigma & Q^\sigma \\ S^\sigma & R^\sigma \end{bmatrix}$ is a center element z of F. With P,Q,R,S also P,Q,S,R is a harmonic set; and it follows from (II) that

$$z = \begin{bmatrix} P^\sigma & Q^\sigma \\ S^\sigma & R^\sigma \end{bmatrix} = \begin{bmatrix} P^\sigma & Q^\sigma \\ R^\sigma & S^\sigma \end{bmatrix} = z^{-1} \text{ or } z = \pm 1.$$

Since σ maps the four distinct points P,Q,R,S upon four distinct points, it is impossible that $z = 1$; and thus we have shown that σ maps harmonic sets upon harmonic sets. By an argument quite similar to the one used in the proof of Proposition 4 we may deduce now from Proposition 3 that σ-admissible permutations of F are semi-automorphisms; and thus (III) is a consequence of (II). That (I) is a consequence of (III), is a fairly immediate consequence of Lemma 2.

Lemma 3: *Suppose that σ is a one-to-one mapping of the points on the line L upon the points on the line L^σ.*

(*a*) *σ is induced in L by an auto-projectivity of the F-space A if, and only if, the σ-admissible permutations of F are automorphisms.*

(*b*) *σ is induced in L by a collineation of the F-space A if, and only if, the σ-admissible permutations of F are inner automorphisms.*

The proof is easily constructed once one remembers that projectivities are induced by semi-linear transformations [III.1, First Fundamental Theorem of Projective Geometry] and that a semi-linear transformation induces a collineation if, and only if, the component automorphism of F is inner [III.2, Lemma 1].

If the σ-admissible permutations of the field F are anti-automorphisms but not automorphisms, then σ cannot be induced by an auto-projectivity. It is, however, possible to deduce these mappings in some fashion from auto-dualities by means of the theory developed in the next chapter. We leave this to the interested reader.

It is clear from the discussion of Remark 8 that cross ratios will not suffice to characterize those mappings of the points on a line which are induced by auto-projectivities. Thus we need a certain generalization of the concept of cross ratio.

If P,Q,R are three distinct points on the line L, then we may represent them in the form: $P = Fp$, $Q = Fq$, $R = Fr$ subject to the condition that $p + q + r = 0$. If X,Y,Z are points on L none of which equals Q, then these points may be represented in one and only one way in the form $X = F(p + xq)$, $Y = F(p + yq)$, $Z = F(p + zq)$. If we select another admissible representation: $P = Fp'$, $Q = Fq'$, $R = Fr'$ subject to the condition $p' + q' + r' = 0$, then there exists a number $g \neq 0$ in F such that $p' = gp$, $q' = gq$, $r' = gr$; and we find that

$$X = F(p' + gxg^{-1}q'),\ Y = F(p' + gyg^{-1}q'),\ Z = F(p' + gzg^{-1}q').$$

Hence the second representation leads us to the conjugate triplet

$$g(x,y,z)g^{-1} = (gxg^{-1}, gyg^{-1}, gzg^{-1})$$

of numbers in F. It is easy to see that by changing the admissible representations we obtain a full class of conjugate triplets of numbers in F. Using the notation $\langle (x,y,x) \rangle$ for the totality of triplets $g(x,y,z)g^{-1}$ with $g \neq 0$ in F, we may now define

DEFINITION 2 : $\begin{bmatrix} Fp & Fq & F(p+q) \\ F(p+xq) & F(p+yq) & F(p+zq) \end{bmatrix} = \langle (x,y,z) \rangle.$

We note that $\begin{bmatrix} P & Q & R \\ X & Y & Z \end{bmatrix}$ is defined whenever the points P,Q,R,X,Y,Z are collinear, the points P,Q,R are different from each other and none of the points X,Y,Z equals Q. If furthermore

$$\begin{bmatrix} P & Q & R \\ X & Y & Z \end{bmatrix} = \langle (x,y,z) \rangle,$$

then

$$\begin{bmatrix} P & Q \\ X & R \end{bmatrix} = \langle x \rangle, \begin{bmatrix} P & Q \\ Y & R \end{bmatrix} = \langle y \rangle, \begin{bmatrix} P & Q \\ Z & R \end{bmatrix} = \langle z \rangle;$$

but the converse will not always be true except if x,y,z belong all three to the center of F.

Proposition 6: *Suppose that the center of the field F contains at least three elements, and that σ is a one-to-one mapping of the points on the line L upon the points on the line L^{σ}. Then σ is induced by an auto-projectivity of the F-space A if, and only if, there exists an automorphism α of the field F such that*

$$\begin{bmatrix} P^{\sigma} & Q^{\sigma} & R^{\sigma} \\ X^{\sigma} & Y^{\sigma} & Z^{\sigma} \end{bmatrix} = \begin{bmatrix} P & Q & R \\ X & Y & Z \end{bmatrix}^{\alpha} \textit{for all [admissible] } P,Q,R,X,Y,Z \textit{ on } L.$$

PROOF: It suffices to prove the sufficiency of the condition. If the condition is satisfied, then there exists a σ-admissible permutation τ of F which satisfies

$$\langle (x^{\tau},y^{\tau},z^{\tau}) \rangle = \langle (x^{\alpha},y^{\alpha},z^{\alpha}) \rangle \text{ for } x,y,z \text{ in } A.$$

One notes furthermore easily that $\tau\alpha^{-1}$ is a σ'-admissible permutation of F where σ' is an [easily constructed] permutation of the points on L which preserves cross ratios and has at least three fixed points. It follows from Proposition 3 that $\tau\alpha^{-1}$ is a semi-automorphism β of the field F such that (x,y,z) and $(x^{\beta},y^{\beta},z^{\beta})$ are conjugate in F. Consequently there exists to every pair x,y of elements in F an element $g \neq 0$ in F such that

$$x^{\beta} = g^{-1}xg, \; y^{\beta} = g^{-1}yg, \; (xy)^{\beta} = g^{-1}xyg.$$

But this implies

$$(xy)^{\beta} = g^{-1}xg\, g^{-1}yg = x^{\beta}y^{\beta}.$$

Hence β is an automorphism of F. Since α is an automorphism of F, τ is an automorphism of F; and now it follows from Lemma 3 that σ is induced by an auto-projectivity of the F-space A.

The discussion of Remark 8 makes it evident that this new concept, though sufficient to characterize the mappings induced by auto-projectivities, will not suffice to characterize those induced by collineations, again with the exception of certain special situations. What distinguishes the mapping induced by collineations from the others, is the fact that the former admit of geometrical construction; and this we are going to show now.

Suppose that the lines L' and L'' belong to the same plane of the F-space A; and that P is some point in this plane which is neither on L' nor on

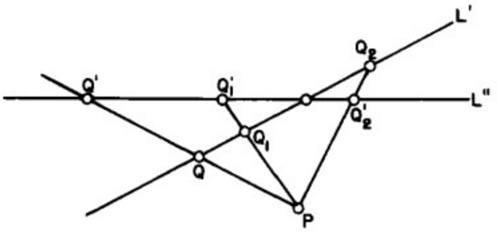

Fig. 6

L''. Then $L' \oplus P = L'' \oplus P$ is a plane carrying the lines L' and L''. If Q' is a point on L', then $Q'' = L'' \cap (P + Q')$ is a point on L'' [as follows from II.2, Rank Formula]. Likewise $L' \cap (P + Q'')$ is a point on L' for every point Q'' on L''; and these two operations are reciprocals of each other, since one deduces from Dedekind's Law that

$$\begin{aligned} L' \cap (P + [L'' \cap (P + Q')]) &= L' \cap (P + L'') \cap (P + Q') \\ &= L' \cap (P + Q') = Q', \end{aligned}$$

if we only note that $L' \leqslant P + L''$. This implies in particular that the mapping of the point Q' on L' upon the point $L'' \cap (P + Q')$ on L'' is one-to-one and exhaustive; and this mapping we shall call *the projection of the line L' from the point P upon the line L''*. [Note that this projection is the identity mapping, if $L' = L''$.]

Suppose now that $L_0, L_1, \cdots, L_k$ are lines in the F-space A and that L_i, L_{i+1} are always coplanar lines. If P_i is some point neither on L_i nor on L_{i+1}, such that $L_i + P_i = P_i + L_{i+1}$, then the projection σ_i of the line L_i from the point P_i upon the line L_{i+1} is well defined. We may form the product $\sigma = \sigma_0\sigma_1 \cdots \sigma_{k+1}$ which is a one-to-one mapping of the totality of points on L_0 upon the totality of points on L_k. Any such mapping σ of the points on L_0 upon the points on L_k shall be called *a linear mapping of the line L_0 upon the line L_k*. [Various names have been given in the literature to what we called here, for purely algebraical reasons, a linear mapping.]

Proposition 7: *The mapping σ of the points on the line L' upon the points on the line L'' is a linear mapping if, and only if, σ is induced by a collineation of the F-space A.*

Proof: We want to show first that linear mappings are induced by collineations. Since every linear mapping is a product of projections, and since every product of collineations is itself a collineation, it suffices to prove that every projection is induced by a collineation. Consider therefore two different coplanar lines L' and L'' and a point P on the plane

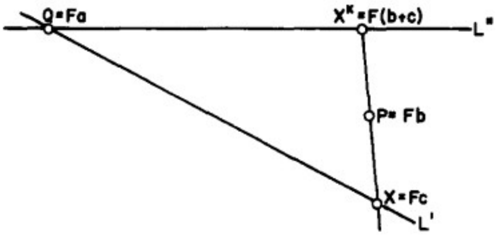

Fig. 7

$L' + L''$ which is neither on L' nor on L''. Then $L' + L'' = L'' + P = P + L'$ is a plane; and the lines L' and L'' meet in a point Q. Consider some point X on L' such that $X \neq Q$; and denote by $\varkappa$ the projection of L' from P onto L''. Then $X,P,X^{\varkappa}$ are three distinct collinear points; and as usual we can find elements b,c such that $P = Fb$, $X = Fc$, $X^{\varkappa} = F(b + c)$; and we let a be some element such that $Q = Fa$. Then there exists a linear transformation τ of the F-space A such that $a = a^{\tau}$, $b = b^{\tau}$, $c^{\tau} = b + c$ which leaves invariant every element in some space complementary to $L' + L''$. Every point on L' has the form $F(ua + vc)$. From

$$(ua + vc)^{\tau} = ua + v(b + c) = (ua + vc) + vb$$

we infer that $[F(ua + vc)]^{\tau}$ is the intersection $[F(ua + vc)]^{\varkappa}$ of the lines $L'' = Fa + F(b + c)$ and $F(ua + vc) + P$. Thus $\varkappa$ is induced by τ; and this shows, as we remarked before, that every linear mapping is induced by a collineation of the F-space A.

Suppose next that the mapping σ of the line L' upon the line L'' is induced by a collineation of the F-space A. Every collineation is induced by a linear transformation; and thus we may assume that σ is induced by the linear transformation η of the F-space A.

Case 1: $L' \neq L''$.

Since L' carries at least three points, there exist two different points Fu and Fv on L' such that neither $(Fu)^{\sigma} = Fu^{\eta}$ nor $(Fv)^{\sigma} = Fv^{\eta}$ is on L'. At most one of the points Fu and Fv is on L''; and thus we may assume without loss in generality that Fv is not on L''. If we let $u^{\eta} = u'$, $v^{\eta} = v'$, then it follows from our choice of u and v that the triplets u,v,u' and v,u',v' are independent. Now we define linear transformations ν,ω of the planes $Fu + Fv + Fu'$ and $Fv + Fu' + Fv'$ respectively by the rules

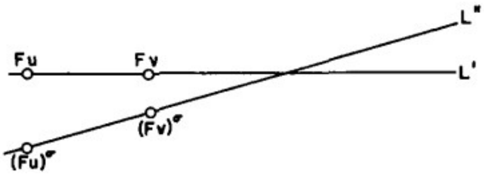

Fig. 8

$$u^{\nu} = u',\ v^{\nu} = v,\ u'^{\nu} = 2u' - u; \qquad v^{\omega} = v',\ u'^{\omega} = u',\ v'^{\omega} = 2v' - v.$$

One verifies that ν induces a projection of the line $Fu + Fv = L'$ from the point $F(u' - u)$ upon the line $Fu' + Fv$; that ω induces a projection of the line $Fu' + Fv$ from the point $F(v' - v)$ upon the line $Fu' + Fv' = L''$; and that $\nu\omega$ induces a linear transformation of L' upon L'' which coincides with the linear transformation η. Thus we have represented σ as a product of two projections.

Case 2: $L' = L''$.

Since the F-space A has rank not less than 3, there exists a line L different from $L' = L''$. There exists a projection σ' of L' upon L; and we have shown in the first part of the proof that σ' is induced by a collineation and therefore by a linear transformation η' of the F-space A. The linear transformation $\eta\eta'$ of the F-space A induces the mapping $\sigma\sigma'$ of the line L' upon the line $L \neq L'$, since σ maps L' upon $L'' = L'$. From what we have shown in Case 1 it follows that $\sigma\sigma'$ is the product of two projections. Since the inverse of a projection is likewise a projection, we have shown that σ is the product of three projections. This completes the proof.

APPENDIX III

Projective Ordering of a Space

Suppose that an algebraical ordering of the field F is given. By this we mean that *a domain of positivity* P has been distinguished in F. Such a subset P meets the following requirements:

(*a*) 0 is not in P.
(*b*) If x and y are in P, then $x + y$ and xy are in P.
(*c*) If $x \neq 0$ is not in P, then $-x$ is in P.

The numbers in P are referred to as positive numbers. [The reader should verify the fact that the definition

$$x < y \text{ if, and only if, } y - x \text{ is in } P$$

leads to an algebraical ordering of the field F which has the properties we expect an algebraical ordering to have.]

One proves:

(*d*) If $x \neq 0$, then x^2 is in P and either x, x^{-1} are both in P or x, x^{-1} are both not in P.

We leave the simple verification to the reader. From (*d*) one deduces easily.

(*e*) If y is in P, then $x^{-1}yx$ is in P for every $x \neq 0$ in F.

Consider now four distinct points P, Q, R, S on a line L in the F-space A. Then their cross ratio $\begin{bmatrix} P & Q \\ S & R \end{bmatrix}$ is a complete class of conjugate numbers in F none of which is 0 [or 1]. Thus it follows from (*e*) that either all the numbers in the cross ratio belong to P or none of them is in P. In the first case we term the cross ratio *positive* and in the second case *negative*. In a similar fashion we may see that either all the numbers in the cross ratio are *smaller than* 1 or all of them are *greater than* 1. [For $f^{-1}xf < 1$ if, and only if, $1 - f^{-1}xf = f^{-1}(1 - x)f$ belongs to P; and this is equivalent to saying that $1 - x$ is in P or that $x < 1$.] Now we may define:

The pair P, Q separates the pair R, S if, and only if, the cross ratio $\begin{bmatrix} P & Q \\ S & R \end{bmatrix}$ is both positive and smaller than 1.

That this soc. cyclical ordering of the points on L has all the properties we expect of it, the reader will easily verify using the symmetry properties of cross ratios. [For an account of the basic properties of cyclical order see, for instance, Coxeter (1), p. 22-24.] This ordering is furthermore invariant under all projections and collineations as follows from III.4, Proposition 7 and III.4, Lemma 2.

REMARK: The theory of commutative ordered fields is well developed [Artin-Schreier Theory; see, for instance, van der Waerden: Moderne Algebra, vol. 1]. But as regards non-commutative ordered fields there is known not much more than their existence [see, for instance, Reidemeister (1)] and the equivalence of orderability and formal reality recently established by I. Szele.

Another approach to the problem of order in projective spaces is given by E. Sperner: Beziehungen zwischen geometrischer und algebraischer Anordnung, *Sitzungsberichte der Heidelberger Akademie der Wissenschaften*; Math.-nat. Kl., 1949 (10), and E. Sperner: Die Ordnungsfunktionen einer Geometrie, *Math. Ann.*, vol. 121 (1949), pp. 107 ss.

lutorial anti-automorphism of F, such that R consists exactly of those numbers in F which are left invariant by α, then a discussion quite similar to the one under Application 1 leads now to the following normal form of f:

$$f(x,y) = \sum_{i=1}^{p} x_i y_i^{\alpha} - \sum_{i=p+1}^{r(A)} x_i y_i^{\alpha}$$

where p is again the number of positive points in maximal O-sets.

Remark 6: In the preceding examples the index of inertia is actually equal to the index $i(\sigma)$ introduced in section IV.4. In general one can only prove that $i(\sigma)$ does not exceed the index of inertia, but it is fairly easy to construct examples where the index of inertia actually exceeds the index $i(\sigma)$.

APPENDIX II

Projective Relations between Lines Induced by Polarities

If σ is a polarity of the linear manifold (F,A), and if L is a line, then A/L^{σ} has rank 2 [since the only proper subspaces of L are points, the only subspaces properly between L^{σ} and A are hyperplanes; and this is equivalent to saying that $r(A/L^{\sigma}) = 2$]. If L' is some line satisfying $L' \cap L^{\sigma} = 0$, then it follows from $r(A/L^{\sigma}) = 2$ that $A = L' \oplus L^{\sigma}$. But this is equivalent to $A = L'^{\sigma} \oplus L$ so that we have shown:

The following properties of the lines L and L' are equivalent:

$$L' \cap L^{\sigma} = 0,\ A = L' \oplus L^{\sigma},\ A = L \oplus L'^{\sigma},\ 0 = L \cap L'^{\sigma}.$$

Consider now a pair of lines L and L' meeting these equivalent requirements. If P is a point on L, then $L' \cap P^{\sigma} = P'$ is a point, since the hyperplane P^{σ} contains L^{σ} and satisfies

$$P^{\sigma} = L^{\sigma} \oplus (P^{\sigma} \cap L') = L^{\sigma} \oplus P'.$$

Furthermore we deduce from Dedekind's Law that

$$L \cap P'^{\sigma} = L \cap (L' \cap P^{\sigma})^{\sigma} = L \cap (L'^{\sigma} + P) = P + (L \cap L'^{\sigma}) = P.$$

Thus we see that mapping the point P on L onto the point $P' = L' \cap P^{\sigma}$ on L' and mapping the point Q on L' onto the point $L \cap Q^{\sigma}$ on L are reciprocal mappings; and this shows in particular that these two mappings are both one-to-one and exhaustive. It will be convenient to term the mapping of the point $P \leqslant L$ onto the point $P^{\sigma} \cap L'$ *the σ-mapping of the line L upon the line L'*; and we note that we can speak of this σ-mapping if, and only if, $A = L' \oplus L^\sigma$. Our objective in the present appendix is an investigation of these mappings.

Lemma 1: *Assume that the polarity σ is represented by the symmetrical α-form $f(x,y)$, that $L = Fp + Fq$ is a line in the linear manifold (F,A), and that the lines L and L' satisfy $A = L' \oplus L^\sigma$. Then there exist elements p',q' such that*

$$L' = Fp' + Fq',\ Fq' = L' \cap (Fq)^\sigma,\ F(p' + x^\alpha q') = L' \cap [F(p + xq)]^\sigma$$

for every number x in F.

Proof: We let $P' = L' \cap P^\sigma$ for every point P on L. Then mapping P onto P' is the σ-mapping of L upon L'; and this mapping is one-to-one and exhaustive, since $A = L' \oplus L^\sigma$, as we have pointed out before. The points $(Fp)'$, $(Fq)'$ and $[F(p + q)]'$ are consequently three distinct points on L'; and we may as usual show the existence of elements p'', q'' such that $(Fp)' = Fp''$, $(Fq)' = Fq''$, $[F(p + q)]' = F(p'' + q'')$. From $Fp'' \leqslant (Fp)^\sigma$ we deduce $f(p,p'') = f(p'',p) = 0$, since σ is represented by f. If $f(p'',q)$ were 0 too, then it would follow that $f(p'',L) = 0$ so that Fp'' would be on L^σ. But $L' \cap L^\sigma = 0$ by hypothesis and Fp'' is a point on L'. Hence $t = f(p'',q) \neq 0$; and we may let $p' = t^{-1}p''$, $q' = t^{-1}q''$. Then we have naturally

$$(Fp)' = Fp',\ (Fq)' = Fq',\ [F(p + q)]' = F(p' + q'),\ 1 = f(p',q)$$

so that in particular $L' = Fp' + Fq'$. As before we note that $f(p,p') = f(p',p) = 0$, $f(q,q') = f(q',q) = 0$; and we find likewise

$$0 = f(p + q,p' + q') = f(p,p') + f(p,q') + f(q,p') + f(q,q') = f(p,q') + 1$$

or $f(p,q') = f(q',p) = -1$, since $f(x,y) = f(y,x)^\alpha$ because of the assumed symmetry of the form f. Now we verify that

$$\begin{aligned} f(p + xq,p' + x^\alpha q') &= f(p,p') + f(p,q')x + xf(q,p') + xf(q,q')x \\ &= -x + x = 0, \end{aligned}$$

since α is involutorial. Hence $F(p' + x^\alpha q')$ is on $[F(p + xq)]^\sigma$ as well as on L'; and now our Lemma is an immediate consequence of the fact that the σ-mapping of L upon L' is a one-to-one and exhaustive mapping of the points on L onto the points on L'.

Proposition 1: *Suppose that the linear manifold (F,A) has rank not less than 3 and that the polarity σ of (F,A) is not a null system.*

(*a*) *The σ-mappings of lines are induced by auto-projectivities of (F,A) if, and only if, F is commutative.*

(*b*) *The σ-mapping of lines are induced by collineations of (F,A) if, and only if, σ may be represented by bilinear forms.*

Proof: It is a consequence of IV.3, Theorem 1 that σ may be represented by a symmetrical α-form f where α is an involutorial anti-automorphism of the field F. If L is a line, then there exists a subspace T of A such that $A = L \oplus T$. Naturally $L' = T^\sigma$ is a line such that $A = L \oplus L'^\sigma$; and thus we have shown that there exist σ-mappings of all lines.

It follows from Lemma 1 and III.4, Lemma 3 that the σ-mappings of lines are induced by auto-projectivities if, and only if, α is an automorphism of F; and that the σ-mappings of lines are induced by collineations if, and only if, α is an inner automorphism of A. But the anti-automorphism α of F is an automorphism if, and only if, F is commutative; and α is inner if, and only if, $\alpha = 1$; and this completes the proof of our proposition.

Remark 1: If the lines L and L' satisfy $A = L \oplus L'^\sigma$, then it follows from Lemma 1 and the definition of cross ratios [in III.4] that

$$\begin{bmatrix} L' \cap P^\sigma & L' \cap Q^\sigma \\ L' \cap S^\sigma & L' \cap R^\sigma \end{bmatrix} = \begin{bmatrix} P & Q \\ S & R \end{bmatrix}^\alpha$$

holds for any four distinct points P,Q,R,S on L, provided σ is represented by a symmetrical α-form. Thus apart from auto-projectivities also the polarities provide a means of constructing mappings of the points on a line which conserve equality of cross ratios.

Proposition 2: *Assume that L is a line and σ a polarity of the linear manifold (F,A).*

(*a*) *If $L \cap L^\sigma$ is a point, then $L \cap L^\sigma$ is the one and only one N-point on L.*

(*b*) *If σ is represented by a semi-bilinear form, if the characteristic of F is not 2, and if L carries one and only one N-point, then $L \cap L^\sigma$ is a point.*

Proof: If $P = L \cap L^\sigma$ is a point, then $0 < L^\sigma$ and $L < A$ so that $3 \leqslant r(A)$. Hence σ may be represented by a semi-bilinear form [IV.1, Proposition 1]. From $P \leqslant L \leqslant L + L^\sigma = (L^\sigma \cap L)^\sigma = P^\sigma$ we infer that P is an N-point on L. Assume that Q is a second N-point on L. Then $L = P + Q$, $Q \leqslant L \leqslant P^\sigma$; and it follows from IV.4, Lemma 3 that L is an N-line. Consequently we deduce from IV.4, Corollary 1 that $L \cap L^\sigma = 0$ or L, contradicting our hypotheses that $L \cap L^\sigma$ is a point. Thus P is the only N-point on L. Hence (*a*) is true.

Assume now that σ may be represented by some semi-bilinear form, that the characteristic of F is not 2, and that L carries one and only one N-point P. The line L carries some point $P' \neq P$. Then P' is on L, but not on P'^σ; and this implies in particular that L is not part of the hyperplane P'^σ. Hence $P'' = L \cap P'^\sigma$ is a point which is different from P', since otherwise P' would be an N-point. Either $P'' = P$ or else there exist, as usual, elements p', p'' such that $P' = Fp'$, $P = F(p' + p'')$, $P'' = Fp''$. There exists an α-form $f(x,y)$ which represents σ and which satisfies

$1 = f(p',p')$, since P' is not an N-point; and it follows from IV.3, Proposition 1 that $f(x,y)$ is α-symmetrical and $\alpha^2 = 1$. Since P'' is on P'^{σ} we have $0 = f(p'',p') = f(p',p'')$; and since P is an N-point, we have

$$0 = f(p' + p'',p' + p'') = f(p',p') + f(p'',p'') = 1 + f(p'',p'')$$

or $f(p'',p'') = -1$. Since the characteristic of F is not 2, the point $F(p' - p'')$ is different from P; and this point is clearly an N-point, since $0 = f(p' - p'',p' - p'')$. Thus we have been led to a contradiction by assuming that $P \neq P''$. Hence $P = P'' = L \cap P'^{\sigma}$. Consequently

$$P \leqslant L \cap P^{\sigma} \cap P'^{\sigma} = L \cap (P + P')^{\sigma} = L \cap L^{\sigma},$$

since P is an N-point on L. It is impossible that $L = L \cap L^{\sigma}$, since then every point on L would be an N-point. Since L is a line, this implies $P = L \cap L^{\sigma}$, completing the proof.

Remark 2: If A is a plane and the characteristic of F is different from 2, then the point L^{σ} is the pole of the line L; and Proposition 2 asserts that the pole of the line L is on L if, and only if, L carries one and only one N-point.

Remark 3: If $A = L$ is a line, then $L^{\sigma} = 0$, and every permutation of the points on L which possesses one and only one fixed point provides an example of a polarity for which (*b*) is not valid. Thus the hypothesis that σ be represented by a semi-bilinear form is indispensable. We note that this hypothesis is satisfied whenever $3 \leqslant r(A)$ as follows from IV. 1, Proposition 1.

Remark 4: If the characteristic of the field F is 2, then (*b*) ceases to be valid, as follows from the following often used example. Denote by F any commutative field of characteristic 2 and by (F,A) the plane over F. If we represent the elements in A, as we may, by triplets $x = (x_1, x_2, x_3)$ of numbers x_i in F, then we may consider the bilinear form

$$f(x,y) = \sum_{i=1}^{3} x_i y_i$$

[= scalar product]. The point $F(x_1,x_2,x_3)$ is an N-point if, and only if, it is on the line $\sum_{i=1}^{3} x_i = 0$, since $f(x,x) = \sum_{i=1}^{3} x_i^2 = \left[\sum_{i=1}^{3} x_i\right]^2$ as the characteristic of F is 2. This N-line L is met by every other line in the plane so that every line not L carries one and only one N-point. But the line $x_1 = 0$ has the pole $F(1,0,0)$ which is not on its polar so that this line carries one and only one N-point, though it does not carry its pole.

Lemma 2: *The involutorial anti-automorphism α of the field F is the identity-automorphism if, and only if,*

(*a*) $rr^\alpha = 1$ *implies* $r = \pm 1$ *and*

(*b*) $xx^\alpha = x^\alpha x$ *for every* x *in* F *whenever the characteristic of* F *is two.*

REMARK: It seems to be an open question whether condition (*b*) is a consequence of condition (*a*).

PROOF: The necessity of our conditions is fairly obvious. Assume now the validity of condition (*a*). Then we prove first that

(*a*.1) $xx^\alpha = x^\alpha x$ *implies* $x^\alpha = \pm x$.

Since this is certainly true, if $x = 0$, we may assume that $x \neq 0$; and then we may form $r = x^{-1}x^\alpha$. Since x and x^α commute, we find that

$$rr^\alpha = x^{-1}x^\alpha x x^{-\alpha} = 1.$$

It follows from (*a*) that $r = \pm 1$; and this is clearly equivalent to $x^\alpha = \pm x$.

If the field F has characteristic 2, then $\alpha = 1$ is an immediate consequence of (*a*.1) and (*b*) and therefore of (*a*) and (*b*).

Assume next that the characteristic of F is different from 2; and assume the validity of (*a*) and (*a*.1). If t is any element in F, then the element $s = (t^\alpha - t) - 1$ certainly commutes with the element

$$s^\alpha = t - t^\alpha - 1 = -(t^\alpha - t) - 1 = -s - 2.$$

Hence it follows from (*a*.1) that

$$t - t^\alpha - 1 = s^\alpha = \pm s = \pm (t^\alpha - t - 1).$$

The minus sign is impossible in this equation, since this would imply $-1 = +1$ contradicting our assumption that the characteristic of F is not two. Hence we have $t - t^\alpha - 1 = t^\alpha - t - 1$ or $2t^\alpha = 2t$; and this implies $t^\alpha = t$, since we assumed the characteristic of F to be different from 2. Thus we have shown that $\alpha = 1$; and this completes the proof.

Proposition 3: *Suppose that the polarity σ of the linear manifold (F,A) possesses N-points and that $3 \leqslant r(A)$. Then σ may be represented by ordinary bilinear forms if, and only if,*

(*a*) *lines containing more than two N-points are N-lines and*

(*b*) F *is commutative.*

If the characteristic of F is different from 2, then condition (b) is a consequence of condition (a).

PROOF: Since $3 \leqslant r(A)$, it is possible to represent σ by a semi-bilinear form [IV.1, Proposition 1]; and it should be noted that this will be the only application of the hypothesis $3 \leqslant r(A)$. It follows from IV.1, Proposition 3 that every form representing σ is an ordinary bilinear form, if one of the representing forms has this property.

Assume now that it is possible to represent σ by ordinary bilinear forms. Then the identity automorphism is an anti-automorphism of F so that F is a commutative field. Suppose now that the line L carries the three distinct N-points P,Q,R. Then there exist elements p,q such that $P = Fp$, $Q = Fq$, $R = F(p + q)$. If f is some ordinary bilinear form representing σ, then we have

$$0 = f(p,p) = f(q,q) = f(p,q) + f(q,p);$$

and it follows from the commutativity of F and the bilinearity of f that

$$\begin{aligned} f(xp + yq, xp + yq) &= xf(p,p)x + xf(p,q)y + yf(q,p)x + yf(q,q)y \\ &= xy[f(p,q) + f(q,p)] = 0. \end{aligned}$$

Hence L is an N-line. This completes the proof of the necessity of conditions (*a*) and (*b*). The reader ought to investigate the connection between condition (*a*), Proposition 1 and the fact that a linear transformation of a line with three fixed points is the identity.

We assume now the validity of (*a*). There exists at least one N-point P. We distinguish two cases.

Case 1: Every point, not on P^σ, is an N-point.

If Q is a point on P^σ, but $Q \neq P$, then $Q^\sigma \neq P^\sigma$ so that the hyperplane Q^σ carries at least one point Q' not on P^σ. Then the line $L = Q + Q'$ is not on P^σ and meets therefore P^σ in the point Q. If $Q = Fq$, $Q' = Fq'$ and $R = F(q + q')$, then Q' and R are certainly not on P^σ and are therefore N-points. If f is any semi-bilinear form representing σ, then we have consequently

$$\begin{aligned} &0 = f(q,q') = f(q',q) = f(q',q') \text{ and} \\ &0 = f(q + q', q + q') = f(q,q) \end{aligned}$$

so that Q itself is an N-point. Thus we have shown that every point in A is an N-point. Hence σ is a null system; and it follows from IV.2, Proposition 1 that f is an ordinary bilinear form.

Case 2: There exists a point W which is neither an N-point nor on P^σ.

Let $W = Fw$. Then it is possible to select an α-form f which represents σ and satisfies $f(w,w) = 1$; and we may infer from IV.3, Proposition 1 that α is involutorial and f symmetrical. We have $f(w,P) \neq 0$, since W is not on P^σ; and consequently we may select an element p such that $P = Fp$ and $1 = f(w,p)$. Because of the symmetry of f we have $f(p,w) = 1$; and $f(p,p) = 0$, since P is an N-point. Every point on the line $L = P + W$ with the exception of W has the form $F(p + xw)$; and the correspondence between the numbers x in F and the points different from W on L is a one-to-one correspondence. The point $F(p + xw)$ is an N-point if, and only if,

$$0 = f(p + xw, p + xw) = x + x^\alpha + xx^\alpha = (x + 1)(x + 1)^\alpha - 1.$$

The number of N-points on L is consequently exactly the number of solutions x of the equation $(x+1)(x+1)^{\alpha}=1$, if we remember that W is not an N-point. As this point W is on L, the line L is not an N-line; and it follows from condition (a) that L carries at most two N-points. Consequently we have shown that:

(a^{*}) *The equation* $(x+1)(x+1)^{\alpha}=1$ *has at most two solutions* x *in* F.

If we let $y=x+1$, then we see that (a^{*}) is equivalent with the assertion that the equation $yy^{\alpha}=1$ has at most two solutions y in F. This equation has certainly the solutions $y=\pm 1$. If it possessed a solution $z\neq\pm 1$, then $z^{-1}\neq z$ would be a further solution which is different from ± 1; and thus we would have at least three solutions of $yy^{\alpha}=1$ [at least four if $+1\neq -1$]. Since this is impossible, we have shown that:

(a^{**}) $jj^{\alpha}=1$ *implies* $j=\pm 1$.

Thus we have seen that our present condition (a) implies the validity of Lemma 2, (a); and Lemma 2, (b) is certainly a consequence of our present condition (b) which we need apply only in case the characteristic of F is two. Thus we may deduce $\alpha=1$ from Lemma 2; and we have shown again that σ may be represented by ordinary bilinear forms. This completes the proof.

Remark 5: The question whether our condition (b) is a consequence of our condition (a) is equivalent to the corresponding question concerning Lemma 2, since (a^{**}) has been shown to be a consequence of (a) alone. On the other hand it is completely impossible to omit the hypothesis assuring the existence of N-points, as may be seen from easily constructed examples of "positive definite semi-bilinear forms."

Remark 6: Suppose that the polarity σ of the linear manifold (F,A) possesses N-points, that lines carrying more than two N-points are N-lines, that $3\leqslant r(A)$ and that the characteristic of F is two. Then we show:

(c) *Lines carrying at least two N-points are N-lines.*

Suppose namely that P and Q are different N-points and that f is some semi-bilinear form representing σ. As the characteristic of F is two, we may assume without loss in generality that f is symmetrical. If firstly P is on Q^{σ}, then we have

$$0=f(P,P)=f(P,Q)=f(Q,P)=f(Q,Q);$$

and this implies clearly that $0=f(P+Q,P+Q)$ so that $P+Q$ is an N-line. If secondly P is not on Q^{σ}, then $f(P,Q)\neq 0$; and we may select elements p and q such that $P=Fp$, $Q=Fq$ and $1=f(p,q)=f(q,p)$. Since we have $0=f(p,p)=f(q,q)$, it follows that

$$f(p+q,p+q)=f(p,q)+f(q,p)=2=0;$$

and we have shown the existence of a third N-point on $P + Q$. It follows from our hypothesis that $P + Q$ is an N-line; and this completes the proof of (c).

From (c) one deduces without difficulty that:

(d) *The totality of N-points is a subspace.*

Some information on such a subspace may be found in IV.4.

Proposition 4: *If each of the lines L' and L'' carries at least two N-points, though neither of them is an N-line, then L' and L'' carry the same number of N-points.*

Proof: This proposition is vacuously true, if either $r(A) < 3$ or our polarity σ is a null system. Thus we assume that σ is not a null system and that $3 \leqslant r(A)$. Then it follows from IV.3, Theorem 1 that σ may be represented by a symmetrical α-form f with $\alpha^2 = 1$. Consider now a line L which is not an N-line, but carries the two distinct N-points P and Q. Then P is not on Q^σ, since otherwise L would be an N-line [IV.4, Lemma 3]. Let $Q = Fq$. Then $f(q,q) = 0$, but $f(P,q) \neq 0$. Consequently there exists p such that $P = Fp$ and $f(p,q) = 1$. Since f is symmetrical, we have $f(q,p) = 1$; and since P is an N-point, we have $f(p,p) = 0$. To every point X on L different from P and Q, there exists one and only one number $x \neq 0$ in F such that $X = F(p + xq)$. This point is an N-point if, and only if,

$$0 = f(p + xq, p + xq) = x + x^\alpha.$$

If we denote now by C the cardinal number of elements x in F such that $x^\alpha = -x$ [the skew-symmetric elements in F], then we have found that:

The number of N-points on L is exactly $C + 1$.

This last assertion is actually slightly sharper than our proposition.

APPENDIX III

The Theorem of Pascal

Our discussion of the celebrated Theorem of Pascal is rather similar in intent to our previous discussion of the Theorem of Pappus [III, Appendix II]. Whereas this theorem is of universal validity in the classical theory of conics, it will be shown that from our more general point of view it must be considered to be valid only under quite exceptional circumstances. The reader may consult Coxeter [1] or Levi [1] for a discussion of Pascal's Theorem in its classical framework.

It will be convenient to assume throughout this appendix that the linear manifold (F,A) is a plane $[r(A) = 3]$. This will simplify our dis-

( )) " && ' 0 0 H !

We remark finally that the name *hyperplane* will be used for elements H such that A/H is a point. If A has finite rank, then $r(A) = r(H) + 1$; and if A has infinite rank, then $r(A) = r(H)$. Note that the rank condition defines hyperplanes in the finite case only.

Whenever possible, we shall make use of the appropriate geometrical terminology. Thus we shall speak of lines passing through a point, carrying a point, meeting in a point etc.

VII.3. The Theorem of Desargues

The considerations of the present section are almost identical with those customary in ordinary three dimensional projective geometry. Thus we shall omit some of the details.

Proposition 1: *Assume that the three lines L, L', L'' pass through the point P, but are not contained in a plane. Assume furthermore that Q, R are points on L, that Q', R' are points on L' and that Q'', R'' are points on L'' and that none of these points equals P. Assume finally that $Q + Q' \neq R + R'$, $Q' + Q'' \neq R' + R''$ and $Q'' + Q \neq R'' + R$. Then $(Q + Q') \cap (R + R')$, $(Q' + Q'') \cap (R' + R'')$, $(Q'' + Q) \cap (R'' + R)$ are collinear points.*

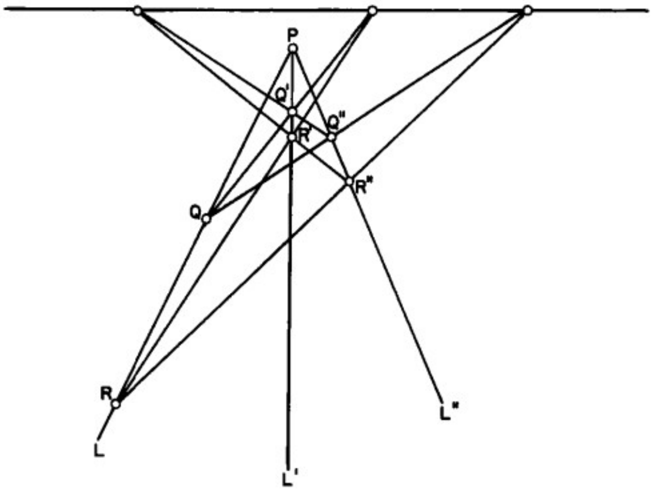

Fig. 13

Proof: We note first that $L + L'$, $L' + L''$ and $L'' + L$ are three distinct planes. Next we note that $Q + Q' + Q''$ and $R + R' + R''$ are two distinct planes. Finally we remark that $Q + Q'$ and $R + R'$ are two distinct lines meeting in the point $(Q + Q') \cap (R + R')$; and likewise we see that $(Q' + Q'') \cap (R' + R'')$ and $(Q'' + Q) \cap (R'' + R)$ are points. But all these points are on the intersection of the distinct planes $Q + Q' + Q''$ and $R + R' + R''$. But their intersection is clearly a line, since they are contained in the element $L + L' + L''$ of rank 4. This completes the proof.

Proposition 2: *Assume that* $3 < r(A)$. *Suppose that the three distinct lines* L, L', L'' *pass through the point* P, *that the points* Q, R *are on* L, *the points* Q', R' *on* L' *and the points* Q'', R'' *on* L'', *and that none of these points equals* P. *If finally* $Q + Q' \neq R + R'$, $Q' + Q'' \neq R' + R''$ *and* $Q'' + Q \neq R'' + R$, *then* $(Q + Q') \cap (R + R')$, $(Q' + Q'') \cap (R' + R'')$ *and* $(Q'' + Q) \cap (R'' + R)$ *are collinear points.*

The reduction of Proposition 2 to Proposition 1 may be effected in the usual fashion. [See e.g. Veblen-Young [1], p. 41.]

If we omit in Proposition 2 the hypothesis that $3 < r(A)$ or in Proposition 1 the hypothesis that L, L', L'' are not coplanar, then these Propositions cease to be true. At this point begins the investigation of the Theory of Projective Planes [which may or may not be Desarguesian]; and this theory is completely outside the scope of our investigation. It is, however, necessary for our purposes that we are assured of the validity of the Theorem of Desargues; and thus we impose the following further postulate.

IX. *If the three distinct lines* L, L', L'' *pass through the point* P, *if the points* Q, R *are on* L, *the points* Q', R' *on* L' *and the points* Q'', R'' *on* L'', *if none of these points equals* P, *if* $Q + Q' \neq R + R'$, $Q' + Q'' \neq R' + R''$ *and* $Q'' + Q = R'' + R$, *then* $(Q + Q') \cap (R + R')$, $(Q' + Q'') \cap (R' + R'')$, $(Q'' + Q) \cap (R'' + R)$ *are collinear points.*

VERIFICATION OF POSTULATE IX IN $S(F,A)$:

If the F-space A has rank not less than 4, then the validity of IX is a consequence of Proposition 2. If the F-space A has rank less than 4, then we form $A \oplus A$ which more comprehensive F-space has rank greater than 3, provided $r(A) = 3$ [if $r(A) < 3$, then IX is trivially satisfied]. Hence IX holds in $A \oplus A$ and consequently in the subspace A of $A \oplus A$. It would not have been difficult to verify the validity of IX by direct computation, a useful exercise.

Proposition 3: *Assume the validity of Postulates* I *to* IX. *If* P, Q, R *are three different, but collinear points, if* $P', P'', Q', Q'', R', R''$ *are points such that* $P' + Q'$ *and* $P'' + Q''$ *are different lines meeting in* R, $Q' + R'$ *and* $Q'' + R''$ *are different lines meeting in* P, $R' + P'$ *and* $R'' + P''$ *are different lines meeting in* Q, *and if* $P' + P''$, $Q' + Q''$ *and* $R' + R''$ *are three distinct lines, then these lines* $P' + P''$, $Q' + Q''$ *and* $R' + R''$ *are copunctual* [*have a point in common*].

This dualized theorem of Desargues may be verified as follows. If $3 < r(A)$, then the considerations used in proving Proposition 2 may be used [mutatis mutandis]; and if $3 = r(A)$, then the principle of duality may be applied to Postulate IX. We leave the details to the reader.

VII.4. The Imbedding Theorem

The objective of the present section is the proof of the following

Imbedding Theorem: *If the partially ordered set S satisfies Postulates* I *to* VIII, *and if the maximal element A in S has rank not less than* 3, *then the following condition is necessary and sufficient for the validity of the Theorem of Desargues [Postulate* IX] *in S:*

IX*. *S is contained in a partially ordered set T which is different from S and which satisfies Postulates* I *to* VIII.

If in particular the maximal element A has rank greater than 3, then the validity of IX is a consequence of VII.3, Proposition 2; and thus it follows from the Imbedding Theorem that S has also the Imbedding Property IX*. This is the principal reason why we have to prove the comparatively deep Imbedding Theorem instead of substituting for Postulate IX the Postulate IX*.

The Imbedding Theorem will be exploited in the next section. The following remark may indicate how this can be done. If S is properly contained in T, then there exists in T an element B such that A is a hyperplane with respect to B or B is a point over A. One may then construct the homothetic group of B over A; and this group contains in a way the additive group and the field of a linear manifold whose system of subspaces is projectively equivalent with S [see III, Appendix I].

That the Theorem of Desargues [Postulate IX] is a consequence of IX*, may be deduced from VII.3, Proposition 2, since the maximal element B of the containing system T certainly satisfies $A < B$ so that $3 < r(B)$.

Throughout the remainder of this section [which may be omitted in a first reading] we shall be concerned with the proof of the sufficiency of IX. Thus we assume throughout that Postulates I to IX are satisfied by S and that its maximal element A has rank not less than 3. We begin by constructing

THE BASIC QUADRANGLE:

It consists of four lines L_o, L_r, L_s, L_t in S which are coplanar, though no three of these lines are copunctual.

The existence of this basic quadrangle is easily deduced from the fact that there exist at least three independent points $[3 \leqslant r(A)]$ and that every line carries at least three distinct points [VIII].

The Rationality of the Moduli Space of Curves of Genus 3 after P. Katsylo

Christian Böhning

Mathematisches Institut
Bunsenstrasse 3-5
37073 Göttingen, Germany
`boehning@uni-math.gwdg.de`

Summary. This article is a survey of P. Katsylo's proof that the moduli space $\mathfrak{M}_3$ of smooth projective complex curves of genus 3 is rational. We hope to make the argument more comprehensible and transparent by emphasizing the underlying geometry in the proof and its key structural features.

Key words: Rationality, moduli spaces of curves

2000 Mathematics Subject Classification codes: 14E08, 14H10, 14H45

1 Introduction

The question whether or not $\mathfrak{M}_3$ is a rational variety had been open for a long time until an affirmative answer was finally given by P. Katsylo in 1996. There is a well-known transition in the behavior of the moduli spaces $\mathfrak{M}_g$ of smooth projective complex curves of genus g from unirational for small g to general type for larger values of g; the moral reason that $\mathfrak{M}_3$ should have a good chance to be rational is that it is birational to a quotient of a projective space by a *connected* linear algebraic group. No variety of this form has been proved to be irrational up to now. More precisely, $\mathfrak{M}_3$ is birational to the moduli space of plane quartic curves for $\mathrm{PGL}_3\,\mathbb{C}$-equivalence. All the moduli spaces $C(d)$ of plane curves of given degree d are conjectured to be rational (see [Dol2, p.162]; in fact, there it is conjectured that all the moduli spaces of hypersurfaces of given degree d in $\mathbb{P}^n$ for the $\mathrm{PGL}_{n+1}\,\mathbb{C}$-action are rational).

There are heuristic reasons that the spaces $C(d)$ should be rational at least for all large enough values for d. It should not be completely out of reach to prove this rigorously and we hope to return to this problem in the future. In any case, one might guess that irregular behavior of $C(d)$ is most likely to be found for small values of d, and showing rationality for $C(4)$ turned out to be exceptionally hard.

To Yuri Ivanovich Manin on the occasion of his 70th birthday

Summary. We establish algebraicity criteria for formal germs of curves in algebraic varieties over number fields and apply them to derive a rationality criterion for formal germs of functions on algebraic curves that extends the classical rationality theorems of Borel–ŨDwork and Polya–ŨBertrandias, valid over the projective line, to arbitrary algebraic curves over a number field. The formulation and the proof of these criteria involve some basic notions in Arakelov geometry, combined with complex and rigid analytic geometry (notably, potential theory over complex and p-adic curves). We also discuss geometric analogues, pertaining to the algebraic geometry of projective surfaces of these arithmetic criteria.

Key words: Arakelov geometry, capacity theory, BorelŨ–Dwork rationality criterion, algebricity of formal subschemes, rigid analytic geometry, slope inequality.

2000 Mathematics Subject Classifications: 14G40 (Primary); 14G22, 31A15, 14B20 (Secondary)

1 Introduction

The purpose of this article is to establish *algebraicity criteria* for *formal germs of curves* in algebraic varieties over number fields and to apply them to derive a *rationality criterion* for *formal germs of functions*, which extends the classical rationality theorems of Borel–Dwork [6], [22] and Pólya–Bertrandias [1, Chapter 5], [43], (see also [16]), valid over the projective line, to arbitrary algebraic curves over a number field.

Our algebraicity criteria improve on those in [12] and [13], which themselves were inspired by the papers [19] and [20] of D. V. and G. V. Chudnovsky

Y. Tschinkel and Y. Zarhin (eds.), *Algebra, Arithmetic, and Geometry*,
Progress in Mathematics 269, DOI 10.1007/978-0-8176-4745-2_3,
© Springer Science+Business Media, LLC 2009

and by the subsequent works by André [2] and Graftieaux [26, 27]. As in [12] and [13], our results will be proved by means of a geometric version of "transcendence techniques," which avoids the traditional constructions of "auxiliary polynomials" and the explicit use of Siegel's lemma, replacing them by a few basic concepts of Arakelov geometry. In the proofs, our main objects of interest will be some evaluation maps, defined on the spaces of global sections of powers of an ample line bundle on a projective variety by restricting these sections to formal subschemes or to subschemes of finite lengths. Arakelov geometry enters through the estimates satisfied by the heights of the evaluation maps, and the slopes and Arakelov degrees of the hermitian vector bundles defined by spaces of sections (see [17] and [14] for more details and references on this approach).

Our main motivation in investigating the algebraicity and rationality criteria presented in this article has been the desire to obtain theorems respecting the classical principle of number theory that "all places of number fields should appear on an equal footing"—which actually is not the case in "classical" Arakelov geometry and in its applications in [12]. A closely related aim has been to establish arithmetic theorems whose geometric counterparts (obtained through the analogy between number fields and function fields) have simple formulations and proofs. These concerns led us to two technical developments in this paper: the use of (rigid) analytic geometry over p-adic fields to define and estimate local invariants of formal curves over number fields,[3] and the derivation of a rationality criterion from an algebraicity criterion by means of the Hodge index theorem on (algebraic or arithmetic) surfaces.

Let us describe the contents of this article in more detail.

In Section 2, we discuss geometric analogues of our arithmetic theorems. Actually, these are classical results in algebraic geometry, going back to Hartshorne [32] and Hironaka–Matsumura [35]. For instance, our algebraicity result admits as analogue the following fact. *Let* X *be a quasiprojective variety over a field* k*, and let* Y *be a smooth projective integral curve in* X*; let* $\widehat{S}$ *be a smooth formal germ of surface through* Y (that is, a smooth formal subscheme of dimension 2, containing Y, of the completion $\widehat{X}_Y$). *If the degree* $\deg_Y N_Y\widehat{S}$ *of the normal bundle to* Y *in* $\widehat{S}$ *is positive, then* $\widehat{S}$ *is algebraic.*

Our point is that, transposed to a geometric setting, the arguments leading to our algebraicity and rationality criteria in the arithmetic setting—which rely on the consideration of suitable evaluation maps and on the Hodge index theorem—provide simple proofs of these nontrivial algebro-geometric results, in which the geometric punch line of the arguments appears more clearly.

In Section 3, we introduce the notion of *A-analytic curve* in an algebraic variety X over a number field K. By definition, this will be a smooth formal curve $\widehat{C}$ through a rational point P in $X(K)$—that is, a smooth formal subscheme of dimension 1 in the completion $\widehat{X}_P$—which, firstly, is analytic at every place of K, finite or infinite. Namely, if v denotes any such place and K_v the corresponding completion of K, the formal curve $\widehat{C}_{K_v}$ in X_{K_v} deduced from $\widehat{C}$ by the extension of scalars $K \hookrightarrow K_v$ is the formal curve defined by a K_v-analytic curve in $X(K_v)$. Moreover the v-adic radius r_v (in $]0,1]$) of the open ball in $X(K_v)$ in which $\widehat{C}_{K_v}$ "analytically extends" is required to "stay close to 1 when v varies," in the sense that the series $\sum_v \log r_v^{-1}$ has to be convergent. The precise formulation of this condition relies on the notion of *size* of a smooth analytic germ in an algebraic variety over a p-adic field. This notion was introduced in [12, 3.1]; we review it in Section 3.A, adding some complements.

---

[3] Since the first version of this paper was written, the relevance of rigid analytic geometry à la Berkovich to develop a non-archimedean potential theory on p-adic curves, and consequently a "modern" version of Arakelov geometry of arithmetic surfaces satisfying the above principle of "equality of places," has been largely demonstrated by A. Thuillier in his thesis [51].

With the above notation, if $\mathscr{X}$ is a model of X over the ring of integers $\mathscr{O}_K$ of K, and if P extends to an integral point $\mathscr{P}$ in $\mathscr{X}(\mathscr{O}_K)$, then a formal curve $\widehat{C}$ through P is A-analytic if it is analytic at each archimedean place of K and extends to a smooth formal surface $\widehat{\mathscr{C}}$ in $\widehat{\mathscr{X}}_{\mathscr{P}}$. For a general formal curve $\widehat{C}$ that is analytic at archimedean places, being an A-analytic germ may be seen as a weakened form of the existence of such a smooth extension $\widehat{\mathscr{C}}$ of $\widehat{C}$ along $\mathscr{P}$. In this way, an A-analytic curve through the point P appears as an arithmetic counterpart of the smooth formal surface $\widehat{S}$ along the curve Y in the geometric algebraicity criterion above.

The tools needed to formulate the arithmetic counterpart of the positivity condition $\deg_Y N_Y \widehat{S} > 0$ are developed in Sections 4 and 5. We first show in Section 4 how, for any germ of analytic curve $\widehat{C}$ through a rational point P in some algebraic variety X over a local field K, one is led to introduce the so-called *canonical seminorm* $\|\cdot\|^{\mathrm{can}}_{X,\widehat{C}}$ on the K-line $T_P\widehat{C}$ through the consideration of the metric properties of the evaluation maps involved in our geometric version of the method of auxiliary polynomials. This extends a definition introduced in [13] when $K = \mathbf{C}$. In Section 5, we discuss the construction of Green functions and capacities on rigid analytic curves over p-adic fields. We then extend the comparison of "canonical seminorms" and "capacitary metrics" in [13], 3.4, to the non-archimedean setting.

In Section 6, we apply these notions to formulate and establish our algebraicity results. If $\widehat{C}$ is an A-analytic curve through a rational point P in an algebraic variety X over some number field K, then the K-line $T_P\widehat{C}$ may be equipped with a "K_v-adic semi-norm" for every place v by the above construction—namely, the seminorm $\|\cdot\|^{\mathrm{can}}_{X_{K_v},\widehat{C}_{K_v}}$ on

$$T_P\widehat{C}_{K_v} \simeq T_P\widehat{C} \otimes_K K_v.$$

The so-defined metrized K-line $\overline{T_P\widehat{C}}$ has a well-defined Arakelov degree in $]-\infty,+\infty]$, and our main algebraicity criterion asserts that $\widehat{C}$ *is algebraic if the Arakelov degree* $\widehat{\deg}\, \overline{T_P\widehat{C}}$ *is positive.* Actually, the converse implication also holds: when $\widehat{C}$ is algebraic, the canonical seminorms $\|.\|^{\mathrm{can}}_{X_{K_v},\widehat{C}_{K_v}}$ all vanish, and $\widehat{\deg}\,\overline{T_P\widehat{C}} = +\infty$.

Finally, in Section 7, we derive an extension of the classical theorems of Borel, Dwork, Pólya, and Bertrandias, which gives a criterion for the rationality of a formal germ of function φ on some algebraic curve Y over a number field. By considering the graph of φ—a formal curve $\widehat{C}$ in the surface $X := Y \times \mathbf{A}^1$—we easily obtain the algebraicity of φ as a corollary of our previous algebraicity criterion. In this way, we are reduced to establishing a rationality criterion for an algebraic formal germ. Actually, rationality results for algebraic functions on the projective line have been investigated by Harbater [30], and used by Ihara [36] to study the fundamental group of some arithmetic surfaces. Ihara's results have been extended in [11] using Arakelov geometry on arithmetic surfaces. Our rationality argument in Section 7, based on the Hodge index theorem on arithmetic surfaces of Faltings–Hriljac, is a variation on the proof of the Lefschetz theorem on arithmetic surfaces in [11].

It is a pleasure to thank A. Ducros for his helpful advice on rigid analytic geometry during the preparation of this article.

Some of the results below were presented, in a preliminary form, during the "Arithmetic Geometry and Number Theory" conference in honor of N. Katz, in Princeton, December 2003, and were announced in [14].

During the preparation of this article, the authors benefitted from the support of the Institut Universitaire de France.

It would be difficult to acknowledge fairly the multifaceted influences of Yuri Ivanovich Manin on our work. We hope that this article will appear as a tribute, not only to his multiple contributions to algebraic geometry and number theory, but also to his global vision of mathematics, emphasizing geometric insights and analogies. The presentation of this vision in his 25th-Arbeitstagung report *New Dimensions in Geometry* [38] has been, since it was written, a source of wonder and inspiration to one of the authors, and we allowed ourselves to borrow the terminology "*A*-analytic" from the "*A*-geometry" programmatically discussed in [38]. It is an honor for us to dedicate this article to Yuri Ivanovich Manin.

2 Preliminary: the geometric case

The theorems we want to prove in this paper are analogues in arithmetic geometry of classical algebro-geometric results going back—at least in an implicit form—to Hartshorne, Hironaka, and Matsumura ([31],[34],[35]). Conversely, in this section we give short proofs of algebraic analogues of our main arithmetic theorems.

Proposition 2.1. *Let $\mathscr{X}$ be a quasi-projective scheme over a field k and let $\mathscr{P}$ be a projective connected subscheme of dimension 1 in $\mathscr{X}$. Let $\widehat{\mathscr{C}}$ be a formal*

Cyclic Homology with Coefficients

D. Kaledin*

Steklov Math Institute, Moscow, Russia
`kaledin@mccme.ru`

To Yu. I. Manin, the founder, on the occasion of his 70th birthday

Summary. We propose a category which can serve as the category of coefficients for the cyclic homology $HC_*(A)$ of an associative algebra A over a field k. The construction is categorical in nature, and essentially uses only the tensor category A-bimod of A–*bimodules*; objects of our category are A–bimodules with an additional structure. We also generalize the construction to a more general tensor k-linear tensor category C instead of A-bimod. We add some remarks about Getzler's version of the Gauss–Manin connection for the periodic cyclic homology $HP_*(A)$.

Key words: cyclic homology, Gauss–Manin connection, tensor categories

2000 Mathematics Subject Classifications: 19D55, 18E25, 18G10

Introduction

Ever since it was discovered in 1982 by A. Connes [C1] and B. Tsygan [Ts], cyclic homology has occupied a strange place in the realm of homological algebra. Normally in homological algebra problems, one expects to start from some data, for instance a topological space X, then construct some abelian category, such as the category of sheaves on X, and then define the cohomology of X by computing the derived functors of some natural functor, such as the global sections functor $\Gamma(X,-)$. Admittedly, this is a modern formulation, but it was certainly current already in 1982. Cyclic homology starts with an associative algebra A, and defines its homology groups $HC_\bullet(A)$, but there are absolutely no derived functors in sight. Originally, groups $HC_\bullet(A)$ were defined as the homology of an explicit complex, which anyone trained to use triangulated categories cannot help but take as an insult. Later, A.

Connes [C2] improved on the definition by introducing the abelian category of so-called cyclic vector spaces. However, the passage from A to its associated cyclic vector space $A_\#$ is still done by an explicit *ad hoc* formula. It is as if we were to know the bar-complex that computes the homology of a group, without knowing the definition of the homology of a group.

This situation undoubtedly irked many people over the years, but to the best of my knowledge, no satisfactory solution has been proposed, and it may not exist; indeed, many relations to the de Rham homology notwithstanding, it is not clear whether cyclic homology properly forms a part of homological algebra at all (to the point that for instance in [FT], the word "homology" is not used at all for $HC_\bullet(A)$, and it is called instead *additive K-theory* of A). In the great codification of homological algebra done in [GM1], cyclic homology appears only in the exercises. This is not surprising, since the main unifying idea of [GM1] is the ideology of "linearization": homological algebra linearizes geometry, just as functional analysis used to do 50 years ago; triangulated categories and adjoint functors are modern-day versions of Banach spaces and adjoint linear operators. This has been an immensely successful and clarifying point of view in general, but $HC_\bullet(A)$ sticks out on a complete tangent: there is simply no natural place for it in this framework.

This paper arose as one more attempt to propose a solution to the difficulty: to find a natural triangulated category where $HC_\bullet(-)$ would be able to live with a certain level of comfort (and with all the standard corollaries such as the notion of cyclic homology with coefficients, the ability to compute cyclic homology by whatever resolution is convenient, not just the bar resolution, and so on).

In a sense, our attempt has been successful: we define a triangulated category that can serve as the natural "category of coefficients" for cyclic homology of an algebra A, and we prove the comparison theorem that shows that when the coefficients are trivial, the new definition of cyclic homology is equivalent to the old one. In fact, the algebra A enters into the construction only through the category $A\text{-}\mathsf{bimod}$ of A-bimodules; we also show how to generalize the construction so that $A\text{-}\mathsf{bimod}$ is replaced with a more general tensor abelian category $\mathcal{C}$.

From a different point of view, though, out attempt failed miserably: the correspondence $A \mapsto A_\#$, being thrown out of the window, immediately returns through the door in a new and "higher-level" disguise: it is now applied not to the algebra A, but to the tensor category $\mathcal{C} = A\text{-}\mathsf{bimod}$. Then in practice, the freedom to choose an arbitrary resolution to compute the derived functors leads, in our approach to $HC_\bullet(-)$, to complexes that are even larger than the original complex, and at some point the whole exercise starts to look pointless.

Still, we believe that all said and done, some point can be found, and some things are clarified in our approach; one such thing is, for instance, the version of Gauss–Manin connection for cyclic homology discovered by E. Getzler [Ge]. Moreover, we do propose a definition of cyclic homology that – makes sense for a general tensor category; and in some particular questions, even the computations can be simplified. As for the presence of the $A_{\#}$-construction, this might be in the nature of things, after all: not a bug in the theory, but a necessary feature. However, we leave it to the reader to be the judge.

The paper is organized as follows. In Section 1 we recall A. Connes's second definition of cyclic homology, which uses the cyclic category Λ; we also recall some facts about homology of small categories that we will need. We have tried to give only the absolute minimum; the reader not familiar with the material will have to consult the references. In Section 2 we introduce our main object: the notion of a *cyclic bimodule* over an associative algebra A, and the derived category of such bimodules. We also introduce cyclic homology $HC_{\bullet}(A, M)$ with coefficients in a cyclic bimodule M. In Section 3 we give a very short derivation of the Gauss–Manin connection; strictly speaking, the language of cyclic bimodules is not needed for this, but we believe that it shows more clearly what is really going on. In Section 4, we show how to replace the category $A\text{-}\mathsf{bimod}$ everywhere with a more general tensor abelian category $\mathcal{C}$. Section 5 is a postface, or a "discussion" (as is done in medical journals); we discuss some of the further things one might (and should) do with cyclic bimodules, and how to correct some deficiencies of the theory developed in Sections 2 and 4.

Acknowledgments.

In the course of this work, I have benefited greatly from discussions with A. Beilinson, E. Getzler, V. Ginzburg, A. Kuznetsov, N. Markarian, D. Tamarkin, and B. Tsygan. I am grateful to Northwestern Univeristy, where part of this work was done, and where some of the results were presented in seminars, with great indulgence from the audience toward the unfinished state of the work. And last but not least, it is a great pleasure and a great opportunity to dedicate this paper to Yuri Ivanovich Manin on his birthday. Besides all the usual things, I would like to stress that it is the book [GM1], and [GM2] to a lesser extent, that shaped the way we look at homological algebra today, at least "we" of my generation and of the Moscow school. Without Manin's decisive influence, this paper certainly would not have appeared (as in fact at least half of the papers I have written).

1 Recollection on cyclic homology.

We start by recalling, extremely briefly, A. Connes' approach to cyclic homology, which was originally introduced in [C2] (for detailed overviews, see, e.g., [L, Section 6] or [FT, Appendix]; a brief but complete exposition using the same language and notation as in this paper can be found in [Ka, Section 1]).

Curves of Low Degrees on Fano Varieties

Olivier Debarre

Mathematics Subject Classification codes (2010): 14C05, 14C30, 14C34, 14D20, 14E05, 14E08, 14E20, 14H10, 14J10, 14J30, 14J35, 14J45, 14J60, 14J70, 14M20, 14M22, 14N25

1 Introduction

We work over the field of complex numbers. If $X \subset \mathbf{P}^N$ is a smooth projective variety, we let $\mathscr{C}_d^g(X)$ be the (quasi-projective) subscheme of the Hilbert scheme of X corresponding to smooth, irreducible, genus-g, degree-d curves on X.

These schemes, and their compactifications $\overline{\mathscr{C}}_d^g(X)$, particularly for low d and g, have proved very useful in the study of the geometry and the period maps of some Fano varieties of low degrees.

In this informal survey article, we explain, mainly without proofs, what is known (or conjectured) in the following cases: cubic threefolds, Fano threefolds of degree 14 and index 1, cubic fourfolds, Fano varieties of degree 10, coindex 3, and dimensions 3, 4, or 5.

In the case of a smooth cubic threefold $X \subset \mathbf{P}^4$ (Sect. 2), Hilbert schemes of curves have long been used to parametrize useful subvarieties of the intermediate Jacobian $J(X)$. For example, the (smooth projective) surface $\mathscr{C}_1^0(X)$ parametrizing lines contained in X was an essential ingredient in the proofs by Clemens and Griffiths of the non-rationality of X and of the Torelli theorem (that $J(X)$ determines X). The Abel–Jacobi maps $\mathrm{aj} : \overline{\mathscr{C}}_d^g(X) \to J(X)$ have been since proved in some cases to be mrc fibrations (see Sect. 2 for definitions and results).

Curves on Fano threefolds can also be used to construct interesting birational correspondences. This is illustrated in Sect. 2.9, where it is explained that Fano threefolds of degree 14 and index 1 are birational to cubic threefolds. The situation is very rich and gives rise to a beautiful description of the period maps for these Fano threefolds.

In Sect. 3, we move on to smooth cubic fourfolds $Y \subset \mathbf{P}^5$, for which there are no intermediate Jacobians. Nevertheless, the mrc fibrations of $\overline{\mathscr{C}}^g_d(Y)$ should be substitutes for the Abel–Jacobi maps and should provide interesting information. In another direction, ideas of Mukai show how to construct *symplectic forms* on some moduli spaces of sheaves (Sect. 3.1). This can be used to prove that the space of lines $\mathscr{C}^0_1(Y)$ is a symplectic fourfold (Beauville and Donagi), whose Hodge structure is closely related to that of Y. This was the basis of Voisin's proof of the injectivity of the period map for smooth cubic fourfolds. This period map is now completely described by work of Looijenga and Laza and identifies the moduli space of smooth cubic fourfolds with an explicit open subset of the Baily–Borel compactification of the period domain (Sect. 3.2). Analogous results are available for the moduli space of smooth cubic threefolds (Sect. 3.3).

Mukai's construction was also shown to apply to Fano fourfolds X^4_{10} of degree 10 and index 2 (Example 3.5). In this case, the scheme $\overline{\mathscr{C}}^0_2(X^4_{10})$ leads to the construction of a symplectic fourfold called a *double EPW sextic* (Iliev and Manivel, O'Grady).

In Sect. 4, we study in some details the period maps of these Fano varieties of degree 10, in dimensions 3, 4, and 5. There is beautiful geometry at work here, with intriguing interplay with that of EPW sextics (work in progress with Iliev and Manivel).

2 Cubic Threefolds

The *maximal rationally connected fibration* (mrc fibration for short) of a smooth proper (complex) variety Y is a rational dominant map $\rho : Y \dashrightarrow R(Y)$ such that for $z \in R(Y)$ very general, the fiber $\rho^{-1}(z)$ is proper and rationally connected (two general points can be joined by a rational curve), and any rational curve in Y that meets $\rho^{-1}(z)$ is contained in $\rho^{-1}(z)$. The mrc fibration exists and is unique up to birational equivalence. The variety $R(Y)$ is called the reduction of Y.

Let $X \subset \mathbf{P}^4$ be a general (although some results are known for *any smooth* X) cubic hypersurface. The intermediate Jacobian

$$J(X) := H^{2,1}(X)^\vee / H_3(X, \mathbf{Z})$$

is a 5-dimensional principally polarized abelian variety. We let $\mathscr{X}_3$ be the (irreducible, 10-dimensional) moduli space for smooth cubic threefolds, and we let $\mathscr{A}_n$ be the moduli space for principally polarized abelian varieties of dimension n. Taking X to $J(X)$ defines the *period map* $\mathscr{X}_3 \to \mathscr{A}_5$. We have:

- For $g = 0$ or $d \leq 5$, $\mathscr{C}_d^g(X)$ is integral of dimension $2d$ ([7], Theorem 1.1);
- For $d \leq 5$, the *Abel–Jacobi map* $\mathrm{aj} : \overline{\mathscr{C}}{}_d^g(X) \to J(X)$ induces the mrc fibration ([6], Theorem 1.1);
- For $d \geq 4$, $\mathrm{aj} : \overline{\mathscr{C}}{}_d^0(X) \to J(X)$ is dominant with irreducible general fibers.

It is natural to ask whether the Abel–Jacobi map $\mathrm{aj} : \overline{\mathscr{C}}{}_d^0(X) \to J(X)$ is the mrc fibration for all $d \geq 4$ (i.e., are general fibers rationally connected?).

2.1 Lines

- $\mathscr{C}_1^0(X)$ (which parametrizes lines on X) is a smooth projective irreducible surface of general type;
- The image of $\mathrm{aj} : \mathscr{C}_1^0(X) \to J(X)$ is a surface S with minimal class $[\Theta]^3/3!$ and $S - S$ is a theta divisor Θ;
- aj induces an isomorphism between the Albanese variety of $\mathscr{C}_1^0(X)$ and $J(X)$ ([2]).

The second item yields a proof of Torelli: *the period map* $\mathscr{X}_3 \to \mathscr{A}_5$ *is injective.*

2.2 Conics

- $\overline{\mathscr{C}}{}_2^0(X)$ is a smooth projective irreducible fourfold;
- $\mathrm{aj} : \overline{\mathscr{C}}{}_2^0(X) \to J(X)$ is a $\mathbf{P}^2$-bundle over the surface S of Sect. 2.1 (a conic is uniquely determined by the plane that it spans and the residual line in X). The mrc fibration is therefore $\overline{\mathscr{C}}{}_2^0(X) \to S$.

2.3 Plane Cubics

- $\overline{\mathscr{C}}{}_3^1(X)$ is isomorphic to the Grassmannian $G(3,5)$;
- The Abel–Jacobi map is therefore constant.

2.4 Twisted Cubics

- $\mathrm{aj} : \mathscr{C}_3^0(X) \to J(X)$ is birational to a $\mathbf{P}^2$-bundle over a theta divisor Θ ([6], Sect. 4). The mrc fibration is therefore $\overline{\mathscr{C}}{}_3^0(X) \to \Theta$.

2.5 Elliptic Quartics

- $\mathrm{aj} : \mathscr{C}_4^1(X) \to J(X)$ is birational to a $\mathbf{P}^6$-bundle over the surface S of Sect. 2.1 ([6], Sect. 4.1). The mrc fibration is therefore $\overline{\mathscr{C}}{}_4^1(X) \to S$.

2.6 Normal Rational Quartics

- $\mathrm{aj} : \overline{\mathscr{C}}{}_4^0(X) \to J(X)$ is dominant and the general fiber is birational to X ([9], Theorem 5.2), hence unirational. It is therefore the mrc fibration.

2.7 Normal Elliptic Quintics

- $\mathscr{C}_5^1(X)$ is an irreducible tenfold;
- There is a factorization ([14], Theorem 5.6; [9], Theorem 3.2)

$$\mathrm{aj} : \overline{\mathscr{C}}{}_5^1(X) \xrightarrow{\alpha} M_X(2;0,2) \xrightarrow{\beta} J(X),$$

  where

  - $M_X(2;0,2)$ is some component of the moduli space of rank-2 stable vector bundles on X with Chern classes $c_1 = 0$ and $c_2 = 2$;
  - α is a $\mathbf{P}^5$-bundle over a dense open subset of $M_X(2;0,2)$;
  - β is birational (this is proved in [9] via ingenious geometrical constructions).

  In particular, $\overline{\mathscr{C}}{}_5^1(X) \to J(X)$ is therefore the mrc fibration.

This is seen as follows. The map α is obtained via the Serre construction: to $C \in \mathscr{C}_5^1(X)$, one associates a stable rank-2 vector bundle $\mathscr{E}_C$ on X with Chern classes $c_1 = 0$ and $c_2 = 2$ such that C is the zero-locus of a section of $\mathscr{E}_C(1)$.

The fibers of α are $\mathbf{P}(H^0(X, \mathscr{E}_C(1))) \simeq \mathbf{P}^5$; hence the Abel–Jacobi map factors through α.

According to Murre, the Chow group of algebraic 1-cycles of fixed degree on X modulo rational equivalence is canonically isomorphic to $J(X)$. The map β can then be defined directly as $\mathscr{E} \mapsto c_2(\mathscr{E})$.

2.8 Normal Elliptic Sextics

- $\mathscr{C}_6^1(X)$ is an irreducible 12-fold;
- $\mathrm{aj} : \overline{\mathscr{C}}{}_6^1(X) \to J(X)$ is the mrc fibration ([21], Theorem 2.1).

2.9 Fano Threefolds of Degree 14 and Index 1

There is a very interesting relationship between cubic threefolds and Fano threefolds of degree 14 and index 1 [9, 10, 14]. The latter are obtained as linear sections of $G(2,6) \subset \mathbf{P}^{14}$ by a $\mathbf{P}^9$.

Let $X \subset \mathbf{P}^4$ be a smooth cubic threefold, let C be general in $\mathscr{C}_5^1(X)$, and let $\pi : \tilde{X} \to X$ be its blow-up, with exceptional divisor E. We have

$$-K_{\tilde{X}} \underset{\text{lin}}{\equiv} -\pi^* K_X - E \underset{\text{lin}}{\equiv} 2\pi^* H - E.$$

This linear system induces a morphism $\tilde{X} \to \mathbf{P}^4$ which induces a small contraction φ onto the normalization $\bar{X}$ of its image. Its non-trivial fibers are the strict transforms of the 25 lines bisecant to C: the divisor E is φ-ample hence there is a flop

$$\chi : \tilde{X} \xrightarrow{\varphi} \bar{X} \xleftarrow{\varphi'} \tilde{X}',$$

where $\tilde{X}'$ is smooth projective and $\chi(E)$ is φ'-antiample.

We have $\rho(\tilde{X}') = 2$. Since the extremal ray generated by the classes of curves contracted by φ' has $K_{\tilde{X}'}$-degree 0 and $K_{\tilde{X}'}$ is not nef ($-K_{\tilde{X}'} \underset{\text{lin}}{\equiv} \varphi'^* \bar{H}$), the other extremal ray is $K_{\tilde{X}'}$-negative and defines a contraction $\pi' : \tilde{X}' \to X'$. One checks that:

- X' is a smooth Fano threefold of degree 14 and index 1, with Picard group generated by $H' := -K_{X'}$;
- π' is the blowup of a smooth elliptic quintic curve $C' \subset X'$, with exceptional divisor $E' \underset{\text{lin}}{\equiv} 5\varphi'^* \bar{H} - 3\chi_*(E)$ and $\chi^* \pi'^* H' \underset{\text{lin}}{\equiv} 7H - 4E$.

Conversely, given a general elliptic quintic curve C' in a smooth Fano threefold X' of degree 14 and index 1, one can reverse the construction above and obtain a cubic threefold X with a quintic curve $C \subset X$. In other words, if $\mathscr{C}_5^1(\mathscr{X}_3)$ denotes the moduli space of all pairs (X, C) as above, and $\mathscr{C}_5^1(\mathscr{X}_{14})$ the moduli space of all pairs (X', C'), we have a birational isomorphism

$$\mathscr{C}_5^1(\mathscr{X}_3) \dashrightarrow \mathscr{C}_5^1(\mathscr{X}_{14})$$

between (irreducible, 20-dimensional) varieties. We have the following two properties.

- *The intermediate Jacobians of X and X' are isomorphic* (this holds because $J(X) \times J(C) \simeq J(X') \times J(C')$, $J(X')$ is not a product, and $J(X)$ and $J(X')$ have the same dimension). Since we have Torelli for cubic threefolds (Sect. 2.1), the cubic obtained from a pair (X', C') only depends on X'.
- *The variety X' only depends on the vector bundle $\mathscr{E}_C$* defined in Sect. 2.7 (Kuznetsov proves in [10] that if $\mathscr{S}$ is the rank-2 tautological vector bundle on $G(2,6)$, the variety $\mathbf{P}(\mathscr{S}|_{X'})$ is obtained by a flop of $\mathbf{P}(\mathscr{E}_C)$).

So, if $\mathscr{X}_{14}$ is the moduli space for smooth Fano threefolds of degree 14 and index 1, and if $\mathscr{M}_{\mathscr{X}_3}(2;0,2)$ is the moduli space of pairs $(X,\mathscr{E})$, with $[\mathscr{E}] \in M_X(2;0,2)$ (see Sect. 2.7), we get a commutative diagram:

$$\begin{tikzcd}
\text{dim. 20} & \mathscr{C}^1_5(\mathscr{X}_3) \arrow[rr, dashed, leftrightarrow] \arrow[d, "\mathbf{P}^5-\text{bundle}"'] & & \mathscr{C}^1_5(\mathscr{X}_{14}) \arrow[d] & \text{dim. 20} \\
\text{dim. 15} & \mathscr{M}_{\mathscr{X}_3}(2;0,2) \arrow[rr, "\gamma", "\text{isom.}"'] \arrow[d] & & \mathscr{X}_{14} \arrow[lld, "\delta"] \arrow[ld, "\text{period map}"] & \text{dim. 15} \\
\text{dim. 10} & \mathscr{X}_3 \arrow[rd, hook, "\text{period map}"'] & & & \\
 & & \mathscr{A}_5. & &
\end{tikzcd}$$

The map γ is actually an isomorphism of stacks and the fiber of δ (between stacks) at $[X]$ is the (quasi-projective) moduli space of stable rank-2 vector bundles $\mathscr{E}$ such that $c_1(\mathscr{E}) = 0$ and $H^1(X,\mathscr{E}(-1)) = 0$ (instanton bundles), an open subset of $J(X)$ ([10], Theorem 2.9).

3 Cubic Fourfolds

Let $Y \subset \mathbf{P}^5$ be a general cubic hypersurface.

The variety $\overline{\mathscr{C}}^0_d(Y)$ is integral of dimension $3d+1$ ([5], Proposition 2.4). To study these varieties, one could use, instead of the Abel–Jacobi map, their mrc fibration [5]. Here is what is known, or conjectured:

- $\mathscr{C}^0_1(Y)$ is a symplectic fourfold [1] hence is its own reduction;
- The map $\overline{\mathscr{C}}^0_2(Y) \dashrightarrow \mathscr{C}^0_1(Y)$ given by residuation is a $\mathbf{P}^3$-bundle so this is the mrc fibration;
- $\overline{\mathscr{C}}^0_3(Y)$ is uniruled: a general cubic curve lies on a unique cubic surface and moves in a 2-dimensional linear system on it; so its reduction has dimension ≤ 8;
- There is a map $\overline{\mathscr{C}}^0_4(Y) \dashrightarrow \mathscr{J}(Y)$ (where $\mathscr{J}(Y) \to (\mathbf{P}^5)^\vee$ is the relative intermediate Jacobian of smooth hyperplane sections of Y) whose general fibers are these cubic threefolds (Sect. 2.6) hence are unirational; moreover, $\mathscr{J}(Y)$ should be non-uniruled (see also Example 3.4 below), so this should be the mrc fibration;
- For $d \geq 5$ odd, there is ([5], Theorem 1.2; [11]) a holomorphic 2-form on (a smooth non-singular model of) $\mathscr{C}^0_d(Y)$ which is *non-degenerate at a general point.* In particular, $\overline{\mathscr{C}}^0_d(Y)$ is not uniruled.

3.1 Constructing Symplectic Forms on Moduli Spaces

Mukai proved in 1984 that the moduli space $\mathscr{M}$ of simple sheaves on a K3 or abelian surface carries a closed non-degenerate holomorphic 2-form: the tangent space to $\mathscr{M}$ at a point $[\mathscr{F}]$ representing a simple sheaf $\mathscr{F}$ on a smooth projective variety Z is isomorphic to $\mathrm{Ext}^1(\mathscr{F},\mathscr{F})$. The Yoneda coupling

$$\mathrm{Ext}^1(\mathscr{F},\mathscr{F}) \times \mathrm{Ext}^1(\mathscr{F},\mathscr{F}) \longrightarrow \mathrm{Ext}^2(\mathscr{F},\mathscr{F})$$

is skew-symmetric whenever $[\mathscr{F}]$ is a *smooth* point of $\mathscr{M}$. When Z is a symplectic surface S with a symplectic holomorphic form $\omega \in H^0(S,\Omega_S^2)$, Mukai composes the Yoneda coupling with the map

$$\mathrm{Ext}^2(\mathscr{F},\mathscr{F}) \xrightarrow{\mathrm{Tr}} H^2(S,\mathscr{O}_S) \xrightarrow{\cup\omega} H^2(S,\Omega_S^2) = \mathbf{C},$$

and this defines the symplectic structure on the smooth locus of $\mathscr{M}$.

Over an n-dimensional variety Z such that $h^{q,q+2}(Z) \neq 0$ for some integer q, we:

- Pick a non-zero element $\omega \in H^{n-q-2}(Z,\Omega_Z^{n-q})$;
- Use the exterior power $\mathrm{At}(\mathscr{F})^{\wedge q} \in \mathrm{Ext}^q(\mathscr{F},\mathscr{F}\otimes\Omega_Z^q)$ of the Atiyah class[1] $\mathrm{At}(\mathscr{F}) \in \mathrm{Ext}^1(\mathscr{F},\mathscr{F}\otimes\Omega_Z^1)$.

We then define

$$\mathrm{Ext}^2(\mathscr{F},\mathscr{F}) \xrightarrow{\mathrm{At}(\mathscr{F})^{\wedge q}\circ\bullet} \mathrm{Ext}^{q+2}(\mathscr{F},\mathscr{F}\otimes\Omega_Z^q) \xrightarrow{\mathrm{Tr}}$$
$$H^{q+2}(Z,\Omega_Z^q) \xrightarrow{\cup\omega} H^n(Z,\Omega_Z^n) \simeq \mathbf{C}.$$

Composing the Yoneda coupling with this map provides a closed (possibly degenerate) 2-form on the smooth locus of the moduli space.

Example 3.3. Let $Y \subset \mathbf{P}^5$ be a smooth cubic fourfold. Since $h^{1,3}(Y) = 1$, the construction provides a (unique) 2-form on the smooth loci of moduli spaces of sheaves on Y. Kuznetsov and Markushevich use this construction in a roundabout

---

[1] Let $\Delta : Z \to Z\times Z$ be the diagonal embedding and let $\Delta(Z)^{(2)} \subset Z\times Z$ be the closed subscheme defined by the sheaf of ideals $\mathscr{I}^2_{\Delta(Z)}$. Since $\mathscr{I}_{\Delta(Z)}/\mathscr{I}^2_{\Delta(Z)} \simeq \Omega_Z$; we have an exact sequence

$$0 \to \Delta_*\Omega_Z \to \mathscr{O}_{\Delta(Z)^{(2)}} \to \Delta_*\mathscr{O}_Z \to 0.$$

If $\mathscr{F}$ is a locally free sheaf on Z, we obtain an exact sequence

$$0 \to \mathscr{F}\otimes\Omega_Z \to p_{1*}(p_2^*(\mathscr{F}\otimes\mathscr{O}_{\Delta(Z)^{(2)}})) \to \mathscr{F} \to 0,$$

hence an extension class $\mathrm{At}_{\mathscr{F}} \in \mathrm{Ext}^1(\mathscr{F},\mathscr{F}\otimes\Omega_Z)$. The same construction can be extended to any coherent sheaf on Z by working in the derived category (Illusie).

way to produce a symplectic structure on the (smooth) fourfold $\mathscr{C}_1^0(Y)$ of lines $L \subset Y$ (originally constructed by Beauville and Donagi by a deformation argument; note that the simple-minded idea to look at sheaves of the form $\mathscr{O}_L$ does not work).

Example 3.4. Let $Y \subset \mathbf{P}^5$ be a smooth cubic fourfold. Let $\mathscr{N}_Y$ be the (quasi-projective) moduli space of sheaves on Y of the form $i_*\mathscr{E}$, where $i : X \to Y$ is a non-singular hyperplane section of Y and $[\mathscr{E}] \in M_X(2;0,2)$. By Sect. 2.7, $\mathscr{N}_Y$ is a torsor under the (symplectic) relative intermediate Jacobian $\mathscr{J}(Y)$ of smooth hyperplane sections of Y. The Donagi–Markman symplectic structure ([4], 8.5.2) on $\mathscr{J}(Y)$ induces a symplectic structure on $\mathscr{N}_Y$ which should be the same as the Kuznetsov–Markushevich structure ([11, 15], Theorem 7.3 and Remark 7.5). Note that since we do not know whether the Donagi–Markman symplectic form on $\mathscr{J}(Y)$ extends to a smooth compactification, we cannot deduce that $\mathscr{J}(Y)$ is not uniruled.

Example 3.5. Let X_{10}^4 be a smooth Fano fourfold obtained by intersecting the Grassmannian $G(2,5)$ in its Plücker embedding with a general hyperplane and a general quadric (see Sect. 4). We have $h^{1,3}(X_{10}^4) = 1$. The Hilbert scheme $\overline{\mathscr{C}}_2^0(X_{10}^4)$ of (possibly degenerate) conics in X_{10}^4 is smooth [8]; hence it is endowed, by the construction above, with a canonical global holomorphic 2-form. Since $\overline{\mathscr{C}}_2^0(X_{10}^4)$ has dimension 5, this form must be degenerate.

There is a naturally defined morphism

$$\overline{\mathscr{C}}_2^0(X_{10}^4) \to \mathbf{P}(\mathrm{I}_{X_{10}^4}(2)) \simeq \mathbf{P}^5$$

whose image is an *Eisenbud–Popescu–Walter* (EPW for short) *sextic hypersurface* $Z_{X_{10}^4} \subset \mathbf{P}^5$ (see [16] for the definition of these sextics). In the Stein factorization

$$\overline{\mathscr{C}}_2^0(X_{10}^4) \to Y_{X_{10}^4} \to Z_{X_{10}^4},$$

the projective variety $Y_{X_{10}^4}$ is a smooth fourfold over which $\overline{\mathscr{C}}_2^0(X_{10}^4)$ is (essentially) a smooth fibration in projective lines. The 2-form on $\overline{\mathscr{C}}_2^0(X_{10}^4)$ thus descends to $Y_{X_{10}^4}$ and makes $Y_{X_{10}^4}$ into a holomorphic symplectic fourfold [8, 16] called a *double EPW sextic.*

3.2 Periods for Cubic Fourfolds

Let $Y \subset \mathbf{P}^5$ be a smooth cubic fourfold. Since Y has even dimension, it has no intermediate Jacobian but still an interesting Hodge structure “of K3-type”:

$$\begin{array}{lccccc} H^4(Y,\mathbf{C})_{\mathrm{prim}} = & H^{1,3}(Y) & \oplus & H^{2,2}(Y)_{\mathrm{prim}} & \oplus & H^{3,1}(Y) \\ \text{dimensions:} & 1 & & 20 & & 1 \end{array}$$

with period domain

$$\mathscr{D}^{20} = \{[\omega] \in \mathbf{P}^{21} \mid Q(\omega,\omega) = 0,\ Q(\omega,\bar{\omega}) > 0\},$$

a 20-dimensional bounded symmetric domain of type IV (where Q is the (non-degenerate) intersection form on $H^4(Y,\mathbf{C})$). Let $\mathscr{Y}_3$ be the (irreducible, 20-dimensional) moduli space for smooth cubic fourfolds. We get a period map

$$\mathscr{Y}_3 \to \mathscr{D}^{20}/\Gamma,$$

where Γ is an explicit discrete arithmetic group. Voisin proved that it is injective and its (open) image was determined in [12].

3.3 Periods for Cubic Threefolds

One can construct another period map for cubic threefolds (compare with Sect. 2): to such a cubic $X \subset \mathbf{P}^4$, we associate the cyclic triple cover $Y_X \to \mathbf{P}^4$ branched along X. It is a cubic fourfold; hence this construction defines a map $\mathscr{X}_3 \to \mathscr{Y}_3 \to \mathscr{D}^{20}/\Gamma$.

Because of the presence of an automorphism of Y_X of order 3, we can restrict the image and define a period map (Allcock–Carlson–Toledo)

$$\mathscr{X}_3 \to \mathscr{D}^{10}/\Gamma',$$

where

$$\mathscr{D}^{10} := \{\omega \in \mathbf{P}^{10} \mid Q(\omega,\bar{\omega}) < 0\} \simeq \mathbf{B}^{10}$$

and Γ' is a discrete arithmetic group. Again, it is an isomorphism onto an explicitly described open subset of $\mathscr{D}^{10}/\Gamma'$.

4 Fano Varieties of Degree 10

Let V_5 be a 5-dimensional complex vector space. We define, for $k \in \{3,4,5\}$, a smooth, degree-10, coindex-3, Fano k-fold by

$$X_{10}^k := G(2,V_5) \cap \mathbf{P}^{k+4} \cap \Omega \subset \mathbf{P}(\wedge^2 V_5),$$

where $\mathbf{P}^{k+4}$ is a general $(k+4)$-plane and Ω a general quadric. Let $\mathscr{X}_{10}^k$ be the moduli stack for smooth varieties of this type.

Enriques proved that all (smooth) X_{10}^3, X_{10}^4, and X_{10}^5 are unirational. A general X_{10}^3 is not rational, whereas all (smooth) X_{10}^5 are rational [19]. Some smooth X_{10}^4 are rational ([17, 18]), but the rationality of a general X_{10}^4 is an open question.

We have

$$I_{X_{10}^k}(2) \simeq \mathbf{C}\Omega \oplus V_5,$$

where V_5 corresponds to the rank-6 *Plücker quadrics* $\omega \mapsto \omega \wedge \omega \wedge v$ ($v \in V_5$). In the 5-plane $\mathbf{P}(I_{X_{10}^k}(2))$, the degree-$(k+5)$ hypersurface corresponding to singular quadrics decomposes as

$$(k-1)\mathbf{P}(V_5) + Z^\vee_{X_{10}^k},$$

where $Z^\vee_{X_{10}^k} \subset \mathbf{P}(I_{X_{10}^k}(2))$ is an *EPW sextic* ([8], Sect. 2.2; this is indeed the projective dual of the sextic defined in Example 3.5 when $k=4$).

If $\mathscr{E}\mathscr{P}\mathscr{W}$ is the (irreducible, 20-dimensional) moduli space of EPW sextics, we get morphisms

$$\mathrm{epw}^k : \mathscr{X}_{10}^k \to \mathscr{E}\mathscr{P}\mathscr{W},$$

which are *dominant* ([8], Corollary 4.17). Note that

$$\begin{aligned}
\dim(\mathscr{X}_{10}^5) &= 25,\\
\dim(\mathscr{X}_{10}^4) &= 24,\\
\dim(\mathscr{X}_{10}^3) &= 22.
\end{aligned}$$

Proposition 4.1 (Debarre–Iliev–Manivel). *For a general EPW sextic Z, with projective dual $Z^\vee$, the fiber $(\mathrm{epw}^3)^{-1}([Z])$ is isomorphic to the smooth surface* $\mathrm{Sing}(Z^\vee)$.

4.1 Gushel Degenerations

The link between these Fano varieties of various dimensions can be made through a construction of Gushel analogous to what we did with cubics in Sect. 3.3.

Let $CG \subset \mathbf{P}(\mathbf{C} \oplus \wedge^2 V_5)$ be the cone, with vertex $v = \mathbf{P}(\mathbf{C})$, over the Grassmannian $G(2,V_5)$. Intersect CG with a general quadric $\Omega \subset \mathbf{P}(\mathbf{C} \oplus \wedge^2 V_5)$ and a linear space $\mathbf{P}^{k+4}$ to get a Fano variety T^k of dimension k. There are two cases:

- Either $v \notin \mathbf{P}^{k+4}$, in which case T^k is isomorphic to the intersection X_{10}^k of $G(2,V_5)$ with the projection of $\mathbf{P}^{k+4}$ to $\mathbf{P}(\wedge^2 V_5)$ and a quadric
- Or $v \in \mathbf{P}^{k+4}$, in which case $\mathbf{P}^{k+4}$ is a cone over a $\mathbf{P}^{k+3} \subset \mathbf{P}(\wedge^2 V_5)$ and T^k is a double cover X_G^k of $G(2,V_5) \cap \mathbf{P}^{k+3}$ branched along its intersection X_{10}^{k-1} with a quadric

The second case is a specialization of the first, and the EPW sextics $Z_{X_{10}^k}$ from the first case degenerate to the sextics $Z_{X_G^k}$ from the second case. Moreover, in the second case, *the sextics $Z_{X_G^k}$ and $Z_{X_{10}^{k-1}}$ are the same.*

Let $\mathscr{X}^k_G$ be the moduli stack for smooth varieties of type X^k_{10} and their Gushel degenerations. The Gushel constructions therefore yield morphisms $\mathscr{X}^k_{10} \to \mathscr{X}^{k+1}_G$ such that the diagrams

$$\begin{tikzcd}
\mathscr{X}^k_{10} \arrow[r] \arrow[dr, "\mathrm{epw}^k"'] & \mathscr{X}^{k+1}_G \arrow[d, "\mathrm{epw}^{k+1}_G"] \\
& \mathscr{EPW}
\end{tikzcd}$$

commute.

We can perform a "double Gushel construction" as follows. Let $CCG \subset \mathbf{P}(\mathbf{C}^2 \oplus \wedge^2 V_5)$ be the cone, with vertex $L = \mathbf{P}(\mathbf{C}^2)$, over the Grassmannian $G(2,V_5)$. Intersect CCG with a general quadric $\Omega \subset \mathbf{P}(\mathbf{C}^2 \oplus \wedge^2 V_5)$ and a codimension-2 linear space $\mathbf{P}^9$ to get a Fano variety T of dimension 5.

- If $L \cap \mathbf{P}^9 = \varnothing$, the variety T is smooth of type X^5_{10}.
- If $L \subset \mathbf{P}^9$, in which case $\mathbf{P}^9$ is a cone over a $\mathbf{P}^7 \subset \mathbf{P}(\wedge^2 V_5)$, the corresponding variety T_0 meets L at two points p and q, and the projection from L induces a rational conic bundle $T_0 \dashrightarrow W^4_5 := G(2,V_5) \cap \mathbf{P}^7$, undefined at p and q, whose discriminant locus is a threefold X^3_{10}. Blowing up these two points, we obtain a conic bundle $\hat{T}_0 \to W^4_5$ with two disjoint sections corresponding to the two exceptional divisors. These two sections trivialize the canonical double étale cover $\tilde{X}^3_{10} \to X^3_{10}$ of the discriminant.

We call the singular variety T_0 a double-Gushel degeneration. If we let $\overline{\mathscr{X}}^5_{GG}$ be the moduli stack for smooth varieties of type X^5_{10} and their Gushel and double-Gushel degenerations, we obtain a commutative diagram:

$$\begin{tikzcd}
\mathscr{X}^3_{10} \arrow[r] \arrow[dr, "\mathrm{epw}^3"'] & \mathscr{X}^4_G \arrow[r] \arrow[d, "\mathrm{epw}^4_G"] & \mathscr{X}^5_{GG} \arrow[dl, "\mathrm{epw}^5_{GG}"] \\
& \mathscr{EPW}. &
\end{tikzcd}$$

4.2 Period Maps

Both $H^3(X^3_{10},\mathbf{Q})$ and $H^5(X^5_{10},\mathbf{Q})$ have dimension 20 and carry Hodge structures of weight 1. This gives rise to period maps

$$\wp^3 : \mathscr{X}^3_{10} \to \mathscr{A}_{10} \quad \text{and} \quad \wp^5 : \mathscr{X}^5_{10} \to \mathscr{A}_{10}.$$

By [3], the general fibers of $\wp^3$ are unions of smooth proper surfaces that come in pairs:

- $\mathscr{F}_{X^3_{10}}$, isomorphic to the quotient of $\overline{\mathscr{C}}^0_2(X^3_{10})$ by a fixed-point-free involution, and also to $\mathrm{Sing}(Z^\vee_{X^3_{10}})$.
- $\mathscr{F}^\star_{X^3_{10}}$, the analogous surface for any "line-transform" of X^3_{10}.

In particular, by Proposition 4.1, there is a commutative diagram:

$$\begin{tikzcd}
\mathscr{X}^3 \arrow[r, "\mathrm{epw}^3"] \arrow[dr, "\wp^3"'] & \mathscr{E}\mathscr{P}\mathscr{W} \arrow[r] \arrow[d, "\wp"] & \mathscr{E}\mathscr{P}\mathscr{W}/\text{duality} \arrow[dl, "\bar{\wp}"] \\
& \mathscr{A}_{10}, &
\end{tikzcd}$$

where the map $\bar{\wp}$ is generically finite (presumably birational) onto its image. Since $J(X^3_{10})$ is isomorphic to the Albanese variety of the surface $\overline{\mathscr{C}}^0_2(X^3_{10})$ [13], the map $\wp$ is defined by sending the class of a general EPW sextic Z to the Albanese variety of the canonical double cover of its singular locus (the resulting principally polarized abelian varieties are isomorphic for Z and $Z^\vee$).

Theorem 4.2. *The image of* $\wp^3$ *and the image of* $\wp^5$ *have same closures.*

Proof. This is proved using a double Gushel degeneration (see Sect. 4.1): with the notation above, one proves that intermediate Jacobian $J(\hat{T}_0)$ is still a 10-dimensional principally polarized abelian variety which is a limit of intermediate Jacobians of Fano fivefolds of type X^5_{10}, hence belongs to the closure of $\mathrm{Im}(\wp^5)$.

Since, by Lefschetz theorem, we have $H^5(W^4_5,\mathbf{Q}) = H^3(W^4_5,\mathbf{Q}) = 0$, the following lemma implies that the intermediate Jacobians $J(\hat{T}_0)$ and $J(X^3_{10})$ are isomorphic. This proves already that the image of $\wp^3$ is contained in the closure of the image of $\wp^5$.

Lemma 4.3. *Let* T *and* W *be smooth projective varieties. Assume*

$$H^k(W,\mathbf{Q}) = H^{k-2}(W,\mathbf{Q}) = 0.$$

Let $\pi : T \to W$ *be a conic bundle with smooth irreducible discriminant divisor* $X \subset W$. *Assume further that* $\pi^{-1}(X)$ *is reducible. There is an isomorphism of polarized Hodge structures*

$$H^k(T,\mathbf{Z})/\mathrm{tors} \simeq H^{k-2}(X,\mathbf{Z})/\mathrm{tors}.$$

To finish the proof of the theorem, we prove, by computing the kernel of its differential, that the fibers of $\wp^5$ have dimension at least 5. ☐

Question 4.4. Is $\wp^5$ equal to $\wp \circ \mathrm{epw}^5$?

Question 4.5. Can one extend $\wp$ to the GIT compactification of $\mathscr{E}\mathscr{P}\mathscr{W}$ studied in [20], with values in a suitable compactification of $\mathscr{A}_{10}$?

4 Del Pezzo Surfaces

For the remainder of this article, we study del Pezzo surfaces with a view towards Brauer–Severi varieties. Most, if not all, results of these sections are known in some form or another to the experts. However, our more geometric approach, as well as some of the proofs, are new.

Let us first recall some classical results about del Pezzo surfaces, and refer the reader to [35, Chap. IV] or the surveys [7, 41, 47] for details, proofs, and references. For more results about the classification of geometrically rational surfaces, see [25, 34].

Definition 4.1 A *del Pezzo surface* is a smooth and proper variety X of dimension two over a field k such that ω_X^{-1} is ample. The *degree* of a del Pezzo surface is the self-intersection number of ω_X.

In arbitrary dimension, smooth and proper varieties X over k with ample ω_X^{-1} are called *Fano varieties*. As discussed in Example 3.7, Fano varieties of dimension one over k are the same as Brauer–Severi curves over k.

4.1 Geometry

The degree d of a del Pezzo surface X over a field k satisfies $1 \leq d \leq 9$. Set $\overline{X} := X_{\overline{k}}$. We will say that X is *of product type* if

$$\overline{X} \cong \mathbb{P}^1_{\overline{k}} \times \mathbb{P}^1_{\overline{k}},$$

in which case we have $d = 8$. If X is not of product type, then there exists a birational morphism

$$\overline{f} : \overline{X} \to \mathbb{P}^2_{\overline{k}}$$

that is a blow-up of $(9 - d)$ closed points $P_1, \ldots, P_{9-d}$ in general position, i.e., no 3 of them lie on a line, no 6 of them lie on a conic, and there is no cubic through all these points having a double point in one of them. In particular, if $d = 9$, then $\overline{f}$ is an isomorphism and X is a Brauer–Severi surface over k.

4.2 Arithmetic

By the previous discussion and Lemma 2.13, the *Néron–Severi rank* of a del Pezzo surface X of degree d over k satisfies

$$1 \;\leq\; \rho(X) \;:=\; \text{rank}\,\text{Pic}(X) \;=\; \text{rank}\,\text{Pic}_{(X/k)(\text{fppf})}(k) \;\leq\; 10 - d,$$

and $\rho(X_{\overline{k}}) = 10 - d$.

The following result about geometrically rational surfaces allows using methods from Galois theory even if the ground field k is not perfect. This result is particularly useful in proofs, see also the discussion in [47, Sect. 1.4]. In particular, it applies to del Pezzo surfaces.

Theorem 4.2 (Coombes+ε) *Let X be a smooth and proper variety over k such that $X_{\overline{k}}$ is birational to $\mathbb{P}^2_{\overline{k}}$. Then,*

(1) $X_{k^{\mathrm{sep}}}$ is birationally equivalent to $\mathbb{P}^2_{k^{\mathrm{sep}}}$ via a sequence of blow-ups in points in k^{sep}-rational points and their inverses.
(2) The natural map $\mathrm{Pic}_X(k^{\mathrm{sep}}) \to \mathrm{Pic}_X(\overline{k})$ is an isomorphism.

Proof Assertion (1) is the main result of [11]. Clearly, assertion (2) holds for projective space over any field. Next, let Y be a variety that is smooth and proper over k^{sep}, $\widetilde{Y} \to Y$ be the blow-up of a k^{sep}-rational point, and let $E \subset \widetilde{Y}$ be the exceptional divisor. Then, $\mathrm{Pic}_{\widetilde{Y}}(K) = \mathrm{Pic}_Y(K) \oplus \mathbb{Z} \cdot E$ for $K = k^{\mathrm{sep}}$, as well as for $K = \overline{k}$. Using (1) and these two observations, assertion (2) follows. □

We will also need the following useful observation, due to Lang [33] and Nishimura [39], which implies that having a k-rational point is a birational invariant of smooth and proper varieties over k. We refer to [47, Sect. 1.2] for details and proof.

Lemma 4.3 (Lang–Nishimura) *Let $X \dashrightarrow Y$ be a rational map of varieties over k, such that X is smooth over k, and such that Y is proper over k. If X has a k-rational point, then so has Y.* □

Moreover, we have already seen that a Brauer–Severi variety P over k is isomorphic to projective space over k if and only if P has a k-rational point, and we refer the interested reader to [14] for an algorithm to decide whether a Brauer–Severi surface has a k-rational point. In Definition 2.8, we defined the Amitsur group and showed its birational invariance in Proposition 2.10. Using Iskovskih's classification [25] of geometrically rational surfaces, we obtain the following list and refer to [10, Proposition 5.2] for details and proof.

Theorem 4.4 (Colliot-Thélène–Karpenko–Merkurjev) *Let X be a smooth and proper variety over a perfect field k such that $X_{\overline{k}}$ is birationally equivalent to $\mathbb{P}^2_{\overline{k}}$. Then, $\mathrm{Am}(X)$ is one of the following groups*

$$0, \quad \mathbb{Z}/2\mathbb{Z}, \quad (\mathbb{Z}/2\mathbb{Z})^2, \quad \textit{and} \quad \mathbb{Z}/3\mathbb{Z}.$$

We will see explicit examples of all these groups arising as Amitsur groups of del Pezzo surfaces in the next sections.

We now introduce another important invariant. Namely, if G_k denotes the absolute Galois group of k, and $H \subseteq G_k$ is a closed subgroup, then we consider for a smooth and projective variety X over k the group cohomology

$$H^1\left(H, \mathrm{Pic}_{X/k}(k^{\mathrm{sep}})\right),$$

which is an abelian torsion group. If $b_1(X) = 0$, then $\mathrm{Pic}_{X/k}(k^{\mathrm{sep}})$ is finitely generated by Lemma 2.13 and then, $H^1(H, \mathrm{Pic}_{X/k}(k^{\mathrm{sep}}))$ is a finite abelian group. Moreover, if $X_{k^{\mathrm{sep}}}$ is a rational surface, then $\mathrm{Br}'(X_{k^{\mathrm{sep}}}) = 0$ (see, for example, [35, Theorem 42.8] or [36]) and an appropriate Hochschild–Serre spectral sequence yields an exact sequence

$$0 \to \mathrm{Br}'(X)/\mathrm{Br}(k) \xrightarrow{\alpha} H^1\left(G_k, \mathrm{Pic}_{X/k}(k^{\mathrm{sep}})\right) \to H^3(G_k, (k^{\mathrm{sep}})^{\times}).$$

Moreover, if k is a global field, then the term on the right is zero by a theorem of Tate (see, for example, [38, Chap. VIII.3]), thus, α is an isomorphism, and we obtain an interpretation of this cohomology group in terms of Brauer groups, see [47, Sect. 3.4].

Lemma 4.5 *If P is a Brauer–Severi variety over k, then*

$$H^1\left(H, \mathrm{Pic}_{P/k}(k^{\mathrm{sep}})\right) = 0$$

for all closed subgroups $H \subseteq G_k$.

Proof Since $\mathrm{Pic}_{P/k}(k^{\mathrm{sep}}) \cong \mathbb{Z} \cdot \mathcal{O}_P(1)$ and since G_k acts trivially on the class $\mathcal{O}_P(1)$, the desired H^1 is isomorphic to $\mathrm{Hom}(H, \mathbb{Z})$, see [4, Chap. III.1, Exercise 2], for example. This is zero since H is a profinite group and the homomorphisms to $\mathbb{Z}$ are required to be continuous. □

In Proposition 2.10, we established birational invariance of $\mathrm{Am}(X)$. The following result of Manin [35, Sect. 1 of the Appendix] shows that also the above group cohomology groups are a birational invariants.

Theorem 4.6 (Manin) *For every closed subgroup $H \subseteq G_k$, the group*

$$H^1\left(H, \mathrm{Pic}_{X/k}(k^{\mathrm{sep}})\right)$$

is a birational invariant of smooth and projective varieties over k. □

Remark 4.7 Every birational map between smooth and projective surfaces can be factored into a sequence of blow-ups in closed points, see [35, Chap. III]. Using this, one can give very explicit proofs of Proposition 2.10 and Theorem 4.6 in dimension 2. (For such a proof of Theorem 4.6 in dimension 2, see the proof of [35, Theorem 29.1].)

4.3 Hasse Principle and Weak Approximation

For a global field K, i.e., a finite extension of $\mathbb{Q}$ or of $\mathbb{F}_p(t)$, we denote by $\mathbf{\Omega}_K$ the set of its places, including the infinite ones if K is of characteristic zero. A class $\mathcal{C}$ of varieties over K satisfies

(1) the *Hasse principle*, if for every $X \in \mathcal{C}$ we have $X(K) \neq \emptyset$ if and only if $X(K_\nu) \neq \emptyset$ for all $\nu \in \mathbf{\Omega}_K$. Moreover, $\mathcal{C}$ satisfies

(2) *weak approximation*, if the diagonal embedding

$$X(K) \to \prod_{\nu\in\Omega_K} X(K_\nu)$$

is dense for the product of the ν-adic topologies.

If $\mathcal{C}$ satisfies weak approximation, then it obviously also satisfies the Hasse principle, but the converse need not hold. For example, Brauer–Severi varieties over K satisfy the Hasse principle by a theorem of Châtelet [5], as well as weak approximation. However, both properties may fail for del Pezzo surfaces over K, and we refer to [47] for an introduction to this topic. We end this section by noting that the obstruction to a class $\mathrm{Pic}_{(X/K)(\mathrm{fppf})}(K)$ coming from $\mathrm{Pic}_X(K)$ satisfies the Hasse principle.

Lemma 4.8 *Let X a proper variety over a global field K and let $\mathcal{L} \in \mathrm{Pic}_{(X/K)(\mathrm{fppf})}(K)$. Then, the following are equivalent*

(1) $0 = \delta(\mathcal{L}) \in \mathrm{Br}(K)$, *and*
(2) $0 = \delta(\mathcal{L} \otimes_K K_\nu) \in \mathrm{Br}(K_\nu)$ *for all* $\nu \in \Omega_K$.

PROOF A class in $\mathrm{Br}(K)$ is zero if and only if its image in $\mathrm{Br}(K_\nu)$ is zero for all $\nu \in \Omega_K$ by the Hasse principle for the Brauer group. From this, and functoriality of the exact sequence from Proposition 2.5, the assertion follows. □

For example, if $X(K_\nu) \neq \emptyset$ for all $\nu \in \Omega_X$, then δ is the zero map by Proposition 2.5 and this lemma. In this case, every class in $\mathrm{Pic}_{(X/K)(\mathrm{fppf})}(K)$ comes from an invertible sheaf on X.

5 Del Pezzo Surfaces of Product Type

In this section, we classify degree 8 del Pezzo surfaces of product type over k, i.e., surfaces X over k with $X_{\overline{k}} \cong \mathbb{P}^1_{\overline{k}} \times \mathbb{P}^1_{\overline{k}}$, in terms of Brauer–Severi varieties.

First, for $\mathbb{P}^1_k \times \mathbb{P}^1_k$, the anti-canonical embedding can be written as composition of Veronese- and Segre-maps as follows

$$|-K_{\mathbb{P}^1_k\times\mathbb{P}^1_k}| : \mathbb{P}^1_k \times \mathbb{P}^1_k \xrightarrow{\nu_2\times\nu_2} \mathbb{P}^2_k \times \mathbb{P}^2_k \xrightarrow{\sigma} \mathbb{P}^8_k .$$

Next, the invertible sheaf $\omega^{-1}_{\mathbb{P}^1_k\times\mathbb{P}^1_k}$ is uniquely 2-divisible in the Picard group, and we obtain an embedding as a smooth quadric

$$|-\tfrac{1}{2}K_{\mathbb{P}^1_k\times\mathbb{P}^1_k}| : \mathbb{P}^1_k \times \mathbb{P}^1_k \xrightarrow{\sigma} \mathbb{P}^3_k .$$

Now, let X be a degree 8 del Pezzo surface of product type over k. Then, the anti-canonical linear system yields an embedding of X as a surface of degree 8 into $\mathbb{P}^8_k$.

However, the "half-anti-canonical linear system" exists in general only as a morphism to a Brauer–Severi threefold as the following result shows.

Theorem 5.1 *Let X be a degree 8 del Pezzo surface of product type over a field k. Then, there exist a unique class $\mathcal{L} \in \mathrm{Pic}_{(X/k)(\mathrm{fppf})}(k)$ with $\mathcal{L}^{\otimes 2} \cong \omega_X^{-1}$ and an embedding*

$$|\mathcal{L}| : X \hookrightarrow P$$

into a Brauer–Severi threefold P over k with Brauer class

$$\delta(\mathcal{L}) = [P] \in \mathrm{Br}(k),$$

and such that $X_{\overline{k}}$ is a smooth quadric in $P_{\overline{k}} \cong \mathbb{P}^3_{\overline{k}}$. Moreover, X is rational if and only if X has a k-rational point. In this case, we have $P \cong \mathbb{P}^3_k$.

PROOF To simplify notation, set $L := k^{\mathrm{sep}}$. We have $X(L) \neq \emptyset$, for example, by [18, Proposition A.1.1], as well as $\mathrm{Pic}(X_L) \cong \mathrm{Pic}(X_{\overline{k}}) \cong \mathbb{Z}^2$ by Theorem 4.2. The classes $(1, 0)$ and $(0, 1)$ of $\mathrm{Pic}(X_L)$ give rise to two morphisms $X_L \to \mathbb{P}^1_L$, and we obtain an isomorphism $X_L \cong \mathbb{P}^1_L \times \mathbb{P}^1_L$. By abuse of notation, we re-define $\overline{X}$ to be X_L. Next, the absolute Galois group G_k acts trivially on the canonical class $(-2, -2)$, and thus, the G_k-action on $\mathbb{Z}(1, 1) \subset \mathbb{Z}^2$ is trivial. By Proposition 2.7, we have $\mathrm{Pic}_{X/k}(K)^{G_k} \cong \mathrm{Pic}_{(X/k)(\mathrm{fppf})}(k)$, and, since $(1, 1) \in \mathbb{Z}^2$ is G_k-invariant, the unique invertible sheaf $\mathcal{L}$ on $\overline{X}$ with $\mathcal{L}^{\otimes 2} \cong \omega_{\overline{X}}^{-1}$ descends to a class in $\mathrm{Pic}_{(X/k)(\mathrm{fppf})}(k)$. Over L, the class $\mathcal{L}$ is very ample and defines an embedding of $\overline{X}$ as smooth quadric surface into $\mathbb{P}^3_L$. Thus, by Theorem 3.4, we obtain an embedding $|\mathcal{L}| : X \hookrightarrow P$, where P is a Brauer–Severi threefold over k with $\delta(\mathcal{L}) = [P] \in \mathrm{Br}(k)$.

Finally, if X is rational, then it has a k-rational point, and then, also P has a k-rational point, i.e., $P \cong \mathbb{P}^3_k$. Conversely, if there exists a k-rational point $x \in X$, then X is a quadric in $\mathbb{P}^3_k$, and projection away from x induces a birational map $X \dashrightarrow \mathbb{P}^2_k$. ☐

Next, we establish an explicit classification of degree 8 del Pezzo surfaces of product type in terms of the Néron–Severi rank ρ and Brauer–Severi curves. To simplify notation in the sequel, let us recall the definition of contracted products. If a finite group G acts on a scheme X from the right and it acts on a scheme Y from the left and all schemes and actions are over $\mathrm{Spec}\, k$ for some field k, then we denote the quotient of $X \times_{\mathrm{Spec}\, k} Y$ by the diagonal G-action defined by $(x, y) \mapsto (xg, g^{-1}y)$ for all $g \in G$ by

$$X \wedge^G Y := (X \times_{\mathrm{Spec}\, k} Y)/G.$$

We refer to [19, Chap. III.1.3] for details and applications.

Proposition 5.2 *Let X and $X \subset P$ be as in Theorem 5.1.*

(1) if $\rho(X) = 2$, then

$$X \cong P' \times P'',$$

where P' and P'' are Brauer–Severi curves over k, whose Brauer classes satisfy $[P] = [P'] + [P''] \in \mathrm{Br}(k)$. In particular, $P \cong \mathbb{P}^3_k$ if and only if $P' \cong P''$.

(2) If $\rho(X) = 1$, then there exist a Brauer–Severi curve P' over k and a finite Galois extension K/k with Galois group $H := \mathbb{Z}/2\mathbb{Z}$, such that X arises as twisted self-product

$$X \cong (P' \times P')_K/H = \operatorname{Spec} K \wedge^H (P' \times P'),$$

where the H-action permutes the factors of $P'_K \times P'_K$. Moreover, $P \cong \mathbb{P}^3_k$ and P' is a hyperplane section of $X \subset \mathbb{P}^3_k$.

Proof We keep the notations and assumptions from the proof of Theorem 5.1. The G_k-action fixes the class $(1, 1)$. Since the G_k-action preserves the intersection pairing on $\mathrm{Pic}_{X/k}(k^{\mathrm{sep}})$, it follows that G_k acts on $\mathbb{Z}(1, -1)$ either trivially, or by sign changes. We have $\rho(X) = 2$ in the first case, and $\rho(X) = 1$ in the latter.

First, assume that $\rho(X) = 2$. By Theorem 3.4, the classes $(1, 0)$ and $(0, 1)$ give rise to morphisms to Brauer–Severi curves $X \to P'$ and $X \to P''$ of class $[P'] = \delta((1, 0))$ and $[P''] = \delta((0, 1))$ in $\mathrm{Br}(k)$, respectively. Thus, we obtain a morphism $X \to P' \times P''$, which is an isomorphism because it is an isomorphism over k^{sep}. Since δ is a homomorphism, we find $[P] = \delta(\mathcal{L}) = \delta((1, 1)) = \delta((1, 0)) + \delta((0, 1)) = [P'] + [P'']$. Using that P' and P'' are of period 2, we find that $P \cong \mathbb{P}^3_k$ if and only if $[P] = 0$, i.e., if and only if $[P'] = [P'']$. By Corollary 2.16, the latter is equivalent to $P' \cong P''$.

Second, assume that $\rho(X) = 1$. Then, the G_k-action permutes $(0, 1)$ and $(1, 0)$, i.e., it permutes the factors of $\mathbb{P}^1_{k^{\mathrm{sep}}} \times \mathbb{P}^1_{k^{\mathrm{sep}}}$. Thus, there exists a unique quadratic Galois extension K/k, such that $\mathrm{Gal}(k^{\mathrm{sep}}/K)$ acts trivially on $\mathrm{Pic}_{X/k}(k^{\mathrm{sep}})$ and by the previous analysis we have $X_K := Q'' \times Q'''$ for two Brauer–Severi curves Q'', Q''' over K. Using these and the $H := \mathrm{Gal}(K/k)$-action, we obtain a H-stable diagonal embedding $Q' \subset X_K$ of a Brauer–Severi curve over K, and then, the two projections induce isomorphisms $Q' \cong Q''$ and $Q' \cong Q'''$ over K. Taking the quotient by H, we obtain a Brauer–Severi curve $P' := Q'/H \subset X$ over k. Clearly, $P'_K \cong Q'$ and we obtain the description of X as twisted self-product. On X, the curve P' is a section of the class $(1, 1)$, which implies that this class comes from an invertible sheaf, and thus, $0 = \delta((1, 1)) \in \mathrm{Br}(k)$ by Proposition 2.5. Since $\delta((1, 1)) = [P]$, we conclude $P \cong \mathbb{P}^3_k$. □

Remark 5.3 In the case of quadrics in $\mathbb{P}^3$, similar results were already established in [9]. A related, but somewhat different view on degree 8 del Pezzo surfaces of product type was taken in (the proof of) [10, Proposition 5.2]: If X is such a surface, then there exists a quadratic Galois extension K/k and a Brauer–Severi curve C over K, such that $X \cong \mathrm{Res}_{K/k} C$, where $\mathrm{Res}_{K/k}$ denotes Weil restriction, see also [41].

Corollary 5.4 *Let X be as in Theorem 5.1. Then,*

$$H^1\left(H, \mathrm{Pic}_{X/k}(k^{\mathrm{sep}})\right) = 0$$

for all closed subgroups $H \subseteq G_k$, and

$$\mathrm{Am}(X) \cong \begin{cases} 0 & \textit{if } \rho = 1 \textit{ or if } X \cong \mathbb{P}^1_k \times \mathbb{P}^1_k, \\ (\mathbb{Z}/2\mathbb{Z})^2 & \textit{if } \rho = 2 \textit{ and } \mathbb{P}^1_k \not\cong P' \not\cong P'' \not\cong \mathbb{P}^1_k, \\ (\mathbb{Z}/2\mathbb{Z}) & \textit{in the remaining } \rho = 2\textit{-cases.} \end{cases}$$

PROOF Set $H^1(H) := H^1(H, \mathrm{Pic}_{X/k}(k^{\mathrm{sep}}))$. If $\rho = 2$, then the G_k-action on $\mathrm{Pic}_{X/k}(k^{\mathrm{sep}})$ is trivial, and we find $H^1(H) = 0$ as in the proof of Lemma 4.5. Moreover, $\mathrm{Am}(X)$ is generated by $\delta((0,1)$ and $\delta((1,0))$, i.e., by $[P']$ and $[P'']$ in $\mathrm{Br}(k)$. From this, the assertions on $\mathrm{Am}(X)$ follow in case $\rho = 2$.

If $\rho = 1$, then there exists an isomorphism $\mathrm{Pic}_{X/k}(k^{\mathrm{sep}}) \cong \mathbb{Z}^2$, such that the G_k-action factors through a surjective homomorphism $G_k \to \mathbb{Z}/2\mathbb{Z}$ and acts on $\mathbb{Z}^2$ via $(a,b) \mapsto (b,a)$. In particular, we find $H^1(\mathbb{Z}/2\mathbb{Z}, \mathbb{Z}^2) = 0$ with respect to this action, see, for example, [4, Chap. III.1, Example 2]. From this, we deduce $H^1(H) = 0$ using inflation maps. Moreover, $\mathrm{Am}(X)$ is generated by $\delta((1,1))$, which is zero, since $(1,1)$ is the class of an invertible sheaf. □

Corollary 5.5 *If X is as in Theorem 5.1, then the following are equivalent*

(1) X is birationally equivalent to a Brauer–Severi surface,
(2) X is rational,
(3) X has a k-rational point, and
(4) X is isomorphic to

$$X \cong \mathbb{P}^1_k \times \mathbb{P}^1_k \quad \textit{or to} \quad X \cong \mathrm{Spec}\, K \wedge (\mathbb{P}^1_k \times \mathbb{P}^1_k).$$

PROOF The implications (2) ⇒ (1) and (2) ⇒ (3) are trivial, and we established (3) ⇒ (2) in Theorem 5.1. Moreover, if X is birationally equivalent to a Brauer–Severi surface P, then $\mathrm{Am}(P) = \mathrm{Am}(X)$ is cyclic of order 1 or 3 by Lemma 4.5 and Theorem 4.6. Together with Corollary 5.4, we conclude $\mathrm{Am}(P) = \mathrm{Am}(X) = 0$, i.e., $P \cong \mathbb{P}^2_k$, which establishes (1) ⇒ (2).

Since (4) ⇒ (3) is trivial, it remains to establish (3) ⇒ (4). Thus, we assume $X(k) \neq \emptyset$. If $\rho = 2$, then $X \cong P' \times P''$ and both Brauer–Severi curves P' and P'' have k-rational points, i.e., $X \cong \mathbb{P}^1_k \times \mathbb{P}^1_k$. If $\rho = 1$, we have an embedding $X \subset \mathbb{P}^3_k$ and $X \cong \mathrm{Spec}\, K \wedge (P' \times P')$. Since $X(k) \neq \emptyset$, we have $X(K) \neq \emptyset$, which yields $P'(K) \neq \emptyset$, and thus $P'_K \cong \mathbb{P}^1_K$. A k-rational point on X gives rise to a K-rational and $\mathrm{Gal}(K/k)$-stable point on $X_K \cong \mathbb{P}^1_K \times \mathbb{P}^1_K$. In particular, this point lies on some diagonal $\mathbb{P}^1_K \subset X_K$, and thus, lies on some diagonal $P'' \subseteq X$ with $X \cong \mathrm{Spec}\, K \wedge (P'' \times P'')$. Since $P''(k) \neq \emptyset$, we find $P'' \cong \mathbb{P}^1_k$. □

We refer to Sect. 6.1 for more applications of these results to the arithmetic and geometry of these surfaces.

6 Del Pezzo Surfaces of Large Degree

Let X be a del Pezzo surface of degree d over a field k that is not of product type. Then, there exists a birational morphism

$$\overline{f} : \overline{X} \to \mathbb{P}^2_{\overline{k}}$$

that is a blow-up in $(9-d)$ closed points $P_1, \ldots, P_{9-d}$ in general position. We set $H := \overline{f}^{\,*}\mathcal{O}_{\mathbb{P}^2_{\overline{k}}}(1)$ and let $E_i := \overline{f}^{\,-1}(P_i)$ be the exceptional divisors of $\overline{f}$. Then, there exists an isomorphism of abelian groups

$$\mathrm{Pic}(\overline{X}) \cong \mathbb{Z}H \,\oplus\, \bigoplus_{i=1}^{9-d} \mathbb{Z}E_i .$$

The (-1)-curves of $\overline{X}$ consist of the E_i, of preimages under $\overline{f}$ of lines through two distinct points P_i, of preimages under $\overline{f}$ of quadrics through five distinct points P_i, etc., and we refer to [35, Theorem 26.2] for details. Let $K_{\overline{X}}$ be the canonical divisor class of $\overline{X}$, and let $\widetilde{E}$ be the sum of all (-1)-curves on $\overline{X}$. We leave it to the reader to verify the following table.

d	class of $\widetilde{E}$ in $\mathrm{Pic}(\overline{X})$	relations
9	0	$3H = -K_{\overline{X}}$
8	E_1	$3H = -K_{\overline{X}} + \widetilde{E}$
7	H	$H = \widetilde{E}$
6	$3H - \sum_{i=1}^{3} E_i$	$0 = -K_{\overline{X}} - \widetilde{E}$
5	$6H - 2\sum_{i=1}^{4} E_i$	$0 = -2K_{\overline{X}} - \widetilde{E}$
4	$12H - 4\sum_{i=1}^{5} E_i$	$0 = -4K_{\overline{X}} - \widetilde{E}$
3	$27H - 9\sum_{i=1}^{6} E_i$	$0 = -9K_{\overline{X}} - \widetilde{E}$
2	$84H - 28\sum_{i=1}^{7} E_i$	$0 = -28K_{\overline{X}} - \widetilde{E}$
1	$720H - 240\sum_{i=1}^{8} E_i$	$0 = -240K_{\overline{X}} - \widetilde{E}$

Together with Theorem 3.4, we obtain the following result.

Theorem 6.1 *Let X be a del Pezzo surface of degree $d \geq 7$ over a field k that is not of product type. Then, $\overline{f}$ descends to a birational morphism*

$$f : X \to P$$

to a Brauer–Severi surface P over k, where

$$\delta(H) = [P] \in \mathrm{Br}(k) \quad \textit{and} \quad \mathrm{Am}(X) \cong \mathbb{Z}/\mathrm{per}(P)\mathbb{Z}.$$

Moreover, X is rational if and only if $P \cong \mathbb{P}^2_k$. This is equivalent to X having a k-rational point.

Proof By Theorem 4.2, the invertible sheaf H on $X_{\overline{k}}$ defining $\overline{f}$ already lies in $\mathrm{Pic}_X(k^{\mathrm{sep}})$, i.e., $\overline{f}$ descends to k^{sep}, and by abuse of notation, we re-define $\overline{X}$ to be $X_{k^{\mathrm{sep}}}$. Clearly, the canonical divisor class $K_{\overline{X}}$ is G_k-invariant, and since G_k permutes the (-1)-curves of $\overline{X}$, also the class of $\widetilde{E}$ is G_k-invariant. In particular, $K_{\overline{X}}$ and $\widetilde{E}$ define classes in $\mathrm{Pic}_{X/k}(k^{\mathrm{sep}})^{G_k} \cong \mathrm{Pic}_{(X/k)(\mathrm{fppf})}(k)$. If $d \geq 7$, then the above table shows that there exist positive multiples of H that are integral linear combinations of $K_{\overline{X}}$ and $\widetilde{E}$. Thus, $H \in \mathrm{Pic}_{X/k}(k^{\mathrm{sep}})$ descends to a class in $\mathrm{Pic}_{(X/k)(\mathrm{fppf})}(k)$. By Theorem 3.4, $\overline{f}$ descends to a birational morphism $f : X \to P$, where P is a Brauer–Severi surface of class $\delta(H) \in \mathrm{Br}(k)$. The assertion on $\mathrm{Am}(X)$ follows from Proposition 2.10 and Theorem 2.19.

If X has a k-rational point, then so has P, and then $P \cong \mathbb{P}^2_k$. Since f is a birational morphism, $P \cong \mathbb{P}^2_k$ implies that X is rational. And if X is rational, then it has a k-rational point by Lemma 4.3. □

As an immediate consequence, we obtain rationality and the existence of k-rational points in some cases.

Corollary 6.2 *Let X be as in Theorem 6.1. If $d \in \{7, 8\}$, then X has a k-rational point and $\overline{f}$ descends to a birational morphism $f : X \to \mathbb{P}^2_k$.*

Proof By Theorem 6.1, there exists a birational morphism $X \to P$ that is a blow-up in a closed subscheme $Z \subset P$ of length $(9 - d)$. By Corollary 2.21, we have $P \cong \mathbb{P}^2_k$ if 3 and $(9 - d)$ are coprime. In particular, we have $X(k) \neq \emptyset$ in these cases by Theorem 6.1 and Lemma 4.3. □

Since a del Pezzo surface of degree 9 is a Brauer–Severi surface, it has rational points if and only if it is trivial. In particular, Corollary 6.2 does not hold for $d = 9$.

6.1 Applications to Arithmetic Geometry

We now give a couple of applications of the just established results. Again, we stress that most if not all of these applications are well-known, and merely illustrate the usefulness of studying varieties via Brauer–Severi varieties.

Corollary 6.3 *If X is a del Pezzo surface of degree ≥ 7 over k, then*

$$H^1\left(H,\ \mathrm{Pic}_{X/k}(k^{\mathrm{sep}})\right) = 0.$$

for all closed subgroups $H \subseteq G_k$

PROOF If X is not of product type, then it is birationally equivalent to a Brauer–Severi surface P by Theorem 6.1, and then the statement follows from Theorem 4.6 and Lemma 4.5. If X is of product type, then this is Corollary 5.4. □

For the next application, let us recall that a surface is called *rational* if it is birationally equivalent to $\mathbb{P}^2_k$, and that it is called *unirational* if there exists a dominant and rational map from $\mathbb{P}^2_k$ onto it. The following result is a special case of [35, Theorem 29.4].

Corollary 6.4 *Let X be a del Pezzo surface of degree ≥ 7 over a field k. Then, the following are equivalent:*

(1) X is rational,
(2) X is unirational, and
(3) X has a k-rational point.

PROOF Clearly, we have (1) $\Rightarrow$ (2) $\Rightarrow$ (3), whereas (3) $\Rightarrow$ (1) follows from Corollary 5.5 and Theorem 6.1. □

This leads us to the question whether a del Pezzo surface necessarily has a k-rational point. Over finite fields, this is true and follows from the Weil conjectures, which we will recall in Theorem 8.1 below. By a theorem of Wedderburn, finite fields have trivial Brauer groups, and thus, the following corollary gives existence of k-rational points for more general fields.

Corollary 6.5 *Let X be a del Pezzo surface of degree ≥ 7 over a field k with* $\mathrm{Br}(k) = 0$. *Then, X has a k-rational point, and thus, is rational.*

Proof If X is not of product type, then there exists a birational morphism $f : X \to P$ to a Brauer–Severi surface by Theorem 6.1. Since $\mathrm{Br}(k) = 0$, we have $P \cong \mathbb{P}^2_k$, and Theorem 6.1 gives $X(k) \neq \emptyset$.

Thus, let X be of product type. By Proposition 5.2, X is a product of Brauer–Severi curves ($\rho = 2$), or contains at least a Brauer–Severi curve ($\rho = 1$). Since $\mathrm{Br}(k) = 0$, all Brauer–Severi curves are isomorphic to $\mathbb{P}^1_k$, and thus, contain k-rational points. In particular, we find $X(k) \neq \emptyset$. □

In Sect. 4.3, we discussed the Hasse principle and weak approximation for varieties over global fields. Here, we establish the following.

Corollary 6.6 *Del Pezzo surfaces of degree ≥ 7 over global fields satisfy weak approximation and the Hasse principle.*

Proof If X is not of product type, then it is birationally equivalent to a Brauer–Severi surface by Theorem 6.1, and since the two claimed properties are preserved under birational maps and hold for Brauer–Severi varieties, the assertion follows in this case.

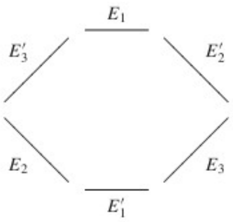
If X is of product type, then there are two cases by Proposition 5.2. If $\rho = 2$, then X is a product of two Brauer–Severi curves, and we conclude as before.

Thus, we may assume $\rho = 1$. Let us first establish the Hasse principle: there exists a quadratic Galois extension L/K, such that $\rho(X_L) = 2$. From $X(K_\nu) \neq \emptyset$ for all $\nu \in \Omega_K$, we find $X_{L_\mu} \cong \mathbb{P}^1_{L_\mu} \times \mathbb{P}^1_{L_\mu}$ for all $\mu \in \Omega_L$, and thus, $X_L \cong \mathbb{P}^1_L \times \mathbb{P}^1_L$ by the Hasse principle for Brauer–Severi curves. As in the proof of Corollary 5.5, we exhibit X as twisted self-product of $\mathbb{P}^1_k$, which has a k-rational point and establishes the Hasse principle. Thus, to establish weak approximation, we may assume that X has a k-rational point. But then, X is rational by Corollary 5.5, and since weak approximation is a birational invariant, the assertion follows. □

7 Del Pezzo Surfaces of Degree 6

In the previous sections, we have seen a close connection between Brauer–Severi varieties and del Pezzo surfaces of degree ≥ 7. In this section, we discuss del Pezzo surfaces of degree 6, which are not so directly linked to Brauer–Severi varieties.

For the geometry and the arithmetic of these surfaces, we refer the interested reader to [6, 35], and the survey [47, Sect. 2.4]. We keep the notation introduced in Sect. 6: If X is a degree 6 del Pezzo surface over a field k, then there exists a blow-up $f_{\overline{k}} : \overline{X} \to \mathbb{P}^2_{\overline{k}}$ in three points in general position with exceptional (-1)-curves E_1, E_2, and E_3. Then, there are six (-1)-curves on X, namely the three exceptional curves E_i, $i = 1, 2, 3$ of $\overline{f}$, as well as the three curves $E_i' := H - E_j - E_k$, $i = 1, 2, 3$ where $\{j, k\} = \{1, 2, 3\} \backslash \{i\}$ and where $H = \overline{f}^* \mathcal{O}_{\mathbb{P}^2}(1)$ as in Sect. 6. These curves intersect in a hexagon as follows.



The absolute Galois group G_k acts on these six (-1)-curves on $X_{k^{\mathrm{sep}}}$, and associated to this action, we have following field extensions of k.

(1) Since G_k acts on the two sets $\{E_1, E_2, E_3\}$ and $\{E_1', E_2', E_3'\}$, there is a group homomorphism

$$\varphi_1 \,:\, G_k \,\to\, S_2 \,\cong\, \mathbb{Z}/2\mathbb{Z}.$$

The fixed field of either of the two sets is a finite separable extension $k \subseteq K$ with $[K : k]|2$, and $k \neq K$ if and only if φ_1 is surjective.

(2) Since G_k acts on the three sets $\{E_i, E_i'\}$, $i = 1, 2, 3$, there is a group homomorphism

$$\varphi_2 \,:\, G_k \,\to\, S_3.$$

There exists a finite separable extension $k \subseteq L$ with $[L : k]|3$, unique up to conjugation in k^{sep}, over which at least one of these three sets is defined. We have $k \neq L$ if and only if 3 divides the order of $\varphi_2(G_k)$. Next, there exists a finite and separable extension $L \subseteq M$ with $[M : L]|2$, over which all three sets are defined.

Combining φ_1 and φ_2, we obtain a group homomorphism

$$G_k \xrightarrow{\varphi_1 \times \varphi_2} \mathbb{Z}/2\mathbb{Z} \times S_3 \,\cong\, D_{2\cdot 6},$$

where $D_{2\cdot 6}$ denotes the dihedral group of order 12, i.e., the automorphism group of the hexagon. Using these field extensions, we obtain the following classification, which uses and slightly extends a classical result of Manin from [35] in case (3).

Theorem 7.1 *Let X be a del Pezzo surface of degree* 6 *over a field k.*

(1) The morphism $\overline{f}$ descends to a birational morphism

$$f \,:\, X \,\to\, P$$

to a Brauer–Severi surface P if and only if $k = K$. In this case, $\rho(X) \geq 2$ and $\mathrm{Am}(X) = \mathrm{Am}(P)$.

(2) There exists a birational morphism $X \to Y$ onto a degree 8 *del Pezzo surface Y of product type if and only if $k = L$. In this case,*

	$\rho(X)$	Y
$k \neq M$	3	$\mathrm{Spec}\, M \wedge (\mathbb{P}^1_k \times \mathbb{P}^1_k)$
$k = M$	4	$\mathbb{P}^1_k \times \mathbb{P}^1_k$

X has a k-rational point, and $\mathrm{Am}(X) = 0$.

(3) If $k \neq K$ and $k \neq L$, then $\rho(X) = 1$, $\mathrm{Am}(X) = 0$, *and the following are equivalent.*

(a) X is birationally equivalent to a Brauer–Severi surface,
(b) X is birationally equivalent to a product of two Brauer–Severi curves,
(c) X is rational, and
(d) X has a k-rational point.

Proof Let us first show (1). If $k = K$, then $F := E_1 + E_2 + E_3$ descends to a class in $\mathrm{Pic}(X_{k^{\mathrm{sep}}})^{G_k} = \mathrm{Pic}_{(X/k)(\mathrm{fppf})}(k)$ and we find $\rho(X) \geq 2$. Thus, also $H = \frac{1}{3}(-K_X + F)$ descends to a class in $\mathrm{Pic}_{(X/k)(\mathrm{fppf})}(k)$, and by Theorem 3.4, we obtain a birational morphism $|H| : X \to P$ to a Brauer–Severi surface, which coincides with $\overline{f}$ over $\overline{k}$. Conversely, if $\overline{f}$ descends to a birational morphism $f : X \to P$, then the exceptional divisor of f is of class F or $E'_1 + E'_2 + E'_3$, and we find $k = K$. Moreover, we have $\mathrm{Am}(X) = \mathrm{Am}(P)$ by Theorem 4.6.

If $k = L$, then, say $E_1 + E'_1$, descends to a class in $\mathrm{Pic}(X_{k^{\mathrm{sep}}})^{G_k}$. Moreover, we find that the classes $\frac{1}{2}(-K_X + E_1 + E'_1) = 2H - E_2 - E_3$ as well as $\frac{1}{2}(-K_X - E_1 - E'_1) = H - E_1$, and thus, the classes H, E_1, and $E'_1 = H - E_2 - E_3$ lie in $\mathrm{Pic}(X_{k^{\mathrm{sep}}})^{G_k}$. The G_k-action is trivial on H and E_1, whereas it is either trivial on the set $\{E_2, E_3\}$ (if $k = M$) or permutes the two (if $k \neq M$). Since the class of E_1 is G_k-invariant and there is a unique effective divisor in this linear system, we find that $\mathbb{P}^1_k \cong E_1 \subset X$. In particular, X has a k-rational point and $\mathrm{Am}(X) = 0$. Using Theorem 3.4 and the fact that X has a k-rational point, we obtain a birational morphism

$$|\frac{1}{2}(-K_X + E_1 + E'_1)| \,:\, X \to Y \subset \mathbb{P}^3_k$$

onto a smooth quadric Y with a k-rational point. In particular, Y is a degree 8 del Pezzo surface of product type. Over k^{sep}, this morphism contracts E_1 and E_1' and thus, we find

$$\mathrm{Pic}(Y_{k^{\mathrm{sep}}}) \cong \left(\mathbb{Z}H \oplus \bigoplus_{i=1}^{3} \mathbb{Z}E_i \right) / \langle E_1, E_1' \rangle \cong \mathbb{Z}\overline{E}_2 \oplus \mathbb{Z}\overline{E}_3.$$

The G_k-action on it is either trivial ($k = M$) or permutes the two summands ($k \neq M$). Using $Y(k) \neq \emptyset$ and Corollary 5.5, we find $\rho(X) = 4$ and $Y \cong \mathbb{P}^1_k \times \mathbb{P}^1_k$ in the first case, and $\rho(X) = 3$ and $Y \cong \mathrm{Spec}\, M \wedge (\mathbb{P}^1_k \times \mathbb{P}^1_k)$ in the latter. Conversely, if there exists a birational morphism $X \to Y$ onto a degree 8 del Pezzo surface of product type, then the exceptional divisor is of class $E_i + E_i'$ for some i, and thus, $k = L$. This establishes (2).

Finally, assume that $k \neq K$ and $k \neq L$. Then, φ_1 is surjective, and $\varphi_2(G_k)$ contains all 3-cycles of S_3. From this, it is not difficult to see that $\mathrm{Pic}(X_{\overline{k}})^{G_k}$ is of rank 1 and generated by the class of K_X. Since this latter class is an invertible sheaf, we find $\mathrm{Am}(X) = 0$. Thus, if X is birationally equivalent to a Brauer–Severi surface P, then $\mathrm{Am}(X) = 0$ together with Lemma 4.5 and Theorem 4.6 implies that $P \cong \mathbb{P}^2_k$. Similarly, if X is birationally equivalent to the product $P' \times P''$ of two Brauer–Severi curves, then $P' \cong P'' \cong \mathbb{P}^1_k$. From this, we obtain the implications $(a) \Leftrightarrow (b) \Leftrightarrow (c) \Rightarrow (d)$. The implication $(d) \Rightarrow (c)$ is due to Manin [35, Theorem 29.4]. □

Remark 7.2 In case (1) of the above theorem it is important to note that P need not be unique, but that $\mathrm{Am}(P)$ is well-defined. More precisely, if we set $F := E_1 + E_2 + E_3$ and $F' = E_1' + E_2' + E_3'$, then Theorem 3.4 provides us with two morphisms to Brauer–Severi surfaces P_1 and P_2

$$\begin{array}{rcl} |H| & = |\tfrac{1}{3}(-K_X + F)| : X & \to P_1 \\ |H'| & := |\tfrac{1}{3}(-K_X + F')| : X & \to P_2 \end{array}$$

Since $H + H' = -K_X$ and $\delta(K_X) = 0$, we find

$$[P_1] = \delta(H) = \delta(-K_X - H') = -\delta(H') = -[P_2] \in \mathrm{Br}(k),$$

and thus, $P_1 \cong P_2$ if and only if both are isomorphic to $\mathbb{P}^2_k$. On the other hand, P_1 and P_2 are birationally equivalent, since we have birational morphisms

$$P_1 \xleftarrow{|H|} X \xrightarrow{|H'|} P_2 \,.$$

Over $\overline{k}$, this becomes the blow-up of three closed points Z followed by the blow-down of the three (-1)-curves that are the strict transforms of lines through any two of the points in Z. This is an example of a *Cremona transformation*.

We remark that a surface of case (3) and without k-rational points is neither birationally equivalent to a Brauer–Severi surface nor to the product of two Brauer–Severi curves. For finer and more detailed classification results for degree 6 del Pezzo surfaces, we refer the interested reader to [2, 10, 13]. Finally, the sum $\widetilde{E}$ of all (-1)-curves on $X_{k^{\mathrm{sep}}}$ is a G_k-invariant divisor, and thus, descends to a curve on X. By [35, Theorem 30.3.1], the complement $X\backslash\widetilde{E}$ is isomorphic to a torsor under a two-dimensional torus over k, which can be used to study the arithmetic and geometry of these surfaces, see also [43].

8 Del Pezzo Surfaces of Small Degree

For the remainder of this article, our results will be less complete and less self-contained. We will circle around questions of birationality of a del Pezzo surface X of degree ≤ 5 to Brauer–Severi surfaces, and about descending the morphism $\overline{f}:\overline{X}\to\mathbb{P}^2_{\overline{k}}$ to k.

8.1 Birationality to Brauer–Severi Surfaces

Let $k=\mathbb{F}_q$ be a finite field of characteristic p, and let X be a smooth and projective surface over k such that $X_{\overline{k}}$ is birationally equivalent to $\mathbb{P}^2$. Then, it follows from the Weil conjectures (in this case already a theorem of Weil himself) that the number of k-rational points is congruent to 1 modulo q, see [35, Chap. IV.27]. In particular, we obtain that

Theorem 8.1 (Weil) *If X is a del Pezzo surface over a finite field $\mathbb{F}_q$, then X has a $\mathbb{F}_q$-rational point.*

Since $\mathrm{Br}(\mathbb{F}_q)=0$ by a theorem of Wedderburn, there are no non-trivial Brauer–Severi varieties over $\mathbb{F}_q$.

Remark 8.2 Let X be a del Pezzo surface of degree ≥ 5 over a field k. Manin [35, Theorem 29.4] showed that X is rational if and only if it contains a k-rational point. Even if X has no k-rational point, Manin [35, Theorem 29.3] showed that

$$H^1\left(H,\ \mathrm{Pic}_{(X/k)(\mathrm{fppf})}(k^{\mathrm{sep}})\right) = 0$$

for all closed subgroups $H\subseteq G_k$. We refer to [8, Théorème 2.B.1] for a general principle explaining this vanishing of cohomology.

In this section, we give a partial generalization to birational maps to Brauer–Severi surfaces.

Lemma 8.3 *Let X be a degree d del Pezzo surface over k. Then,*

(1) There exists an effective zero-cycle Z of degree d on X. If $d \neq 2$ or if $\mathrm{char}(k) \neq 2$, then there exists such a zero-cycle Z, whose closed points have residue fields that are separable over k.
(2) The abelian group $\mathrm{Am}(X)$ is finite and every element has an order dividing d.

PROOF If $d \geq 3$, then ω_X^{-1} is very ample, and $|\omega_X^{-1}|$ embeds X as a surface of degree d into $\mathbb{P}_k^d$. Intersecting X with a linear subspace of codimension 2, we obtain an effective zero-cycle Z of degree d on X. The closed points of Z have automatically separable residue fields if k is finite. Otherwise, k is infinite, and then, the intersection with a generic linear subspace of codimension 2 yields a Z that is smooth over k by [28, Théorème I.6.3]. Thus, in any case, we obtain a Z, whose closed points have residue fields that are separable over k. If $d = 2$, then $|\omega_X^{-1}|$ defines a double cover $X \to \mathbb{P}_k^2$, and the pre-image of a k-rational point yields an effective zero-cycle Z of degree 2 on X. If $\mathrm{char}(k) \neq 2$, then residue fields of closed points of Z are separable over k. If $d = 1$, then $|-K_X|$ has a unique-base point, and in particular, X has a k-rational point. This establishes (1). Since $b_1(X) = 0$, the group $\mathrm{Am}(X)$ is finite by Lemma 2.13. Then, assertion (2) follows from Lemma 2.9. □

Corollary 8.4 *Let X be a del Pezzo surface of degree d over a field k.*

(1) If $d \in \{1, 2, 4, 5, 7, 8\}$ and X is birationally equivalent to a Brauer–Severi surface P, then $P \cong \mathbb{P}_k^2$ and X has a k-rational point.
(2) If $d \in \{1, 3, 5, 7, 9\}$ and X is birationally equivalent to a product $P' \times P''$ of two Brauer–Severi curves, then $P' \cong P'' \cong \mathbb{P}_k^1$ and X has a k-rational point.

PROOF Let X and d be as in (1). Then, every element of $\mathrm{Am}(X)$ is of order dividing d by Lemma 8.3, but also of order dividing 3 by Theorems 2.18 and 4.6. By our assumptions on d, we find $\mathrm{Am}(P) = 0$, and thus, $P \cong \mathbb{P}_k^2$. Since the latter has a k-rational point, so has X by Lemma 4.3. This shows (1). The proof of (2) is similar and we leave it to the reader. □

Combining this with a result of Coray [12], we obtain the following.

Theorem 8.5 *Let X be a del Pezzo surface of degree $d \in \{5, 7, 8\}$ over a perfect field k. Then, the following are equivalent*

(1) There exists a dominant and rational map $P \dashrightarrow X$ from a Brauer–Severi surface P over k,
(2) X is birationally equivalent to a Brauer–Severi surface,
(3) X is rational, and
(4) X has a k-rational point.

PROOF The implications (3) $\Rightarrow$ (2) $\Rightarrow$ (1) are trivial.

Let $\varphi : P \dashrightarrow X$ be as in (1). By Lemma 8.3, there exists a zero-cycle of degree 9 on P, and another one of degree d on X. Using φ, we obtain a zero-cycle of degree dividing 9 on X. By assumption, d is coprime to 9, and thus, there exists a zero-cycle of degree 1 on X. By [12], this implies that X has a k-rational point and establishes (1) $\Rightarrow$ (4).

The implication (4) $\Rightarrow$ (3) is a result of Manin [35, Theorem 29.4]. □

Now, if a del Pezzo surface X over a field k is birationally equivalent to a Brauer–Severi surface, then $H^1(H, \mathrm{Pic}_{X/k}(k^{\mathrm{sep}})) = 0$ for all closed subgroups $H \subseteq G_k$ by Theorem 4.6. Moreover, this vanishing holds for all del Pezzo surfaces of degree ≥ 5, see Remark 8.2. However, for del Pezzo surfaces of degree ≤ 4, these cohomology groups may be non-zero, see [35, Sect. 31], [32, 45, 46]. In particular, del Pezzo surfaces of degree ≤ 4 are in general *not* birationally equivalent to Brauer–Severi surfaces.

For further information concerning geometrically rational surfaces, unirationality, central simple algebras, and connections with cohomological dimension, we refer the interested reader to [10].

8.2 Del Pezzo Surfaces of Degree 5

In order to decide whether a birational map $f_{\overline{k}} : X_{\overline{k}} \to \mathbb{P}^2_{\overline{k}}$ as in Sect. 6 descends to k for a degree 5 del Pezzo surface X over k, we introduce the following notion.

Definition 8.6 Let X be a del Pezzo surface over a field k. A *conic* on X is a geometrically integral curve C on X with $C^2 = 0$ and $-K_X \cdot C = 2$. An element $\mathcal{L} \in \mathrm{Pic}_{(X/k)(\mathrm{fppf})}(k)$ is called a *conic class* if $\mathcal{L} \otimes_k \overline{k} \cong \mathcal{O}_{X_{\overline{k}}}(\overline{C})$ for some conic $\overline{C}$ on $X_{\overline{k}}$.

The following is an analogue of Theorem 6.1 for degree 5 del Pezzo surfaces.

Theorem 8.7 *Let X be a del Pezzo surface of degree 5 over a field k. Then, the following are equivalent:*

(1) There exists a birational morphism $f : X \to P$ to a Brauer–Severi surface, such that $f_{\overline{k}}$ is the blow-up of 4 points in general position.
(2) There exists a birational morphism $f : X \to \mathbb{P}^2_k$, such that $f_{\overline{k}}$ is the blow-up of 4 points in general position.
(3) There exists a class $F \in \mathrm{Pic}_{(X/k)(\mathrm{fppf})}(k)$ such that

$$F_{\overline{k}} \cong \mathcal{O}_{\overline{X}}(E_1 + E_2 + E_3 + E_4),$$

where the E_i are disjoint (-1)-curves on $\overline{X}$.
(4) There exists a conic class in $\mathrm{Pic}_{(X/k)(\mathrm{fppf})}(k)$.

If these equivalent conditions hold, then X has a k-rational point.

PROOF If f is as in (1), then X has a k-rational point by Corollary 8.4. Thus, $P \cong \mathbb{P}^2_k$, and we obtain (1) $\Rightarrow$ (2).

If f is as in (2), then the exceptional divisor of f is a class F as stated in (3), and we obtain (2) $\Rightarrow$ (3).

If f is as in (3), then, using Theorem 3.4, there exists a birational morphism $|\frac{1}{3}(-K_X - F)| : X \to P$ to a Brauer–Severi surface P as in (1), which establishes (3) $\Rightarrow$ (1).

If f is as in (2), let $Z \subset \mathbb{P}^2_k$ be the degree 4 cycle blown up by f. Then $f^*(\mathcal{O}_{\mathbb{P}^2_k}(2)(-Z))$, i.e., the pullback of the pencil of conics through Z, is a conic class on X and establishes (2) $\Rightarrow$ (4).

Finally, if C is a conic class on X, then, using Theorem 3.4, there exists a birational morphism $| - K_X + C| : X \to P$ to a Brauer–Severi surface P as in (1), which establishes (4) $\Rightarrow$ (1). □

Remark 8.8 By theorems of Enriques, Swinnerton-Dyer, Skorobogatov, Shepherd-Barron, Kollár, and Hassett (see [47, Theorem 2.5] for precise references and overview), a degree 5 del Pezzo X over a field k always has a k-rational point. Thus, X is rational by [35, Theorem 29.4], and we have

$$\mathrm{Am}(X) = 0, \quad \text{as well as} \quad H^1(H, \mathrm{Pic}_{X/k}(k^{\mathrm{sep}})) = 0$$

for every closed subgroup $H \subseteq G_k$ by Corollary 2.12, Theorem 4.6, and Lemma 4.5.

8.3 Del Pezzo Surfaces of Degree 4

A classical theorem of Manin [35, Theorem 29.4] states that a del Pezzo surface of degree 4 over a sufficiently large field k is unirational if and only if it contains a k-rational point. Here, we have the following analogue in our setting.

Proposition 8.9 *Let X be a del Pezzo surface of degree 4 over a perfect field k. Then, the following are equivalent*

(1) There exists a dominant rational map $P \dashrightarrow X$ from a Brauer–Severi surface P over k.
(2) X is unirational,
(3) X has a k-rational point,

PROOF The implications (2) $\Rightarrow$ (1) is trivial and (2) $\Rightarrow$ (3) is Lemma 4.3.

The implication (3) $\Rightarrow$ (2) is shown in [35, Theorem 29.4] and [35, Theorem 30.1] if k has at least 23 elements and in [31, Theorem 2.1] and [40, Proposition 5.19] in the remaining cases.

To show (1) $\Rightarrow$ (3), we argue as in the proof of the implication (1) $\Rightarrow$ (4) of Theorem 8.5 by first exhibiting a degree 1 zero-cycle on X, and then, using [12] to deduce the existence of a k-rational point on X. We leave the details to the reader. □

If a field k is finite or perfect of characteristic 2, then a degree 4 del Pezzo surface over k always has a k-rational point, see [35, Theorem 27.1] and [16]. In this case, we also have $\mathrm{Am}(X) = 0$. From Lemma 8.3, we infer that $\mathrm{Am}(X)$ is at most 4-torsion for degree 4 del Pezzo surfaces. For the possibilities of $H^1(G_k, \mathrm{Pic}_{X/k}(k^{\mathrm{sep}}))$, see [45].

The following is an analog of Theorem 6.1 for degree 4 del Pezzo surfaces.

Theorem 8.10 *Let X be a del Pezzo surface of degree 4 over a field k. Then, the following are equivalent:*

(1) There exists a birational morphism $f : X \to P$ to a Brauer–Severi surface, such that $f_{\overline{k}}$ is the blow-up of 5 points in general position.
(2) There exists a birational morphism $f : X \to \mathbb{P}^2_k$, such that $f_{\overline{k}}$ is the blow-up of 5 points in general position.
(3) There exists a curve $\mathbb{P}^1_k \cong E \subset X$ with $E^2 = -1$.
(4) There exists a class $E \in \mathrm{Pic}_{(X/k)(\mathrm{fppf})}(k)$ with $E^2 = K_X \cdot E = -1$.

If these equivalent conditions hold, then X has a k-rational point.

PROOF The implication (2) ⇒ (1) is trivial. If f is as in (1), then X has a k-rational point by Corollary 8.4. Thus, $P \cong \mathbb{P}^2_k$, and we obtain (1) ⇒ (2).

If f is as in (2), let $Z \subset \mathbb{P}^2_k$ be the degree 5 cycle blown up by f. Then $f^*(\mathcal{O}_{\mathbb{P}^2_k}(2)(-Z))$, i.e., the pullback of the class of the unique conic through Z, is a class E as stated in (4) on X and establishes (2) ⇒ (4).

If E is a class as in (4), then, using Theorem 3.4, there exists a birational morphism $|-K_X - E| : X \to P$ to a Brauer–Severi surface P as in (1), which establishes (4) ⇒ (1).

The implication (3) ⇒ (4) is trivial, and if E is a class as in (4), then there exists a unique section of the associated invertible sheaf on k^{sep}. This is necessarily G_k-invariant, thus, descends to a curve on X, and establishes (4) ⇒ (3). □

Remark 8.11 In [44], Skorobogatov called del Pezzo surfaces of degree 4 that satisfy condition (3) above *quasi-split*.

Before proceeding, let us recall a couple of classical results on the geometry of degree 4 del Pezzo surfaces, and refer the interested reader to [44] and [15, Chap. 8.6] for details. The anti-canonical linear system embeds X as a complete intersection of two quadrics in $\mathbb{P}^4_k$, i.e., X is given by $Q_0 = Q_1 = 0$, where Q_0 and Q_1 are two quadratic forms in five variables over k. The *degeneracy locus* of this pencil of quadrics

$$\mathrm{Deg}_X \;:=\; \{\det(t_0 Q_0 + t_1 Q_1) \;=\; 0\} \;\subset\; \mathbb{P}^1_k \;=\; \mathrm{Proj}\, k[t_0, t_1]$$

is a zero-dimensional subscheme, which is étale and of length 5 over k. Over $\overline{k}$, its points correspond to the singular quadrics containing X, all of which are cones over smooth quadric surfaces. Let $\nu_2 : \mathbb{P}^1_k \to \mathbb{P}^2_k$ be the 2-uple Veronese embedding and set

$$Z := \nu_2(\mathrm{Deg}_X) \;\subset\; C := \nu_2(\mathbb{P}^1_k) \;\subset\; \mathbb{P}^2_k.$$

If X contains a k-rational (-1)-curve, i.e., if X is quasi-split, then X is the blow-up of $\mathbb{P}^2_k$ in Z, see Theorem 8.10 and [44, Theorem 2.3].

Proposition 8.12 *Let X be a del Pezzo surface of degree 4 over a field k of characteristic $\neq 2$ with at least 5 elements. Then, the following are equivalent:*

(1) The degeneracy scheme Deg_X has a k-rational point.
(2) There exists a finite morphism $\psi : X \to S$ of degree 2, where S is a del Pezzo surface of degree 8 of product type.

Moreover, if ψ is as in (2), then S is isomorphic to a quadric in $\mathbb{P}^3_k$.

PROOF To show (1) $\Rightarrow$ (2), assume that Deg_X has a k-rational point. Thus, there exists degenerate quadric Q with $X \subset Q \subset \mathbb{P}^4_k$. As explained in the proof of [15, Theorem 8.6.8], Q is a cone over a smooth quadric surface, and the projection away from its vertex $\mathbb{P}^4_k \dashrightarrow \mathbb{P}^3_k$ induces a morphism $X \to \mathbb{P}^3_k$ that is finite of degree 2 onto a smooth quadric surface S. In particular, S is a del Pezzo surface of degree 8 of product type.

To show (2) $\Rightarrow$ (1), let $\psi : X \to S$ be as in the statement. Then, we have a short exact sequence (which even splits since $\mathrm{char}(k) \neq 2$)

$$0 \to \mathcal{O}_S \to \psi_*\mathcal{O}_X \to \mathcal{L}^{-1} \to 0,$$

where $\mathcal{L}$ is an invertible sheaf on S, which is of type $(1, 1)$ on $S_{\overline{k}} \cong \mathbb{P}^1_{\overline{k}} \times \mathbb{P}^1_{\overline{k}}$. In particular, $|\mathcal{L}|$ defines an embedding $\iota : S \to \mathbb{P}^3_k$ as a quadric, and establishes the final assertion. Now, $\iota \circ \psi$ arises from a 4-dimensional subspace V inside the linear system $(\iota \circ \psi)^*\mathcal{O}_{\mathbb{P}^3_k}(1) \cong \omega_X^{-1}$. Thus, $\iota \circ \psi$ is the composition of the anti-canonical embedding $X \to \mathbb{P}^4_k$, followed by a projection $\mathbb{P}^4_k \dashrightarrow \mathbb{P}^3_k$. As explained in the proof of [15, Theorem 8.6.8], such a projection induces a degree 2 morphism onto a quadric if and only if the point of projection is the vertex of a singular quadric in $\mathbb{P}^4_k$ containing X. In particular, this vertex and the corresponding quadric are defined over k, giving rise to a k-rational point of Deg_X. □

In order to refine Proposition 8.12, we will use conic classes as introduced in Definition 8.6.

Proposition 8.13 *Let X be a del Pezzo surface of degree 4 over a field k. Then, the following are equivalent:*

(1) There exists a conic class in $\mathrm{Pic}_{(X/k)(\mathrm{fppf})}(k)$.
(2) There exists a finite morphism $\psi : X \to P' \times P''$ of degree 2, where P' and P'' are a Brauer–Severi curves over k.

Moreover, if ψ is as in (2), then $P' \cong P''$.

PROOF Let $\mathcal{L} \in \mathrm{Pic}_{(X/k)(\mathrm{fppf})}(k)$ be a conic class. By Theorem 3.4, there exist morphisms $|\mathcal{L}| : X \to P'$ and $|\omega_X^{-1} \otimes \mathcal{L}^{-1}| : X \to P''$, where P' and P'' are Brauer–Severi curves over k. Combining them, we obtain a finite morphism $X \to P' \times P''$

of degree 2. As in the proof of (2) ⇒ (1) of Proposition 8.12 we find that $P' \times P''$ embeds into $\mathbb{P}^3$, and thus, $0 = [\mathbb{P}^3_k] = [P'] + [P''] \in \mathrm{Br}(k)$ by Proposition 5.2. This implies $[P'] = [P'']$ since these classes are 2-torsion, and thus, $P' \cong P''$ by Corollary 2.16. This establishes (1) ⇒ (2).

Conversely, let $\psi : X \to P' \times P''$ be as in (2). Then, $\psi^*(\mathcal{O}_{P'}(1) \boxtimes \mathcal{O}_{P''}(1))$ is a conic class, and (1) follows. □

8.4 Del Pezzo Surfaces of Degree 3

For these surfaces, we have the following analogue of Theorem 6.1.

Theorem 8.14 *Let X be a del Pezzo surface of degree 3 over a field k. Then, the following are equivalent:*

(1) There exists a birational morphism $f : X \to P$ to a Brauer–Severi surface, such that $f_{\overline{k}}$ is the blow-up of 6 points in general position.
(2) There exists a class $F \in \mathrm{Pic}_{(X/k)(\mathrm{fppf})}(k)$ such that

$$F_{\overline{k}} \cong \mathcal{O}_{\overline{X}}(E_1 + E_2 + E_3 + E_4 + E_5 + E_6),$$

where the E_i are disjoint (-1)-curves on $\overline{X}$.

Proof The proof is analogous to that of Theorem 8.7, and we leave the details to the reader. □

Note that if the equivalent conditions of this theorem are fulfilled, then X is not minimal. But the converse does not hold in general: If Y is a unirational, but not rational del Pezzo surface of degree 4 over k, and $y \in Y$ is a k-rational point not lying on an exceptional curve, then the blow-up $X \to Y$ in y is a non-minimal degree 3 del Pezzo surface over k with k-rational points that is not birationally equivalent to a Brauer–Severi surface over k.

By [35, Theorem 28.1], a degree 3 del Pezzo surface X is minimal if and only if $\rho(X) = 1$, i.e., $\mathrm{Pic}_{(X/k)(\mathrm{fppf})}(k) = \mathbb{Z} \cdot \omega_X$. In this case, we have $\mathrm{Am}(X) = 0$. In particular, if such a surface is birationally equivalent to a Brauer–Severi surface P, then $P \cong \mathbb{P}^2_k$ by Proposition 2.10 and Theorem 2.19. In particular, X is rational and has a k-rational point in this case.

8.5 Del Pezzo Surfaces of Degree 2

Arguing as in the proof of Theorem 8.5, it follows that if there exists a dominant and rational map $P \dashrightarrow X$ from a Brauer–Severi surface P onto a degree 2 del Pezzo surface over a perfect field k, then X has a k-rational point, and thus $\mathrm{Am}(X) = 0$.

In particular, if X is birationally equivalent to a Brauer–Severi surface, then it is rational, see also Corollary 8.4.

By work of Manin [35, Theorem 29.4], a degree 2 del Pezzo surface over a field k is unirational if it has a k-rational point not lying on an exceptional curve. Together with non-trivial refinements of [17, 42], such surfaces over finite fields are always unirational.

By Lemma 8.3, we have that $\mathrm{Am}(X)$ is at most 2-torsion for degree 2 del Pezzo surfaces. For the possibilities of $H^1(G_k, \mathrm{Pic}_{X/k}(k^{\mathrm{sep}}))$, as well as further information concerning arithmetic questions, we refer to [32].

8.6 Del Pezzo Surfaces of Degree 1

If X is a del Pezzo surface of degree 1, then it has a k-rational point, namely the unique base point of $|-K_X|$. Thus, we have $\mathrm{Am}(X) = 0$, and there are no morphisms or rational maps to non-trivial Brauer–Severi varieties.

Acknowledgements It is a pleasure for me to thank Jörg Jahnel, Andrew Kresch, Raphael Riedl, Ronald van Luijk, and Anthony Várilly-Alvarado for comments and discussions. I especially thank Jean-Louis Colliot-Thélène and Alexei Skorobogatov for providing me with references, discussions, and pointing out mistakes, as well as correcting some of my too naive ideas. Last, but not least, I thank the referee for careful proof-reading and the many useful suggestions.

Birational Geometry via Moduli Spaces

Ivan Cheltsov, Ludmil Katzarkov, and Victor Przyjalkowski

Mathematics Subject Classification codes (2000): 14M25, 14H10, 14Q15, 14D07

1 Introduction

1.1 Moduli Approach to Birational Geometry

In recent years, we have witnessed many significant developments in the Minimal Model Program (MMP) (see, e.g., [10]), based on major advances in the study of singularities of pairs. An alternative approach to MMP, relying on the correspondence between Mori fibrations (MF) and semiorthogonal decompositions (SOD), was proposed by Kawamata [67]; it does not involve the study of discrepancies or the effective cone.

In the meantime, a new epoch, the epoch of wall-crossing, has emerged. At present, after papers of Seiberg–Witten [91], Gaiotto–Moore–Neitzke [40], and Cecotti–Vafa [20] and seminal works by Donaldson–Thomas [33], Joyce–Song [62],

Maulik–Nekrasov–Okounkov–Pandharipande [79, 80], Douglas [35], Bridgeland [13], and Kontsevich–Soibelman [72, 73], the situation with the wall-crossing phenomenon is quite similar to the situation with the theory of Higgs Bundles after Higgs and Hitchin: it was clear that a general "Hodge type" theory existed and that it needed to be developed. This led to major mathematical applications, for example, in uniformization and in the Langlands program, to mention a few. Similarly, in the framework of wall-crossing, it is also apparent that a "Hodge type" theory needs to be developed in order to reap mathematical benefits, e.g., solve some long-standing problems in algebraic geometry.

Already, several attempts have been made to connect homological mirror symmetry (HMS) to birational geometry. For instance, the paper [1] was motivated by the idea that a proof of HMS is likely to involve a detailed study of birational transformations (including, noncommutative) on the A and B sides of HMS. Later, new ideas were introduced in [4, 27, 28, 45, 68, 70]. These can be summarized as follows:

1. The moduli spaces of stability conditions of Fukaya–Seidel categories can be included in a one-parametric family with the moduli space of Landau–Ginzburg (LG) models as a central fiber.
2. The moduli space of LG models determines the birational geometry; this was proved in the toric case in [27].

In this paper, we simultaneously consider all Mori fiber spaces, all Sarkisov links and all relations between Sarkisov links, and explore these in terms of the geometry of moduli space of LG models and the moving schemes involved.

We introduce the following main ideas:

1. All Fano varieties are connected, via their degenerations, by simple basic links—projections of a special kind. We show this for Fano threefolds of Picard rank 1 (see Table 2). This agrees with their toric Landau–Ginzburg models (see Theorem 3.12).
2. All Fano manifolds can be considered together, i.e., there exists a big moduli space of LG models, which includes mirrors of all Fano's. We demonstrate this partially for two- and three-dimensional Fano's.
3. We introduce an analog of the canonical divisor measure for a minimal model. For us, this is the local geometry of singularities and a fiber at infinity of the LG model. The last one affects the geometry of moduli spaces of LG models, the stability conditions. We propose local models for these moduli spaces (stacks). The correspondence between the usual and the categorical approach to birational geometry is displayed in Table 1.
4. Following [28] and the pioneering work [12], we develop the notion of phantom category, emphasizing its connection with the notion of a moving scheme, defined in this paper. Moving schemes determine the geometry of the moduli space of LG models and thus the geometry of the initial manifold. We conjecture:

Table 1 Extended Kawamata program

Classical	Derived
Mori fibrations	SOD or circuits
$(K_X + \Delta)$ log differentials	Moving schemes of the fiber at ∞ in Landau–Ginzburg model described by differentials
Sarkisov links	Two-dimensional faces
Relations between Sarkisov links	Three-dimensional faces

A. For classical surfaces of general type (Campedelli, Godeaux, Burniat, Dolgachev surfaces, quotients of products of higher-genus curves and fake $\mathbb{P}^2$s) there should exist *quasi-phantoms* in their SOD, i.e., nontrivial categories with trivial Hochschild homology. These surfaces are clearly not rational as they have nontrivial fundamental groups, but also since, conjecturally, they have quasi-phantom subcategories in their SOD. On the Landau–Ginzburg side, these quasi-phantoms are described by the moving scheme. The deformation of the Landau–Ginzburg models is determined by the moving scheme so the quasi-phantoms factor in the geometry of the Landau–Ginzburg models. On the mirror side, this translates to the fact that the Ext groups between the quasi-phantom and the rest of the SOD determine the moduli space.

B. For surfaces of general type with trivial fundamental groups (e.g., the Barlow surface, see [28]), we conjecture the existence of a nontrivial *phantom category*, a category with a trivial K^0 group. The deformation of the Landau–Ginzburg models is determined by the moving scheme, so the phantom factors in the geometry of the Landau–Ginzburg models. Similarly, on the mirror side this translates to the fact that the Ext groups between the phantom and the rest of the SOD determine the moduli space.

C. We relate the existence of such phantom categories with nonrationality questions. For surfaces, it is clear that phantoms lead to nonrationality. For threefolds, we exhibit examples (of Sarkisov type) of nonrational threefolds where phantoms conjecturally imply nonrationality. We introduce "higher" categorical invariants detecting nonrationality: gaps of spectra. Conjecturally, these are not present in the Sarkisov examples. These ideas are a natural continuation of [50].

5. We introduce conjectural invariants associated to our moduli spaces—gaps and local differentials. We suggest that these numbers (changed drastically via "wall-crossing") produce strong birational invariants. We relate these invariants to the "Hassett–Kuznetsov–Tschinkel" program (see [46,77])—a program for studying rationality of the four-dimensional cubic and its "relatives."

This paper is organized as follows. In Sects. 2 and 3 we relate degenerations of Fano manifolds via projections. Using mirror symmetry in Sect. 3 we transfer

/4 ?! ! # 8!3 7

these connections to the side of Landau–Ginzburg model. Based on that, in Sect. 4 we suggest a generalization of Kawamata's categorical approach to birational geometry, enhancing it via the geometry of moduli spaces of Landau–Ginzburg models. We give several applications, most notably a conjectural application to the Hassett–Kuznetsov–Tschinkel program. Our approach is based on two categorical nonrationality invariants—phantoms and gaps. Full details will appear in a future paper.

Notations. Smooth del Pezzo threefolds (smooth Fano threefolds of index 2) are denoted by V_n, where n is its degree with respect to a Picard group generator, except for the quadric denoted by Q. Fano threefolds of Picard rank 1, index 1, and degree n are denoted by X_n. The remaining Fano threefolds are denoted by $X_{k.m}$, where k is a Picard rank of a variety and m is its number according to [57]. The Laurent polynomials from the k-th line of Table 2 are denoted by f_k. A toric variety whose fan polytope is a Newton polytope of f_k is denoted by F_k or just a variety number **k**. The Landau–Ginzburg model for a variety X is denoted by $LG(X)$.

2 "Classical" Birational Geometry

In this section we recall some facts from classical birational geometry of three-dimensional Fano varieties. Our presentation of this geometry is adopted to HMS.

2.1 The Importance of Being Gorenstein

Among singular Fano varieties, those with canonical Gorenstein singularities are of special importance. They arise in many different geometrical problems: degeneration of smooth Fano varieties with a special regard to mirror symmetry (see [6,7]), classification of reflexive polytopes (see [74,75]), midpoints of Sarkisov links and bad Sarkisov links (see [22,24]), compactification of certain moduli spaces (see [81]), etc. Historically, Fano varieties with canonical Gorenstein singularities are the original Fano varieties. Indeed, the name *Fano varieties* originated in the works of Iskovskikh (see [54, 55]) that filled the gaps in old results by Fano who studied in [36, 37] anticanonically embedded Fano threefolds with canonical Gorenstein singularities without naming them so (cf. [15]).

In dimension two, canonical singularities are always Gorenstein, so being Gorenstein is a vacuous condition. Surprisingly, the classification of del Pezzo surfaces with canonical singularities is simpler than the classification of smooth del Pezzo surfaces (see [26, 84]). Fano threefolds with canonical Gorenstein singularities are not yet classified, but first steps in this directions are already have been made by Mukai, Jahnke, Radloff, Cheltsov, Shramov, Przyjalkowski, Prokhorov, and Karzhemanov (see [17, 60, 65, 66, 81, 85]).

Curves of Low Degrees on Fano Varieties

1 Introduction

We work over the field of complex numbers. If $X \subset \mathbf{P}^N$ is a smooth projective variety, we let $\mathscr{C}_d^g(X)$ be the (quasi-projective) subscheme of the Hilbert scheme of X corresponding to smooth, irreducible, genus-g, degree-d curves on X.

These schemes, and their compactifications $\overline{\mathscr{C}}_d^g(X)$, particularly for low d and g, have proved very useful in the study of the geometry and the period maps of some Fano varieties of low degrees.

In this informal survey article, we explain, mainly without proofs, what is known (or conjectured) in the following cases: cubic threefolds, Fano threefolds of degree 14 and index 1, cubic fourfolds, Fano varieties of degree 10, coindex 3, and dimensions 3, 4, or 5.

In the case of a smooth cubic threefold $X \subset \mathbf{P}^4$ (Sect. 2), Hilbert schemes of curves have long been used to parametrize useful subvarieties of the intermediate Jacobian $J(X)$. For example, the (smooth projective) surface $\mathscr{C}_1^0(X)$ parametrizing lines contained in X was an essential ingredient in the proofs by Clemens and Griffiths of the non-rationality of X and of the Torelli theorem (that $J(X)$ determines X). The Abel–Jacobi maps $\mathrm{aj} : \overline{\mathscr{C}}_d^g(X) \to J(X)$ have been since proved in some cases to be mrc fibrations (see Sect. 2 for definitions and results).

Curves on Fano threefolds can also be used to construct interesting birational correspondences. This is illustrated in Sect. 2.9, where it is explained that Fano threefolds of degree 14 and index 1 are birational to cubic threefolds. The situation is very rich and gives rise to a beautiful description of the period maps for these Fano threefolds.

In Sect. 3, we move on to smooth cubic fourfolds $Y \subset \mathbf{P}^5$, for which there are no intermediate Jacobians. Nevertheless, the mrc fibrations of $\overline{\mathscr{C}}^g_d(Y)$ should be substitutes for the Abel–Jacobi maps and should provide interesting information. In another direction, ideas of Mukai show how to construct *symplectic forms* on some moduli spaces of sheaves (Sect. 3.1). This can be used to prove that the space of lines $\mathscr{C}^0_1(Y)$ is a symplectic fourfold (Beauville and Donagi), whose Hodge structure is closely related to that of Y. This was the basis of Voisin's proof of the injectivity of the period map for smooth cubic fourfolds. This period map is now completely described by work of Looijenga and Laza and identifies the moduli space of smooth cubic fourfolds with an explicit open subset of the Baily–Borel compactification of the period domain (Sect. 3.2). Analogous results are available for the moduli space of smooth cubic threefolds (Sect. 3.3).

Mukai's construction was also shown to apply to Fano fourfolds X^4_{10} of degree 10 and index 2 (Example 3.5). In this case, the scheme $\overline{\mathscr{C}}^0_2(X^4_{10})$ leads to the construction of a symplectic fourfold called a *double EPW sextic* (Iliev and Manivel, O'Grady).

In Sect. 4, we study in some details the period maps of these Fano varieties of degree 10, in dimensions 3, 4, and 5. There is beautiful geometry at work here, with intriguing interplay with that of EPW sextics (work in progress with Iliev and Manivel).

2 Cubic Threefolds

The *maximal rationally connected fibration* (mrc fibration for short) of a smooth proper (complex) variety Y is a rational dominant map $\rho : Y \dashrightarrow R(Y)$ such that for $z \in R(Y)$ very general, the fiber $\rho^{-1}(z)$ is proper and rationally connected (two general points can be joined by a rational curve), and any rational curve in Y that meets $\rho^{-1}(z)$ is contained in $\rho^{-1}(z)$. The mrc fibration exists and is unique up to birational equivalence. The variety $R(Y)$ is called the reduction of Y.

Let $X \subset \mathbf{P}^4$ be a general (although some results are known for *any smooth* X) cubic hypersurface. The intermediate Jacobian

$$J(X) := H^{2,1}(X)^\vee / H_3(X, \mathbf{Z})$$

is a 5-dimensional principally polarized abelian variety. We let $\mathscr{X}_3$ be the (irreducible, 10-dimensional) moduli space for smooth cubic threefolds, and we let $\mathscr{A}_n$ be the moduli space for principally polarized abelian varieties of dimension n. Taking X to $J(X)$ defines the *period map* $\mathscr{X}_3 \to \mathscr{A}_5$. We have:

- For $g = 0$ or $d \leq 5$, $\mathscr{C}^g_d(X)$ is integral of dimension $2d$ ([7], Theorem 1.1);
- For $d \leq 5$, the *Abel–Jacobi map* $\mathrm{aj} : \overline{\mathscr{C}}^g_d(X) \to J(X)$ induces the mrc fibration ([6], Theorem 1.1);
- For $d \geq 4$, $\mathrm{aj} : \overline{\mathscr{C}}^0_d(X) \to J(X)$ is dominant with irreducible general fibers.

It is natural to ask whether the Abel–Jacobi map $\mathrm{aj} : \overline{\mathscr{C}}^0_d(X) \to J(X)$ is the mrc fibration for all $d \geq 4$ (i.e., are general fibers rationally connected?).

2.1 Lines

- $\mathscr{C}^0_1(X)$ (which parametrizes lines on X) is a smooth projective irreducible surface of general type;
- The image of $\mathrm{aj} : \mathscr{C}^0_1(X) \to J(X)$ is a surface S with minimal class $[\Theta]^3/3!$ and $S - S$ is a theta divisor Θ;
- aj induces an isomorphism between the Albanese variety of $\mathscr{C}^0_1(X)$ and $J(X)$ ([2]).

The second item yields a proof of Torelli: *the period map* $\mathscr{X}_3 \to \mathscr{A}_5$ *is injective.*

2.2 Conics

- $\overline{\mathscr{C}}^0_2(X)$ is a smooth projective irreducible fourfold;
- $\mathrm{aj} : \overline{\mathscr{C}}^0_2(X) \to J(X)$ is a $\mathbf{P}^2$-bundle over the surface S of Sect. 2.1 (a conic is uniquely determined by the plane that it spans and the residual line in X). The mrc fibration is therefore $\overline{\mathscr{C}}^0_2(X) \to S$.

2.3 Plane Cubics

- $\overline{\mathscr{C}}^1_3(X)$ is isomorphic to the Grassmannian $G(3,5)$;
- The Abel–Jacobi map is therefore constant.

2.4 Twisted Cubics

- $\mathrm{aj} : \mathscr{C}^0_3(X) \to J(X)$ is birational to a $\mathbf{P}^2$-bundle over a theta divisor Θ ([6], Sect. 4). The mrc fibration is therefore $\overline{\mathscr{C}}^0_3(X) \to \Theta$.

Preface

1. In 1927–1928 the papers of Wilhelm Blaschke, who was a well-known geometer by that time, and his student T. Thomsen appeared (see [Bl 28] and [T 27]). The papers were devoted to a new topic in differential geometry – web geometry. Many of Blaschke's previous papers were connected with applications of ideas of Felix Klein to differential geometry. These ideas were formulated in Klein's famous "Erlangen program" (1872). According to this program, every geometry studies properties of geometric figures that are invariant under transformations composing a certain group. From this point of view, the foundations of affine differential geometry and conformal differential geometry were presented in Blaschke's books, published in the 1920's.

Blaschke extended the same group-theoretic approach to web geometry. He took the group (more precisely, pseudogroup) of all differentiable transformations of a manifold, where a web is given, as a fundamental group, and studied local web invariants relative to transformations of this group.

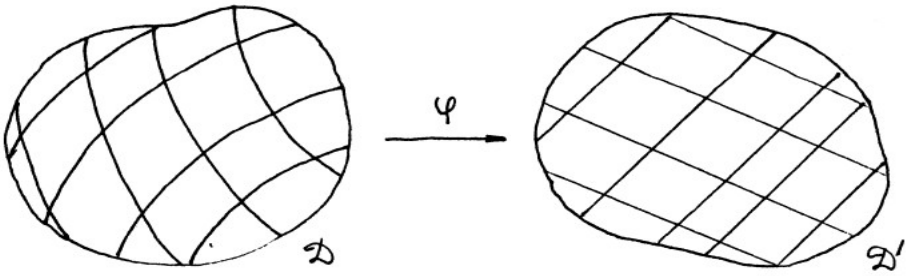

Figure 0.1

Let us explain this approach to web geometry in more detail. Consider a regular family of smooth curves in a two-dimensional domain D. By means of an appropriate differentiable transformation, the domain D can be transferred into a domain D' of an affine plane A^2 in such a way that the family of lines given in D will be transferred into a family of parallel lines of D'. This shows that a family of smooth curves in D does not have local invariants. Two regular families of smooth curves, that are in general position in D, also do not have local invariants since one can always find a diffeomorphism that transfers them into two families of parallel lines of a domain D' of an affine plane A^2 (see Figure 0.1). Thus, the structures, defined in D by one or two families of curves, are locally trivial.

Consider now three regular families of smooth curves in D, that are in general position in D, i.e. form a three-web in the domain D. Such a structure is no longer locally trivial. In fact, in a neighborhood of each point p of the domain D, where the web is given, one can construct a family of hexagonal figures as shown in Figure 0.2.

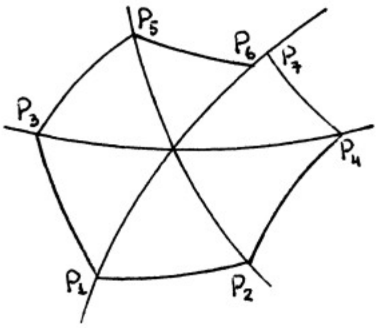

Figure 0.2

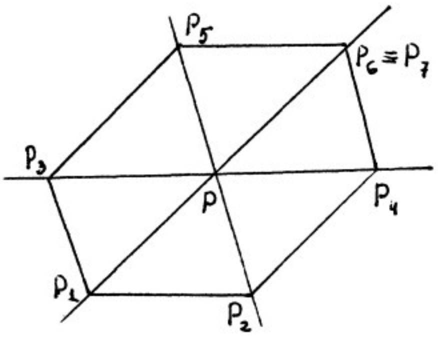

Figure 0.3

In this figure the lines p_1p_6, p_3p_5, p_2p_4 belong to the first family, the lines p_2p_5, p_1p_3, p_4p_7 belong to the second family, and the lines p_3p_4, p_1p_2, p_5p_6 belong to the third family. In the general case, the points p_6 and p_7 of these figures do not coincide, i.e. hexagonal figures are not closed. However, there exist three-webs, on which all hexagonal figures are closed, i.e. on these webs the points p_6 and p_7 coincide. Such three-webs are called hexagonal. For example, the web, formed by three families of parallel lines in an affine plane A_2, is hexagonal (see Figure 0.3). It is remarkable that the converse theorem also holds: any hexagonal three-web in a plane admits a differentiable mapping on a three-web, formed by three families of parallel lines, i.e. such a web is parallelizable. This theorem was first proved by Thomsen in the above mentioned paper [T 27] (see also the book [Bl 55]).

Since the fundamental group in web geometry is the group of arbitrary differentiable mappings, Blaschke refers the theory of webs as one of "topological questions of differential geometry" (Topologische Fragen der Differentialgeometrie). Numerous papers of Blaschke, his students and co-workers as well as the well-known monograph *Web Geometry* (*Geometrie der Gewebe*) [BB 38], written jointly by Blaschke and Bol and published in 1938, were devoted to this subject.

Blaschke noticed the connections of the web theory with many branches of geometry, in particular, with projective geometry. In a projective plane P^2 it is natural to consider a three-web formed by three one-parameter families of curves, each enveloping a curve X_α, $\alpha = 1, 2, 3$. In this case, one straight line from each family passes through a point p of a domain $D \subset P^2$ (Figure 0.4). By a correlative transformation of the plane P^2, these families of straight lines will be transferred into three curves X^*_α in a dual plane P^{2*}, and to each point p there corresponds a straight line p^* (see Figure 0.5). To straight lines of the original rectilinear three-web there correspond pencils in the plane P^{2*} with centers on the curves X^*_α. For this configuration the following remarkable theorem X_α in a plane P^2 is hexagonal if and only if the triple of curves X^*_α in the plane P^{2*}, which is dual to this web, belongs to a cubic curve. This theorem is called the Graf–Sauer theorem and follows from the Chasles' theorem on plane cubic curves. Its proof can be found in the book [Bl 55].

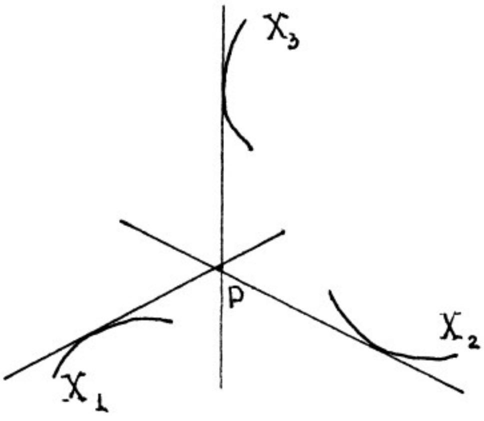

Figure 0.4

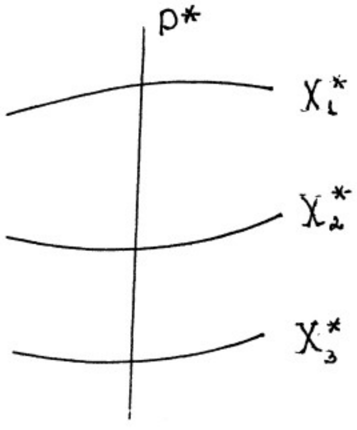

Figure 0.5

At the very beginning of the development of web theory its connection with algebra was discovered. In 1928 and 1932 the papers of K. Reidemeister [R 28] and H. Kneser [Kn 32] were published, in which it was established that a structure that has many of the properties of a three-web, can be constructed from an arbitrary group G. Namely, consider a cartesian square $X = G \times G$, whose elements are pairs (x, y) of elements of G. Call these pairs elements of the considered "three-web". Consider subsets $(x, b), (a, y), \{(x, y) | x \cdot y = c\}$ of the set X, where a, b, c are constants and x, y are variable elements of the group G, and call them lines of this "three-web". In this case, through each point of the web, there pass three lines from different families, and two lines from any two different families intersect at a point. The last two properties of this three-web allow us to consider it as an incidental structure consisting of points and lines. Because of this, the theory of such abstract webs is developed in the same way as the abstract theory of projective planes [Pi 75]. The only difference is that instead of the Pappus and Desargues configurations, which are considered in projective planes, in web theory the Reidemeister and Thomsen figures arise. We will consider these configurations in detail in Chapter 2.

Later on, Bol in his paper [B 37] observed that for construction of the abstract three-web of this type it is possible to use a groupoid of more general kind than a group. At present this kind of groupoid is called a quasigroup. Bol introduced more general closure figures on an abstract three-web, which are called Bol figures. He found that these figures are connected with certain weakened associativity conditions in a quasigroup generating a three-web.

However, it turned out that all these closure conditions cannot be geometrically realized by means of two-dimensional geometric webs, which were considered in the papers of Blaschke and Thomsen: on such webs the hexagonality condition – the weakest among the classical closure conditions – implies the web parallelizability and consequently the realization of all other closure conditions on the web.

Nevertheless all closure conditions indicated above can be realized on multidimensional geometric webs. This was a stimulus for their study. The first works in theory of multidimensional webs were the Bol paper [B 35], where a three-web on a four-dimensional manifold was considered, and the Chern paper [C 36a], where the theory of invariants of a three-web of dimension $2r$ was constructed. These two papers were published in Germany in the 1930's, and after them, for a long time, there were no publications devoted to theory of multidimensional three-webs.

Only at the end of 1960's, was the study of multidimensional three-webs continued. In 1969 the first author of this book published the paper [A 69b], and this paper was followed by an extensive series of his papers as well as his students' papers. At approximately the same time M.A. Akivis' geometry seminar at Moscow Insitute of Steel and Alloys began. Until this day, all of the most important problems of web theory are presented and discussed in this seminar.

Due to the effort of the second author, since 1981 Kalinin State University has regularly published collections of papers under the title *Webs and Quasigroups*. As a result, extensive material in the theory of multidimensional three-webs has been accumulated. The main problems of this theory as well as its connections to related problems of geometry and algebra are presented in the current monograph.

However, because of the size restriction, we cannot include everything we wanted to discuss in this book. Some of the results are given in the book without proofs. Other results are listed only in bibliographical notes and in the Bibliography.

2. We will make a few general remarks for readers of this book. First of all, note that the book is intended for graduate students whose field is differential geometry, and for mathematicians and teachers conducting research in this subject. This book can also be used for a few special courses for graduate students in Mathematics.

In our presentation of material we use the tensorial methods in combination with the methods of exterior differential forms and moving frames of Élie Cartan. The reader is assumed to be familiar with these methods as well as with the basics of modern differential geometry. Many notions of differential geometry are explained briefly in the text and some are given without any explanation. As references, the books [KN 63], [St 83], [CaH 67] and [V 87] are recommended.

All functions, vector and tensor fields and differential forms are considered differentiable sufficiently many times. All variables are assumed to be real, although in many cases this does not exclude a possibility of considering complex variables. For this reason we use the notation $\mathbf{GL}(n)$ here instead of $\mathbf{GL}(n, \mathbf{R})$ or $\mathbf{GL}(n, \mathbf{C})$ as often done.

The book consists of eight chapters. Sections, formulas and figures are numbered within each chapter. Each chapter is accompanied by a set of problems and notes with remarks of historical and bibliographical nature. A sufficiently complete bibliography, a list of notations and index are given at the end of the book.

We asked E.V. Ferapontov to write an appendix devoted to applications of web geometry to some problems of Mathematical Physics. We hope that this supplement enlargens the circle of the readers of our monograph and attracts physicists to the problems considered in the book.

In conclusion, we express our sincere gratitude to V.V. Goldberg, with whom we discussed different aspects of this book in the process of our work on the book, to V.F. Kirichenko and V.V. Timoshenko, who carefully read the manuscript and made many useful suggestions, and to L.V. Goldstein and V.B. Lazareva for their invaluable assistance in preparing the manuscript for publication.

VII. Die Zerlegung von Rechtecken in inkongruente Quadrate

1. Das Problem

Im 19. und 20. Jahrhundert ist es der Forschung gelungen, die Unlösbarkeit einiger Probleme nachzuweisen, mit denen sich die Mathematiker viele Jahrhunderte hindurch beschäftigt hatten. Dazu gehört die Quadratur des Zirkels (Kap. X), das Parallelenproblem und die Dreiteilung des Winkels (Kap. XI). Auf den Gedanken, daß das vorliegende Problem vielleicht unlösbar sei, kam man erst, nachdem Generationen von Mathematikern sich vergebens um die Lösung bemüht hatten.

Manchmal kommt man gerade auf dem umgekehrten Weg zu neuen Einsichten. Als die Frage auftauchte, ob es möglich sei, ein Quadrat in lauter inkongruente Teilquadrate zu zerlegen, waren viele Mathematiker der Ansicht, daß diese Aufgabe nicht lösbar sei. So heißt es noch im Jahre 1930 bei *Kraitschik* [VII 2] (S. 272):

> „... il n'est pas possible de décomposer un carré donné en un nombre fini de carrés inégaux deux à deux. Cette proposition quoique non démontrée paraît être vraie. Elle nous a été communiquée par M. Lusin, professeur à Moscou."

Auch *R. Sprague* beschäftigte sich mit dem Problem zunächst in der Absicht, seine Unlösbarkeit zu beweisen. Er fand[1]) aber dann eine Zerlegung des Quadrats in 55 verschiedene Teilquadrate [VII 4]. Ein Jahr später wurde eine umfangreiche Arbeit von *R. L. Brooks*, *C. A. B. Smith*, *A. H. Stone* und *W. T. Tutte* veröffentlicht, die u. a. die Zerlegung in nur 26 inkongruente Teilquadrate brachte [VII 7].

In den mathematischen Zeitschriften werden Zerlegungsprobleme der hier besprochenen Art gewöhnlich als „Unterhaltungsmathematik" registriert. Es ist aber beachtenswert, daß unser Problem eine technische Bedeutung hat, die auf den ersten Blick gar nicht ersichtlich ist. In den Arbeiten [VII 7] und [VII 10] wird das mathematische Problem sofort elektrotechnisch gedeutet, und in den Beweisen wechseln mathematische und physikalische Argumentationen. Wir wollen in diesem Kapitel unser Problem zunächst rein mathematisch angreifen und erst am Schluß auf die Möglichkeit einer technischen Deutung eingehen.

---

[1]) In der Literatur wird manchmal berichtet (z. B. [VII 10]), daß die Arbeit [VII 7] die erste Zerlegung eines Quadrats in inkongruente Teilquadrate brachte. Das ist aber nicht richtig. — Nach [VII 10] ist die erste Zerlegung eines *Rechtecks* in inkongruente Teilquadrate im Jahre 1925 gefunden worden. Das Buch [VII 2] von *Kraitschik* vom Jahre 1930 enthält als Beispiel nur eine solche Zerlegung, in der Paare gleicher Quadrate und auch zwei gleiche Quadrate mit einer gemeinsamen Seite auftreten.

Beginnen wir mit einigen Verabredungen über eine zweckmäßige Bezeichnung! Abb. 30 zeigt die Zerlegung eines Rechtecks mit dem Seitenverhältnis 33 : 32 in 9, Abb. 31 die eines Quadrats in 24 inkongruente

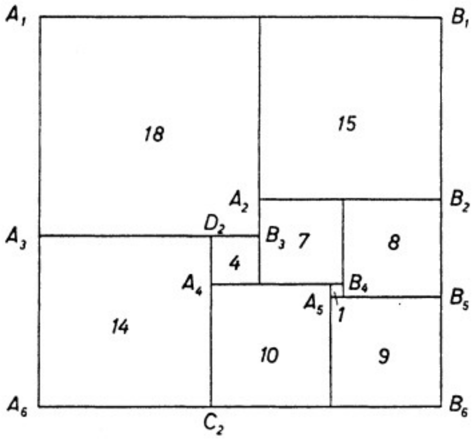

Abb. 30

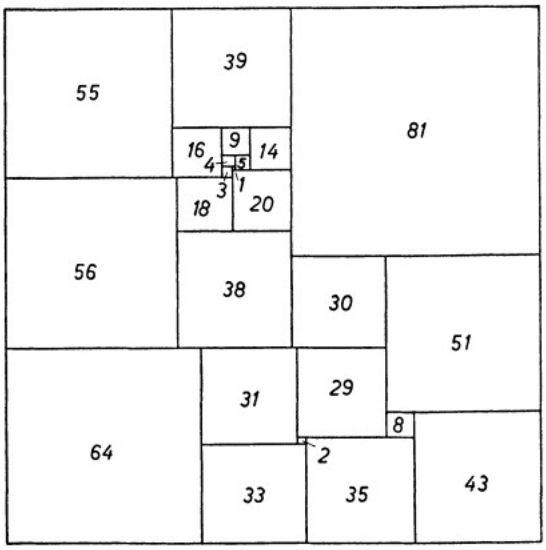

Abb. 31

Quadrate. Da man nicht gut für alle zu diskutierenden Zerlegungen Zeichnungen drucken kann, ist eine einfache und einheitliche Beschreibung einer vorgenommenen Zerlegung wünschenswert. Nach dem Vorschlag von *C. J. Bouwcamp* [VII 8] kann das so geschehen: Rechtecke werden so orientiert, daß die größere Seite waagerecht liegt und in der linken oberen Ecke sich das größte der 4 Eckquadrate befindet (Abb. 30). Wir bezeichnen dann die in einer waagerechten Geraden liegenden aus Quadratseiten zusammengesetzten Strecken der Zerlegungsfigur als *waagerechte Abschnitte*. In Abb. 34 sind das die Strecken $A_\nu B_\nu$ ($\nu = 1, 2, \ldots, 6$). Wir notieren nun die Zerlegung so, daß wir die Seitenlängen aller Teilquadrate aufschreiben. Dabei beginnen wir mit den an dem ersten waagerechten Abschnitt hängenden Quadraten. Sie werden von links nach rechts laufend registriert. Es folgen dann (immer in Klammern zusammengefaßt) die an den folgenden Abschnitten hängenden Quadrate. Unser Code für die Abb. 30 sieht dann so aus:

$$(18{,}15)\quad(7{,}8)\quad(14{,}4)\quad(10{,}1)\quad(9)\,. \tag{1}$$

Die Abb. 31 wäre so zu verschlüsseln:

$$\begin{gathered}(55{,}39{,}81)\quad(16{,}9{,}14)\quad(4{,}5)\quad(3{,}1)\quad(20)\quad(56{,}18)\\(38)\quad(64{,}31{,}29)\quad(8{,}43)\quad(2{,}35)\quad(33)\,.\end{gathered} \tag{2}$$

Der folgende Code (3) gibt dann die Verschlüsselung einer von *R. L. Brooks* [VII 9] stammenden Zerlegung des Quadrats in 38 verschiedene Teilquadrate an:

$$\begin{gathered}(2132{,}1440{,}1348)\quad(256{,}1092)\quad(692{,}584{,}164)\quad(420)\\(108{,}281{,}615)\quad(840{,}758{,}534{,}627{,}173)\quad(454)\quad(199{,}893)\\(120{,}694)\quad(244{,}310)\quad(217{,}984)\quad(82{,}900)\quad(922)\quad(527)\\(1587)\quad(287{,}240)\quad(7{,}1177)\quad(104{,}1130)\quad(1026)\,.\end{gathered} \tag{3}$$

Die Zerlegungen der Abbildungen 30 und 31 weisen einen bemerkenswerten Unterschied auf: In Abb. 31 kann man eine Teilmenge der Teilquadrate zu einem Rechteck zusammenfassen. In Abb. 30 ist das nicht möglich. Das Quadrat der Abb. 31 enthält (links oben) ein Rechteck mit den Seiten $(55 + 39) \cdot (55 + 56)$, das in 13 Teilquadrate zerlegt ist. *Eine Zerlegung in Quadrate, bei der eine Zusammenfassung einer Teilmenge der Quadrate zu einem Rechteck nicht möglich ist, heißt „einfach“.* Die erste von *R. Sprague* angegebene Zerlegung in 55 Teilquadrate war nicht einfach, auch nicht die in [VII 7] angegebene in 26 Teilquadrate. Die kleinste Zahl n, für die bisher eine einfache Zerlegung bekannt ist, ist 38. Die Verschlüsselung dieser Zerlegung ist oben unter (3) aufgeführt. Zerlegungen von Rechtecken in *lauter verschiedene* Quadrate heißen auch „perfekte“ Zerlegungen. Wir haben bisher keine anderen in Betracht gezogen. Es hat aber durchaus Sinn, nach *einfachen imperfekten* Zerlegungen zu fragen. Abb. 32 zeigt eine solche *nicht perfekte aber einfache* Zerlegung eines Quadrats in 13 Teilquadrate.

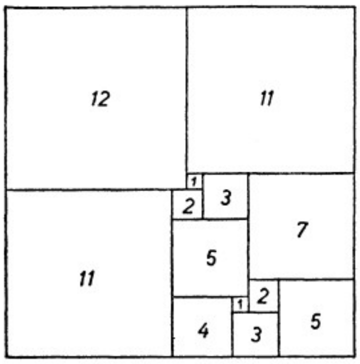

Abb. 32

Es liegen nun folgende Fragen nahe, mit denen wir uns im folgenden beschäftigen wollen:

(6) *Welches ist die kleinste Anzahl n (n', n'') von Quadraten, die für*
(6a) *eine perfekte (einfache, einfache und perfekte) Zerlegung eines Qua-*
(6b) *drats gebraucht werden?*

(6c) *Welches ist die kleinste Anzahl n_R von Teilquadraten bei einer perfekten Zerlegung von Rechtecken?*

(6d) *Für welche Rechtecke ist eine perfekte Zerlegung in Teilquadrate möglich?*

Die Anzahl n (Problem **(6)**) ist noch unbekannt, ebenso n''. Dagegen kennt man n'. Diese Zahl ist 13: Die in Abb. 32 gezeichnete einfache, aber imperfekte Zerlegung kann nicht „verbessert" werden. Auch die Fragen **(6d)** und **(6c)** sind gelöst. Die Antworten auf diese Fragen geben wir am Schluß dieses Artikels.

2. Definition eines Graphen

Eine Reihe von Ergebnissen aus unserem Problemkreis sind offensichtlich durch unermüdliches Probieren gefunden worden. Es liegt aber nahe, nach einem Verfahren zu suchen, durch das man systematisch alle möglichen Rechteckzerlegungen herausfinden kann. Als einen ersten Schritt in dieser Richtung kann man versuchen, die Zahl der zu untersuchenden Möglichkeiten einzuschränken.

Zu diesem Zweck ist eine graphische Darstellung der Zerlegung angebracht, die durch das auf S. 94 beschriebene Code-Verfahren nahegelegt wird. Dort wurden die Quadrate durch Klammern zusammengefaßt, die am gleichen waagerechten Abschnitt hingen. Ersetzt man nun die waagerechten Abschnitte AB durch einen Punkt P_ν (z. B. den Mittelpunkt eines jeden waagerechten Abschnitts), jedes Quadrat durch eine diese Punkte verbindende Strecke, so wird man auf einen Graphen geführt, wie er für die Zerlegung von Abb. 30 in Abb. 33a schematisch

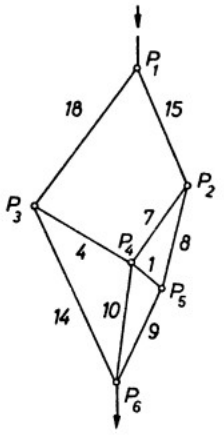

Abb. 33a

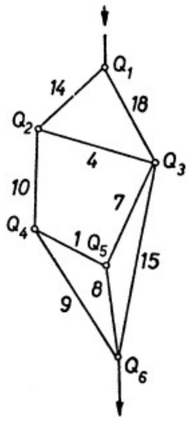

Abb. 33b

dargestellt wird. Die den Strecken angeschriebenen Zahlen sind die Seitenlängen der entsprechenden Quadrate. Die Länge der Strecken des Graphen ist für unsere Zwecke unwesentlich. Es kommt nur auf die topologische Struktur (und die notierten Längen der Quadratseiten) an. Allerdings ist es zweckmäßig, die Punkte des Graphen so zu zeichnen, daß (bei geeigneter Orientierung der Zeichnung) P_ν „höher“ liegt als $P_{\nu+1}$.

Für die spätere systematische Suche nach Zerlegungen des Rechtecks ist es nun wesentlich, daß in einem Graphen mit E Eckpunkten nur der erste und der letzte Punkt (P_1 und P_E) vom Grade 2 sein können. Ein innerer Punkt P_m $(1 < m < E)$ vom Grade 2 wäre ja nur möglich, wenn zwei gleiche Quadrate eine gemeinsame Seite haben. Das ist aber ausdrücklich ausgeschlossen. Deshalb haben wir für die Ecken und Kanten unseres Graphen die Ungleichung

$$3\,E \leqq 2\,K + 2\,. \tag{4}$$

Nach dem Eulerschen Satz für Netze (Satz 1 S. 9)

$$E - K + F = 1$$

folgt daraus für die Zahl F der Flächen („Maschen"):

$$F \geqq \frac{K+1}{3}. \tag{5}$$

Nun kann man in Analogie zu den waagerechten auch die senkrechten Abschnitte einer Rechteckzerlegung einführen. Das sind die aus den in einer Geraden liegenden senkrechten Quadratseiten zusammengesetzten Strecken. In Abb. 30 ist nur der eine senkrechte Abschnitt C_2D_2 als Beispiel eingezeichnet. Jeder senkrechte Abschnitt verbindet zwei Punkte von zwei waagerechten Abschnitten $A_\varrho B_\varrho$ und $A_\sigma B_\sigma$, und die dem senkrechten Abschnitt links und rechts anliegenden Quadrate entsprechen im Graphen solchen Streckenzügen, die P_ϱ und P_σ verbinden. Damit ist eine eindeutige Zuordnung hergestellt zwischen den *inneren* senkrechten Abschnitten und den Flächen des Graphen. Die in (4) und (5) auftretende Zahl F ist zugleich die Zahl der *inneren* senkrechten Abschnitte. Nehmen wir noch die beiden senkrechten Seiten des gegebenen Rechtecks dazu, so haben wir insgesamt $s = F + 2$ senkrechte Abschnitte.

Nun kann man natürlich dem unserer Verabredung entsprechend orientierten Rechteck noch einen zweiten Graphen zuordnen, bei dem die Punkte den senkrechten Abschnitten der Zerlegung entsprechen. Die Strecken dieses dem ersten *dualen* Graphen entsprechen wieder den Teilquadraten, die Maschen des Netzes aber hier den waagerechten Abschnitten. Abb. 33b zeigt den zu Abb. 33a dualen Graphen.

Bezeichnen wir die Ecken, Kanten und Flächen des zweiten (zum ersten dualen) Graphen mit E_1, F_1, K_1, so haben wir analog zu (4) und (5):

$$3\,E_1 \leqq 2\,K + 2\,, \tag{4'}$$

$$F_1 \geqq \frac{K+1}{3} \tag{5'}$$

Dabei ist schon berücksichtigt, daß die Zahl der Kanten in beiden Graphen gleich ist: $K = K_1$. Weiter ist die Zahl der Ecken E_1 im zweiten Graphen gleich der Zahl der senkrechten Abschnitte, also

$$E_1 = F + 2 = s\,. \tag{6}$$

Analog haben wir für E:

$$E = F_1 + 2 = w\,, \tag{7}$$

wobei w die Zahl der waagerechten Abschnitte in der gegebenen Zerlegung ist.

Aus (4), (4′), (5), (5′), (6) und (7) gewinnt man schließlich für die Maschenzahl der beiden Graphen die Abschätzung

$$\frac{K+1}{3} \leqq \begin{Bmatrix} F \\ F_1 \end{Bmatrix} \leqq \frac{2K-4}{3} \tag{8}$$

Diese Ungleichung gibt uns zusammen mit der Eulerschen Gleichung (Satz 1) die Möglichkeit, für die Zerlegung von Rechtecken in eine gegebene Zahl $K = K_1$ von Quadraten die möglichen Zahlen für die Flächen („Maschen") und Ecken des Graphen zu bestimmen. Da nur ganzzahlige Werte in Frage kommen, haben wir für $K = 5, 6, \ldots, 13, 14$ die in der folgenden Tabelle zusammengestellten Möglichkeiten zu berücksichtigen:

K	F	E	K	F	E
5	2	4	10	4 ; 5	7 ; 6
6	—	—	11	4 ; 5 ; 6	8 ; 7 ; 6
7	3	5	12	5 ; 6	8 ; 7
8	3 ; 4	6 ; 5	13	5 ; 6 ; 7	9 ; 8 ; 7
9	4	6	14	5 ; 6 ; 7 ; 8	10 ; 9 ; 8 ; 7

3. Berechnung der Zerlegungen

Wir müssen nun prüfen, welche der nach der Tabelle möglichen Graphen wirklich bei einer Rechteckzerlegung auftreten. Dazu beachten wir die Gesetze, denen die Seitenzahlen der Quadrate unterliegen. Diese Zahlen werden ja den Strecken des Graphen immer beigeschrieben (Abb. 33a und 33b). Die einem waagerechten Abschnitt „aufsitzenden" Quadrate liefern dieselbe Summe der Seitenlängen wie die einem solchen Abschnitt „angehängten". Die entsprechende Aussage gilt für die einem senkrechten Abschnitt rechts und links angelagerten Quadrate. Da die waagerechten Abschnitte den Punkten und die (inneren) senkrechten Abschnitte den Maschen des Graphen entsprechen, ergeben sich daraus Gesetze für die Seitenlängen der Quadrate.

Um diese Gesetze bequem formulieren zu können, wollen wir verabreden, daß einer Strecke $P_\varrho P_\sigma$ eines Graphen eine *negative* Seitenzahl $x_{\varrho\sigma}$ zuzuordnen ist, wenn $\varrho > \sigma$ ist, eine positive, wenn $\varrho < \sigma$. Also: Der Strecke P_3P_4 in Abb. 37a haben wir die Zahl 4 angeschrieben; für P_4P_3 wäre danach -4 die zugeordnete Seitenzahl. Wir wollen weiter sagen, daß zu einem inneren Punkt P_ϱ eines Graphen die Seitenzahlen gehören, die den sämtlichen in P_ϱ zusammenlaufenden Strecken $P_\varrho P_{\sigma_\nu}$ des

Graphen zugeordnet sind. Einer Masche $P_{n_1} P_{n_2} \ldots P_{n_\tau} P_{n_1}$ des Graphen ordnen wir entsprechend die sämtlichen den Strecken $P_{n_\nu} P_{n_\nu + 1}$ angeschriebenen Zahlen $x_{n_\nu\, n_\nu + 1}$ zu, immer unter Beachtung der Vorzeichenregel. Dann folgt sofort aus der Definition der Seitenzahlen und der Vorzeichenregel:

Die algebraische Summe der einem inneren Punkt oder einer Masche zugeordneten Seitenzahlen ist gleich 0:

$$\sum_{\nu=1}^{g} x_{\varrho\sigma_\nu} = 0\,, \qquad \sum_{\nu=1}^{h} x_{n_\nu n_\nu + 1} = 0, \quad n_{h+1} = n_1 . \tag{9}$$

Dabei ist g der Grad des Punktes, h die Eckenzahl der Masche.

Die Suche nach Zerlegungen von Rechtecken (oder womöglich von Quadraten) kann nun so erfolgen: Man zeichnet die nach der Tabelle von S. 98 topologisch möglichen Graphen und prüft, ob für sie eine brauchbare Lösung der diophantischen Gleichungen (9) existiert. Nicht „brauchbar“ sind z. B. solche Lösungen, bei denen ein $x_{ik} = 0$ ist. Auch Lösungen mit $x_{ik} = x_{i\,k+1}$ sind auszuschließen, weil sie ja zu einer Zerlegung mit zwei gleichen benachbarten Quadraten führen würde. Es zeigt sich dann sehr rasch, daß die meisten der topologisch möglichen Graphen keine brauchbaren Zerlegungen liefern.

Nehmen wir als ein Beispiel den ersten Fall unserer Tabelle $K = 5$ (Abb. 34). Daß diese Figur nicht der Graph einer Rechteckzerlegung sein kann, sieht man leicht unmittelbar ein. Wir wollen aber doch die Begründung aus unserer Aussage über die algebraische Summe der Seitenzahlen herleiten, um zu zeigen, wie man auch in komplizierteren Fällen zum Ziel kommen kann.

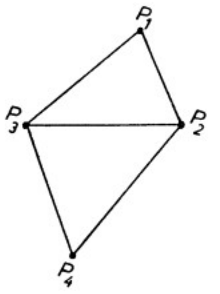

Abb. 34

Es sei (entsprechend unserer Verabredung über die Orientierung der Rechtecke) $x_{13} > x_{12}$ angenommen. Dann müßte sein

$$x_{21} + x_{23} + x_{24} = 0\,, \quad x_{31} + x_{32} + x_{34} = 0\,, \qquad (10)$$
$$x_{13} + x_{34} + x_{42} + x_{21} = 0\,.$$

Daraus folgt nun

$$x_{12} = - x_{21} = x_{23} + x_{24} > x_{24}\,, \quad x_{13} = x_{34} - x_{23} < x_{34}\,,$$

wegen $x_{13} > x_{12}$ also

$$x_{12} + x_{24} < 2\,x_{12} < 2\,x_{13}\,x_{13} + x_{34}$$

im Gegensatz zur 3. Gleichung von (10).

In ähnlicher Weise kann man nun die weiteren Graphen untersuchen. Die systematische Prüfung der Graphen für $K = 6, 7, \ldots$ ist eine nicht besonders schwierige, aber doch recht langwierige Arbeit. *C. J. Bouwkamp* hat diese Untersuchung für $K = 5, 6, \ldots, 13$ vollständig durchgeführt. Es zeigt sich dabei, daß erst bei $K = 9$ brauchbare Lösungen möglich sind. Es treten also bei Zerlegungen von Rechtecken in Quadrate verschiedener Seitenlänge stets mindestens 9 solcher Quadrate auf. Die Abb. 30 zeigt ein Beispiel einer solchen Zerlegung mit $K = 9$.

Mit wachsender Zahl K ergeben sich immer mehr Möglichkeiten. Für $K = 13$ nimmt in der Arbeit von *Bouwkamp* allein die Aufzählung der möglichen Lösungen nach seinem Code-Verfahren mehrere Druckseiten ein. Es gibt ([VII 8] S. 1299) 585 Zerlegungen von Rechtecken in 9, 10, 11, 12 oder 13 inkongruente Quadrate. Unter diesen Rechtecken befindet sich *kein einziges Quadrat*. Dagegen befindet sich unter den 72 für $9 \leqq K \leqq 13$ möglichen imperfekten (aber nicht trivialen) Zerlegungen auch die einfachste „einfache“ (aber nicht perfekte) Zerlegung in 13 Quadrate, die in Abb. 32 dargestellt ist.

Man kann perfekte Quadratzerlegungen aus einfacheren Zerlegungen von Rechtecken aufbauen. Das Verfahren ist schon von *R. Sprague* bei der Konstruktion seines ersten Beispiels benutzt worden [VII 4]. Der Grundgedanke ist folgender: Man zerlege ein Quadrat (Abb. 35) in zwei

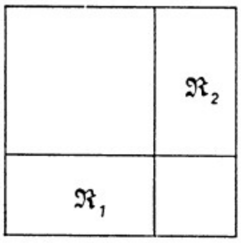

Abb. 35

ungleiche Quadrate $\mathfrak{Q}_1$ und $\mathfrak{Q}_2$ und zwei Rechtecke $\mathfrak{R}_1$ und $\mathfrak{R}_2$. Wenn es gelingt, die Rechtecke $\mathfrak{R}_1$ und $\mathfrak{R}_2$ so in lauter verschiedene Quadrate zu zerlegen, daß keins der Quadrate von $\mathfrak{R}_1$ einem Quadrat von $\mathfrak{R}_2$ gleich ist, wenn ferner alle Teilquadrate von $\mathfrak{R}_\nu$ $(\nu = 1, 2)$ von $\mathfrak{Q}_1$ und $\mathfrak{Q}_2$ verschieden sind, so ist damit eine perfekte (aber nicht einfache!) Zerlegung des ganzen Quadrats erreicht. Durch zwei verschiedene Zerlegungen des Rechtecks mit dem Seitenverhältnis 13 : 16 kam *R. Sprague* auf diese Weise zu einer Zerlegung des Quadrats in 55 Teilquadrate. Mit den Ergebnissen von *Bouwkamp* kann man nach diesem Verfahren auch eine Zerlegung in 28 inkongruente Teilquadrate gewinnen. Es existieren nämlich zwei verschiedene Zerlegungen von Rechtecken mit dem Seitenverhältnis 593 : 422 in je 13 verschiedene Teilquadrate:

$$\begin{array}{ll}
\mathfrak{R}_1: & (222,164,207)\quad (80,41,43)\quad (39,2)\quad (37,215)\quad (200,22)\\
 & \qquad\qquad\qquad\qquad\quad (78)\\
\mathfrak{R}_2: & (247,154,192)\quad (116,38)\quad (230)\quad (175,72)\\
 & \qquad\quad (49,67)\quad (103,18)\quad (85)
\end{array} \tag{11}$$

Es gibt noch einige andere Methoden ([VII 8] S. 74), um aus Rechteckzerlegungen eine perfekte Aufteilung des Quadrats zu gewinnen. Alle so gefundenen Zerlegungen sind nicht einfach. In der Arbeit [VII 7] ist ein Verfahren angegeben, um einfache und perfekte Quadratzerlegungen herauszufinden. Das Verfahren ist freilich recht kompliziert und läßt die Frage offen, welches die kleinste Zahl n'' von Teilquadraten ist, die bei einer einfachen und perfekten Zerlegung auftreten.

4. Die elektrotechnische Deutung

Auf S. 93 wurde schon erwähnt, daß die Zerlegung von Rechtecken in inkongruente Quadrate für ein elektrotechnisches Problem von Bedeutung ist. Wir haben die technische Fragestellung aus der mathematischen Überlegung herausgehalten, wollen aber doch die interessante Deutung unseres Problems nicht übergehen.

An einer homogenen Metallplatte von rechteckiger Gestalt seien an zwei gegenüberliegenden (horizontal orientierten) Seiten Elektroden angebracht. Von einer Elektrode zur andern möge ein konstanter elektrischer Strom fließen. Die Einheit der Stromstärke und der Spannung denken wir uns so gewählt, daß die horizontale Rechteckseite gerade gleich der Stromstärke, die vertikale gleich der Spannung ist. Die Stromlinien verlaufen dann vertikal, die Potentiallinien waagerecht. Es ändert deshalb nichts am Verlauf des Stromes, wenn wir senkrechte Schnitte in der Platte anbringen und in einer waagerechten Strecke einen Leiter vom Widerstand 0 in die Platte einfügen.

Nehmen wir nun an, daß unser Rechteck in lauter inkongruente Quadrate zerlegt sei. Wir schneiden die Platte nun an den senkrechten Seiten der Teilquadrate auf und prägen der Platte an den waagerechten Seiten Elektroden von unendlich hoher Leitfähigkeit ein. Dadurch ändert sich nichts am Strom. Das Verhältnis $V : J$ (Spannung : Stromstärke) ist nach unserer Wahl der Einheiten gerade gleich 1 in *jedem* der Teilquadrate. Jedes Teilquadrat repräsentiert also einen Widerstand von der Größe 1. Man kann nun noch die sämtlichen waagerechten Elektroden in einem Punkt zusammenziehen und die Teilquadrate zu einem Draht zusammenrollen. Dann entsteht aus der rechteckigen Platte ein elektrisches Netzwerk, wie wir es schematisch schon in den Graphen dargestellt haben. Jede nicht triviale Zerlegung eines Rechtecks entspricht dann einem Netzwerk aus Einheitswiderständen, in dem keine einfachen Parallel- oder Reihenschaltungen vorkommen. Ist das zu zerlegenden Rechteck speziell ein Quadrat, so gewinnt man auf diese Weise ein elektrisches Netzwerk aus Widerständen von x Ohm, das als ganzes ebenfalls den Widerstand x Ohm hat. Die Regeln (9) können dann als Kirchhoffsche Gesetze für Stromverzweigungen gedeutet werden.

Für die elektrotechnische Fragestellung ist es unwichtig, ob die auftretenden Teilquadrate alle verschiedene Seitenlängen haben oder nicht. Es kommt nur darauf an, daß die Zerlegung nicht trivial ist, als keine Quadrate mit *gemeinsamer* Seite hat. Der zu der Zerlegung in Abb. 32 gehörende Graph stellt danach das einfachste Netz aus Widerständen von der Größe 1 dar, das selbst den Widerstand 1 hat.

5. Zerlegung von Rechtecken mit kommensurablen Seiten

Schon in der ersten Arbeit über die Zerlegung von Rechtecken hat *Dehn* [VII 1] gezeigt, daß nur für Rechtecke mit kommensurablen Seiten die Zerlegung in lauter ungleiche Quadrate möglich ist. Es dauerte recht lange, bis der Beweis gelang, daß jedes Rechteck mit kommensurablen Seiten auch tatsächlich in der vorgeschriebenen Weise zerlegbar ist [VII 5].

Wir wollen uns darauf beschränken, den Grundgedanken eines solchen Zerlegungsverfahrens zu skizzieren. Man zeigt zuerst, daß das Einheitsquadrat auf unendlich viele verschiedene Arten in inkongruente Quadrate zerlegt werden kann. Dabei kommt es darauf an, daß in einer solchen Folge

$$\mathfrak{Z}_1, \mathfrak{Z}_2, \mathfrak{Z}_3, \ldots \tag{12}$$

von Zerlegungen jedes Quadrat von $\mathfrak{Z}_\nu$ von jedem von $\mathfrak{Z}_\mu$ verschieden ist. Solche Folge (12) von Zerlegungen kann man z. B. erhalten, indem

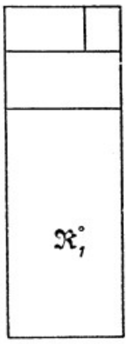

Abb. 36

man von einem Rechteck $\mathfrak{R}$ ausgeht, das auf zwei verschiedene Weisen in inkongruente Quadrate zerlegt werden kann. Diese mit der Quadratzerlegung versehenen Rechtecke wollen wir $\mathfrak{R}_1{}^0$ und $\mathfrak{R}_2{}^0$ nennen.[1])

Man erhält nun eine Folge von Rechteckpaaren $\mathfrak{R}_1^\nu$ und $\mathfrak{R}_2^\nu$, indem man an eine der kleineren Seiten von $\mathfrak{R}_1^{\nu-1}$ bzw. $\mathfrak{R}_2^{\nu-1}$ ein ähnliches Bild dieser Rechtecke anlegt (Abb. 36).[2]).

Dabei soll in jedes der Rechtecke die Zerlegung in Teilquadrate eingetragen sein. Aus den Rechteckpaaren werden nun Quadrate $\mathfrak{Q}_\nu$ $(\nu = 1, 2, 3, \ldots)$ nach dem Muster von Abb. 35 aufgebaut, und durch eine geeignete Ähnlichkeitstransformation gewinnt man daraus eine Folge (12) von Zerlegungen des Einheitsquadrats. Es muß nur bewiesen werden, daß die in den verschiedenen Zerlegungen $\mathfrak{Z}_\nu$ auftretenden Teilquadrate voneinander verschieden sind[3]).

Auf diese Weise hat man eine Möglichkeit gewonnen, jedes Rechteck mit kommensurablen Seiten in lauter verschiedene Quadrate zu zerlegen. In der Tat: Man braucht ja nur das gegebene Rechteck durch äquidistante Parallelen in lauter gleiche Quadrate zu zerlegen und auf jedes der so entstehenden Quadrate q_ϱ $(\varrho = 1, 2, \ldots, m)$ die Zerlegung $\mathfrak{Z}_\varrho$ $(\varrho = 1, 2, 3, \ldots, m)$ anzuwenden. Auf diese Weise hat man eine perfekte, aber natürlich nicht einfache Zerlegung des gegebenen Rechtecks gewonnen.

Von den auf S. 95 formulierten Fragen **(6)**, **(6a)**, **(6b)**, **(6c)** und **(6d)** sind **(6)** und **(6b)** noch offen, die anderen sind durch die Ausführungen der Abschnitte VII 3 und VII 5 beantwortet. Für die Zahlen n, n' und n'' (S. 95) haben wir die Aussagen:

$$13 < n \leqq 24\,, \quad n' = 13\,, \quad 13 < n'' \leqq 38\,.$$

---

[1]) *R. Sprague* hat in seiner Arbeit [VII 5] ein Rechteckpaar benutzt, das ein in 55 Teilquadrate zerlegtes Quadrat liefert. Bei Benutzung des Beispiels (11) kommt man auf ein Quadrat, das in 28 inkongruente Teilquadrate zerlegt ist.

[2]) Auch andere Verfahren zum Aufbau perfekter Quadrate aus zerlegten Rechtecken können zum Aufbau einer Folge (12) benutzt werden, z. B. die von *Bouwkamp* ([VII 8] S. 74) angegebenen.

[3]) Wir übergeben diesen Beweis. Siehe dazu [VII 5].

Life of Pi

In the early nineteenth century, news of boy wonder George Parker Bidder, the son of a Devonshire stonemason, reached the ears of Queen Charlotte. She had a question for him:

> ‘From the Land’s-end, Cornwall, to Farret’s-head, in Scotland, is found by measurement to be 838 miles; how long would a snail be creeping that distance, at the rate of 8 feet per day?’

The exchange and the answer – 553,080 days – is mentioned in a popular book of the time, *A short Account of George Bidder, the celebrated Mental Calculator: with a Variety of the most difficult Questions, Proposed to him at the principal Towns in the Kingdom, and his surprising rapid Answers!* The pages list the child’s greatest calculations, including such classics as ‘What is the square root of 119,550,669,121?’ (345,761, answered in half a minute) and ‘How many pounds weight of sugar are there in 232 hogsheads, each weighing 12cwt. 1qr. 22lbs?’ (323,408lbs, also answered in half a minute.)

Arabic numerals made doing sums easier for everyone, but an unexpected consequence was the discovery that certain people were blessed with truly astonishing arithmetical skills. Often, these prodigies excelled in no other way than their facility with numbers. One of the earliest-known examples was a Derbyshire farmhand, Jedediah Buxton, who amazed locals with his abilities in multiplication despite being barely able to read. He could, for example, calculate the value of a farthing when doubled 140 times. (The answer is 39 digits long, with 2 shillings 8 pence left over.) In 1754, curiosity about Buxton’s talent led to him being invited to visit London, where he was examined by members of the Royal Society. He seems to have had some of the symptoms of high-functioning autism, for when he was taken to see Shakespeare’s *Richard III* he was left nonplussed by the experience, although he notified his hosts that the actors had taken 5202 steps and spoken 14,445 words.

In the nineteenth century ‘lightning calculators’ were international stage stars. Some showed aptitude at an extraordinarily young age. Zerah Colburn, from Vermont, was five when he gave his first public demonstration and eight when he sailed to England with dreams of big-time success. (Colburn was born with hexadactyly, but it is not known if his extra fingers gave him an advantage when learning to count.) A contemporary of Colburn's was the Devonshire lad George Parker Bidder. The two prodigies crossed paths in 1818, when Colburn was 14 and Bidder 12, and the encounter, in a London pub, inevitably led to a maths duel.

Colburn was asked how long it would take a balloon to circumnavigate the globe if the balloon were travelling at 3878 feet per minute and the world were 24,912 miles around. It was a suitably international question for the unofficial title of smartest alec on Earth. But after deliberating for nine minutes, Colburn failed to give an answer. A London newspaper gushed that his opponent, on the other hand, took only two minutes before giving the correct reply, '23 days, 13 hours and 18 minutes, [which] was received with marks of great applause. Many other questions were proposed to the American boy, all of which he refused answering; while young Bidder replied to all.' In his charming autobiography, *A memoir of Zerah Colburn, written by himself*, the American gives a different version of the contest. '[Bidder] displayed great strength and power of mind in the higher branches of arithmetic,' he said, before adding dismissively, 'but he was unable to extract the roots, and find the factors of numbers.' The mpionship was left undecided. Edinburgh University subsequently offered to take over Bidder's education. He went on to become an important engineer, at first in railroads and eventually supervising construction of London's Victoria Docks. Colburn, on the other hand, returned to America, became a preacher and died aged 35.

The ability to calculate rapidly has no great correlation with mathematical insight or creativity. Only a few great mathematicians have demonstrated lightning-calculator skills, and many mathematicians have surprisingly poor arithmetic. Alexander Craig Aitken was a well-known lightning calculator in the first half of the twentieth century, unusual in that he was also a professor of mathematics at Edinburgh University. In 1954 Aitken gave a lecture to the Society of Engineers in London, in which he explained some of the methods in his repertoire, such as algebraic shortcuts and – crucially – the importance of memory. To prove his point he rattled off the decimal expansion for $\frac{1}{97}$, which repeats only after 96 digits.

Aitken ended his talk with the rueful comment that when he acquired his first desk calculator his abilities began to deteriorate. ‘Mental calculators may, like the Tasmanian or the Moriori, be doomed to extinction,’ he predicted. ‘Therefore…you may be able to feel an almost anthropological interest in surveying a curious specimen, and some of my auditors here may be able to say in the year 2000 ce, “Yes, I knew one such.”’

This was one calculation, however, that Aitken got wrong.

‘Neurons! On the ready! Go!’

With an impatient snap and swoosh, the contestants in the multiplication round at the Mental Calculation World Cup turned over their papers. The room at Leipzig University was silent as the 17 men and two women contemplated the first question: 29,513,736× 92,842,033.

Arithmetic is back in vogue. Thirty years after the first cheap electronic calculators precipitated a widespread demise in mental calculation skills, a backlash is under way. Newspapers offer up daily maths brainteasers, popular computer games with arithmetic puzzles sharpen our minds and – at the high end – lightning calculators compete in regular international tournaments. The Mental Calculation World Cup was founded in 2004 by German computer scientist Ralf Laue, and takes place every two years. It was the inevitable culmination of Laue’s two hobbies: mental arithmetic and collecting unusual records (such as the Most Grapes Thrown over a Distance of 15ft and Caught in the Mouth in One Minute, which is 55 of them). The internet helped, enabling him to meet kindred spirits – mental arithmeticians are not, in general, extroverts. The global community of human calculators, or ‘mathletes’, was well represented in Leipzig, with contestants from countries as diverse as Peru, Iran, Algeria and Australia.

How do you measure calculating skills? Laue adopted the categories already chosen by *Guinness World Records* – the multiplication of two eight-digit numbers, the addition of ten ten-digit numbers, extracting the square root of six-figure numbers to eight significant figures, and finding the day of the week of any date between 1600 and 2100. The latter is known as a calendar calculation, and is a flashback to the golden age of lightning calculation, when performers would ask a member of the audience their birth date and then instantly name the day of the week it fell on.

Regulation, and a spirit of competitiveness, have come at the expense of theatrics. The youngest contestant at the World Cup, an 11-year-old boy from India, performed the ‘air abacus’ – his hands were jerking wildly around rearranging imaginary beads, while all the others were quiet and still, occasionally jotting down their answers. (The rules say that only the final answer can be written down.) After 8 minutes and 25 seconds, Alberto Coto of Spain stuck his hand up like an excited schoolboy. The 38-year-old had completed ten multiplications of two eight-digit numbers in that time, smashing the world record. It was evidently an awesome accomplishment, yet watching him was as compelling as invigilating an exam.

Conspicuously absent from proceedings in Leipzig, however, was perhaps the world’s most famous mathlete, the French student Alexis Lemaire, who prefers another yardstick to measure computational power. In 2007 Lemaire, aged 27, made international headlines when, at the Science Museum in London, he took just 70.2 seconds to calculate the thirteenth root of:

**85,877,066,894,718,045,602,549,144,850,158,599,202
748,960,878,023,151,390,314,284,284,465,842,798,37

Lemaire’s achievement was undoubtedly the more spectacular. The number has 200 digits, which can barely be pronounced in 70.2 seconds. But did his feat mean that, as he claims, he is the greatest lightning calculator of all time? This is a matter of deep controversy in the calculation milieu, mirroring the battle almost 200 years ago between Zerah Colburn and George Bidder, both exceptional at their own type of sum.

The term ‘thirteenth root of *a*’ refers to the number that when multiplied by itself 13 times equals *a*. Only a fixed amount of numbers when multiplied by themselves 13 times equal a 200-digit number. (It is a large fixed amount. The answer is limited to about 400 trillion possibilities, all 16 digits long and beginning with 2.) Because 13 is prime and considered unlucky, Lemaire’s calculation was vested with an extra aura of mystery. In fact, 13 brings with it some advantages. For instance when 2 is multiplied by itself 13 times, the answer ends in 2. When 3 is multiplied by itself 13 times the answer ends in 3. The same is true for 4, 5, 6, 7, 8 and 9. In other words, the last digit of the thirteenth root of a number is the same as the last digit of the original number. We get this number for free, without having to do any calculation.

Lemaire has worked out algorithms, which he has not divulged, to calculate the other 14 digits in the final answer. Purists, possibly unfairly, say that his skill is less a feat of calculation and more one of memorizing huge strings of numbers. And they point out that Lemaire cannot find the thirteenth root of *any* 200-digit number given to him. At the Science Museum in London he was presented with several hundred numbers and allowed to select the one that he would do the calculation for.

Still, Lemaire's performance was more in keeping with the tradition of the stage calculators of old. Audiences want to feel the 'wow', rather than understand the process. By contrast, at the Mental Calculation World Cup, Coto had no choice about the problem to be solved and used no hidden techniques when he multiplied 29,513,736×92,842,033. He simply used his 1-to 9-times tables. The fastest way to multiply eight digits by eight digits is using the Vedic sutra *Vertically and Cross-Wise*, which breaks the sum into 64 multiplications of single-digit figures. He managed to get the right answer in an average of less than 51 seconds. Knowing what he was doing made it less dazzling, even though it was obviously still a formidable feat.

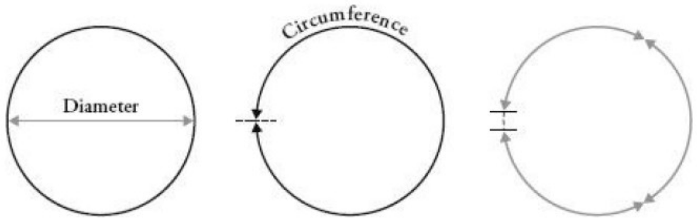
As I talked with competitors in Leipzig, I discovered that many of them had fallen in love with speed arithmetic thanks to Wim Klein, a Dutch lightning calculator who was a celebrity in the 1970s. Klein was already a veteran of circuses and music halls when, in 1958, he was given a job by Europe's top physics institute – the European Organization for Nuclear Research (CERN) in Geneva, providing calculations for the physicists. He was probably the last human calculator to have been employed as one. As computers developed, his skills became redundant, and in retirement he returned to showbiz, appearing frequently on TV. (Klein, in fact, was one of the first to promote thirteenth-root calculations.)

A century before Klein another human calculator, Johann Zacharias Dase, was also employed by the scientific establishment to do their sums for them. Dase was born in Hamburg and started performing as a lightning calculator in his teens, when he was taken under the wing of two eminent mathematicians. In the days before electronic or mechanical calculators, scientists relied on logarithm tables to do complicated multiplications and divisions. As I will explain in more detail later, every number has its own logarithm, which can be calculated using a laborious procedure of adding fractions. Dase calculated the natural logarithms of the first 1,005,000 numbers, each to seven decimal places. It took him three years, and he said he enjoyed the task. Then, on the recommendation of the mathematician Carl Friedrich Gauss, Dase embarked on another enormous project: compiling a table of factors of all the numbers between 7,000,000 and 10,000,000. This means he looked at every number in the range and calculated its factors, which are the whole numbers that divide that number. For example, 7,877,433 has only two factors: 3 and 2,625,811. When Dase died, aged 37, he had completed a substantial part of it.

Yet it was another calculation for which Dase is best remembered. When still a teenager he calculated pi to 200 places, a record for the time.

Circles are everywhere in the natural world – you see them in the full moon, in the eyes of humans and animals and in the cross-section of an egg. Tie a dog to a post and the path it patrols when the lead is taut is a circle. The circle is the simplest two-dimensional geometrical shape. An Egyptian farmer counting how much of a crop to plant in a round field, or a Roman mechanic measuring the length of wood for a wheel would have needed to make calculations involving circles.

The ancient civilizations realized that the ratio of a circle's circumference to its diameter was always the same no matter how big or small you made the circle. (The circumference is the distance around a circle, and the diameter is the distance across it.) The ratio is known as pi, or p, and it works out as just over three. So, if you take the diameter of a circle and curve it around the circumference, you will find that it fits just over three times.



Even though pi is a simple ratio between the basic properties of a circle, the task of finding its exact value has proved to be far from simple. This elusiveness has made pi an object of fascination for thousands of years. It is the only number that is both the name of a song by Kate Bush and a fragrance by Givenchy, whose PR department sent me the following text:

π– PI
BEYOND INFINITY

Four thousand years have passed and the mystery remains.

Although every schoolchild studies, the familiar symbol still manages to hide an abyss of great complexity.

Why choose to symbolise the eternal masculine?

It’s a matter of signs and directions. If is the story of the long struggle to achieve the unattainable, it is also a portrait of the fabled conqueror in search of knowledge.

Pi speaks of men, of all men, of their scientific genius, their taste for adventure, their willingness to act, and of their passions to the extreme.

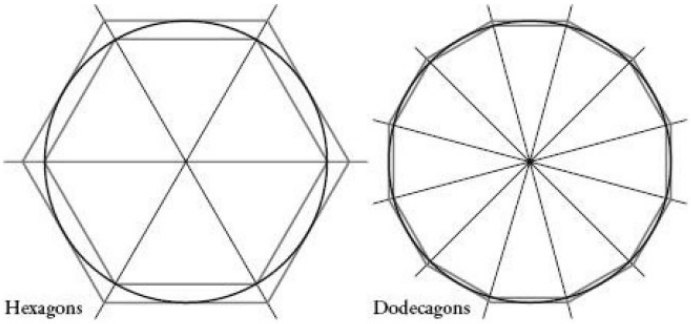
The earliest approximations for pi came from the Babylonians, who used a value of 3 $\frac{1}{8}$, and the Egyptians, who used 4($\frac{8}{9}$, which translate, respectively, into decimals as 3.125 and 3.160. A line in the Bible reveals a situation in which pi is taken as 3: ‘Also he made a molten sea of ten cubits from brim to brim, round in compass, and five cubits the height thereof; and a line of thirty cubits did compass it round about’ (I Kings 7:23).

If the shape of the sea is a circle with a circumference of 30 cubits and a diameter of 10, then pi is $\frac{30}{10}$, or 3. Many excuses have been given for the Bible’s inaccurate value, such as the claim that the sea was in a circular vessel with a thick rim. In this case the quoted 10-cubit diameter covers the sea and the rim (making the true diameter of the sea a little less than 10 cubits), while the circumference of the sea is taken as the inside of the rim. A mystical explanation is much more enticing: due to the peculiarities of Hebrew pronunciation and spelling, the word ‘line’, or *qwh*, is pronounced *qw*. Totting up the numerological values of the letters gives 111 for *qwh* and 106 for *qw*. Multiplying three by $\frac{111}{106}$ gives 3.1415, which is pi correct to five significant figures.

The first genius whose extreme passion for discovery about pi does justice to the aspirations of Givenchy’s aftershave is equally the man who took the most famous bath in the history of science. Archimedes slipped into the tub and noticed that the volume of water he displaced was equal to the volume of his own body under the water. He instantly realized that he could therefore find the volume of any object by submersing it, in particular the crown of the King of Syracuse, and so would be able to ascertain if that piece of royal bling was made of pure gold or not by working out its density. (It wasn’t.) As a result, he ran naked into the streets shouting ‘Eureka! [I have found it!]’, thus displaying – for the citizens of Syracuse, at least – the eternal masculine. Archimedes loved to grapple with problems in the real world, unlike Euclid, who dealt uniquely in abstractions. His many inventions were said to have included a giant catapult and a system of huge mirrors that reflected the sun’s rays with such intensity that they set Roman ships ablaze during the Siege of Syracuse. He was also the first person to come up with an apparatus to capture pi.

To do so he first drew a circle, and then he constructed two hexagons – one that he fitted inside the circle, and one that he put outside it, as in the diagrams below. This already tells us that pi must be somewhere between 3 and 3.46, which is determined by calculating the perimeters of the hexagons. If we let the diameter of the circle be 1, then the perimeter of the inner hexagon is 3, which is less than the circumference of the circle, which is pi, which is less than the perimeter of the outer one, which is $3\sqrt{2}$, or 3.46 to two decimal places. (The way that Archimedes calculated this value was by using a method that was essentially a fiddly precursor to trigonometry, and which is too complicated to go into here.)

So, $3 < \text{pi} < 3.46$.



Now if you were to repeat the calculation using two regular polygons with more than six sides, you would get a narrower bound for pi. This is because the more sides that the polygons have, the closer their perimeters are to the circumference, as we can see in the diagram above that uses a 12-sided polygon. The polygons act like walls closing in on pi, squeezing it from above and from below, between narrower and narrower limits. Archimedes started with a hexagon and eventually constructed polygons of 96 sides, allowing him to calculate pi as follows: $3\frac{10}{71} < \text{pi} < 3\frac{1}{7}$

This translates into $3.14084 < \text{pi} < 3.14289$, an accuracy of two decimal places.

But pi hunters weren’t about to stop there. In order to get closer to the number’s true value, all that was required was to create polygons with more sides. Liu Hui, in third-century China, employed a similar method, using the area of a polygon of 3072 sides to pin pi to five decimal places: 3.14159. Two centuries later Tsu ChungChih and his son Tsu Keng-Chih went one digit further, to 3.141592, with a polygon of 12,288 sides.

The Greeks and the Chinese were hampered by cumbersome notation. When mathematicians were eventually able to use Arabic numerals, the record tumbled. In 1596 the Dutch fencing master Ludolph van Ceulen used a souped-up polygon of 60×2^{29} sides to find pi to 20 decimal places. The pamphlet on which he printed his result ended with the words: ‘whoever wants to, can come closer’, and no one felt the urge as strongly as he did. He went on to calculate pi to 32 and then 35 decimal places – which were engraved on his tombstone. In Germany, *die Ludolphsche Zahl*, Ludolph’s number, is still understood as a term for pi.

For 2000 years the only way to pinpoint pi with accuracy was by using polygons. But, in the seventeenth century, Gottfried Leibniz and John Gregory ushered in a new age of pi appreciation with the formula:

$$\frac{\text{Pi}}{4} = 1 - \frac{1}{3} + \frac{1}{5} - \frac{1}{7} + \frac{1}{9} \cdots$$

In other words, a quarter of pi is equal to one minus a third plus a fifth minus a seventh plus a ninth and so on, alternating the addition and subtraction of unit fractions of the odd numbers as they head to infinity. Before this point scientists were only aware of the scatter-gun randomness of pi’s decimal expansion. Yet here was one of the most elegant and uncomplicated equations in maths. Pi, the poster boy of disorder, it turned out, had some kind of order in his DNA.

Leibniz had devised the formula using ‘the calculus’, a powerful type of mathematics he had discovered, in which a new understanding of infinitesimal amounts was used to calculate areas, curves and gradients. Isaac Newton had also come up with calculus, independently, and the men spent a good deal of time bickering about who had got there first. (For years, Newton was considered to have won the argument, based on the dates of his unpublished manuscripts, but it now appears that a version of calculus was actually first invented in the fourteenth century by the Indian mathematician Madhava.)

The formula that Leibniz found for pi is what is known as an *infinite series*, a sum that goes on and on for ever, and it provides a way to calculate pi. First, we need to multiply both sides of the formula by 4 to get:

$$\text{Pi} = 4 - \frac{4}{3} + \frac{4}{5} - \frac{4}{7} + \frac{4}{9} \cdots$$

Starting with the first term and adding successive terms produces the following progression (converted into decimals):

$$4 \rightarrow 2.667 \rightarrow 3.467 \rightarrow 2.896 \rightarrow 3.340 \rightarrow \ldots$$

The total gets closer and closer to pi in smaller and smaller leaps. Yet this method requires more than 300 terms to get an answer for pi accurate to two decimal places, so it was impracticable for those wanting to use it to find more digits in the decimal expansion.

Eventually, calculus provided other infinite series for pi that were less pretty but more effective for number-crunching. In 1705 the astronomer Abraham Sharp used one to calculate pi to 72 decimal places, smashing van Ceulen’s century-old record of 35. While this was quite an achievement, it was also a useless one. There is no practical reason to know pi to 72 digits, or to 35 digits for that matter. Four decimal places is enough for the engineers of precision instruments. Ten decimal places is sufficient to calculate the circumference of the Earth to within a fraction of a centimetre. With 39 decimal places, it is possible to compute the circumference of a circle surrounding the known universe to within an accuracy of a radius of a hydrogen atom. But practicality wasn’t the point. Application was not a concern to the pi men of the Enlightenment; digit-hunting was an end in itself, a romantic challenge. A year after Sharp’s effort, John Machin reached 100 digits and in 1717 the Frenchman Thomas de Lagny added a further 27. By the turn of the century, the Slovenian Jurij Vega was in the lead with 140.

Zacharias Dase, the German lightning calculator, pushed the record for pi to 200 decimal places in 1844 in an intense two-month burst. Dase used the following series, which looks more convoluted than the pi formula above but is in fact far more user-friendly. This is because, first, it bears down on pi at a respectable rate. An accuracy of two decimal places is reached after the first nine terms. Second, the $\frac{1}{2}$, $\frac{1}{5}$ and $\frac{1}{8}$ that reappear every third term are very convenient to manipulate. If $\frac{1}{5}$ is rewritten as $\frac{2}{10}$ and $\frac{1}{8}$ as $\frac{1}{2}\times\frac{1}{2}\times\frac{1}{2}$, all the multiplications involving those terms can be reduced to combinations of doubling and halving. Dase would have written out a reference table of doubles to help him with his calculations, starting 2, 4, 8, 16, 32, and carried on for as far as he needed – which, since he was calculating pi to 200 places, would be when the final double is 200 digits long. This happens after 667 successive doublings.

Dase used this series:

$$
\begin{aligned}
\frac{\pi}{4} &= \frac{1}{2} - \frac{(\tfrac{1}{2})^3}{3} + \frac{(\tfrac{1}{2})^5}{5} - \dots \\
&\quad + \frac{1}{5} - \frac{(\tfrac{1}{5})^3}{3} + \frac{(\tfrac{1}{5})^5}{5} - \dots \\
&\quad + \frac{1}{8} - \frac{(\tfrac{1}{8})^3}{3} + \frac{(\tfrac{1}{8})^5}{5} - \dots \\
&= \frac{1}{2} + \frac{1}{5} + \frac{1}{8} - \left[\frac{(\tfrac{1}{2})^3}{3} + \frac{(\tfrac{1}{5})^3}{3} + \frac{(\tfrac{1}{8})^3}{3}\right] \\
&\quad + \left[\frac{(\tfrac{1}{2})^5}{5} + \frac{(\tfrac{1}{5})^5}{5} + \frac{(\tfrac{1}{8})^5}{5}\right] - \dots
\end{aligned}
$$

So $\pi = 4\ (0.825 - 0.0449842 + 0.00632 - \dots$

After one term this is 3.3

After two terms this is 3.1200

After three terms this is 3.1452

Dase barely had time to rest on his laurels before the Brits decided to covet his achievement, and within a decade William Rutherford had calculated pi to 440 places. He encouraged his protégé William Shanks, an amateur mathematician who ran a boarding school in County Durham, to go even further. In 1853 he reached 607 digits, and by 1874 he was at 707. His record held for 70 years until D.F. Ferguson, of the Royal Naval College in Chester, found a mistake in Shanks's calculation. He had made an error at the 527th place so all the subsequent numbers were wrong. Ferguson spent the last year of the Second World War calculating pi longhand. One can only assume that he thought the war was already won. By May 1945 he had 530 places, and by July 1946 he reached 620, and no one has ever calculated further using only paper and pen.

Ferguson was the last of the manual digit-hunters and the first of the mechanical. Using a desk calculator he added almost another 200 places in just over a year, so in September 1947 pi was known to 808 decimal places. Computers then changed the race. The first of them to battle pi was the Electronic Numerical Integrator and Computer, or ENIAC, which was built in the final years of the Second World War at the US Army's Ballistic Research Laboratory in Maryland. It was the size of a small house. In September 1949 the ENIAC took 70 hours to calculate pi to 2037 digits – smashing the record by more than a thousand decimal places.

As more and more digits were found in pi, one thing seemed pretty clear: the numbers obeyed no obvious pattern. Yet it was only in 1767 that mathematicians were able to prove that the higgledy-piggledy sequence of digits would never repeat itself. The discovery followed from considering what type of number pi might be.

The most familiar *type* of number is the *natural numbers*. They are the counting numbers starting at one:

1, 2, 3, 4, 5, 6…

The natural numbers, however, are limited in scope because they expand in only one direction. More ul are the *integers,* which are the natural numbers together with zero and the negatives of the natural numbers:

… –4, –3, –2, –1, 0, 1, 2, 3, 4…

The integers cover every positive or negative whole number from minus infinity to plus infinity. If there were a hotel with an unlimited amount of floors and an unlimited amount of lower and lower basements, the buttons in the elevator would be the integers.

Another basic type of number is the *fraction*, which are the numbers written when *a* and *b* are integers but *b* is not 0. The top number in a fraction is the *numerator* and the bottom number is the *denominator*. If we have several fractions, the *lowest common denominator* is the lowest number that can be divided by all the denominators without leaving a remainder. So, if we have $\frac{1}{2}$ and $\frac{3}{10}$, the lowest common denominator is 10, since both 2 and 10 divide into 10. What about the lowest common denominator of $\frac{1}{3}$,$\frac{3}{4}$,$\frac{2}{9}$ and $\frac{7}{13}$? In other words, what is the smallest number that 3, 4, 9 and 13 divide into? The answer is surprisingly big: 468! I mention this to make a semantic rather than a mathematical point. The phrase ‘lowest common denominator’ is often used to describe something basic or unsophisticated. It sounds evocative, but misrepresents the arithmetic. Lowest common denominators can often be big and unconventional: 468 is quite an impressive number! A more arithmetically meaningful phrase for something mainstream and cheap is *highest common* *factor* – which is the largest number that can be divided into every one of a group of numbers. The highest common factor of 3, 4, 9 and 13, for example, is 1, and you can’t get much lower or more unsophisticated than that.

Since fractions are equivalent to ratios between integers, they are also called *rational numbers*, and there is an infinite amount of them. In fact, there is an infinite number of rational numbers between 0 and 1. For example, let’s take every fraction where the numerator is 1 and the denominator is a natural number bigger than or equal to 2. This is the set composed of:

$$\frac{1}{2}, \frac{1}{3}, \frac{1}{4}, \frac{1}{5}, \frac{1}{6} \; \ldots$$

We can go further and prove that there is an infinite number of rational numbers between *any two* rational numbers. Let *c* and *d* be any two rational numbers, with *c* less than *d*. The point halfway between *c* and *d* is a rational number: it is $\frac{(c+d)}{2}$. Call this point *e*. We can now find a point halfway between *c* and *e*. It is $\frac{(c+e)}{2}$. It is rational and also between *c* and *d*. We can carry on ad infinitum, always splitting the distance between *c* and *d* into smaller and smaller parts. No matter how tiny the distance between *c* and *d* is in the first place, there will always n infinite amount of rational numbers in between them.

Since we can always find an infinite number of rational numbers between any two rational numbers, it might be thought that the rational numbers cover every number. Certainly, this is what Pythagoras had hoped. His metaphysics was based on the belief that the world was made up of numbers and the harmonic proportions between them. The existence of a number that could not be described as a ratio diminished his position, at the very least, if it did not contradict it outright. Yet unfortunately for Pythagoras, there *are* numbers that cannot be expressed in terms of fractions, and – rather embarrassingly for him – it is his own theorem that leads us to one. If you have a square where each side has length 1, then the length of the diagonal is the square root of two, which cannot be written as a fraction. (I have included a proof as an appendix.)

Numbers that cannot be written as fractions are called *irrational*. According to legend, their existence was first proved by the Pythagorean disciple Hippasus, which did not endear him to the Brotherhood; he was declared a heretic and was drowned at sea.

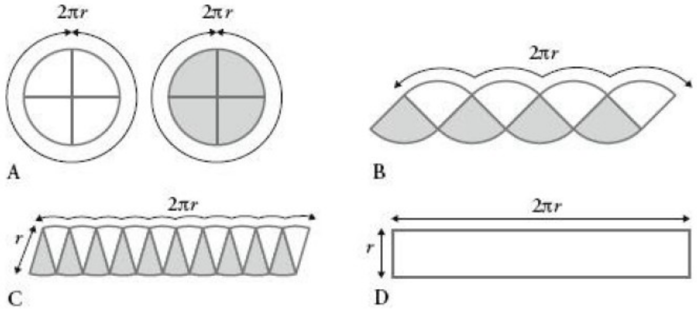
When a rational number is written out as a decimal fraction, either it has a finite amount of digits, in the way that $\frac{1}{2}$ can be written 0.5, or the expansion will end up repeating itself, just as $\frac{1}{3}$ is 0.3333…where the 3s go on for ever. Sometimes the recurring loop is more than one digit, as is the case of $\frac{1}{11}$, which is 0.090909…where the digits 09 repeat for ever, or $\frac{1}{19}$, which is 0.0526315789473684210…where 052631578947368421 repeats for ever. By contrast, and this is the crucial point, when a number is irrational its decimal expansion never repeats.

In 1767 the Swiss mathematician Johann Heinrich Lambert proved that pi was indeed irrational. The early pi-men may have hoped after the initial chaos of 3.14159…that the noise would calm and a pattern ensue. Lambert's discovery confirmed that this was impossible. Pi's decimal expansion cavorts towards infinity in a predestined yet apparently indiscriminate way.

Mathematicians interested in the irrationals wanted to categorize them further. In the eighteenth century they started to speculate about a special type of irrational called *transcendental numbers*. These were numbers so mysterious and evasive that finite mathematics could not capture them. The square root of two, $\sqrt{2}$, for example, is irrational but can be described as the solution to the equation $x^2 = 2$. A transcendental number is an irrational that cannot be described by an equation with a finite amount of terms. When the concept of transcendental numbers was first mooted, no one knew if they even existed.

They did exist, although it took about a hundred years before Joseph Liouville, a French mathematician, came up with a few examples. Pi was not among them. Only after another 40 years did the German Ferdinand von Lindemann prove that pi was indeed transcendental. The number existed beyond the realm of finite algebra.

Lindemann's discovery was a milestone for number theory. It also settled, once and for all, what was probably the most celebrated unsolved problem in mathematics: whether or not it was ple to square the circle. In order to explain how it did this, however, I need to introduce the formula that says that the area of a circle is πr^2, where r is the radius. (The radius is the distance from the centre to the side, or half the diameter.) A visual proof of why this is true is an instance where a pie is the best metaphor for pi. Imagine you have two same-sized circular pies, a white one and a grey one, as below in A. The circumference of each pie is pi times the diameter, or pi times twice the radius, or $2pr$. When sliced into equal segments the pieces can be rearranged, as in B with quarter segments, or as in C with ten segments. In both cases the length of the side remains $2pr$. If we keep on slicing smaller and smaller segments, then the shape would eventually become a rectangle, as in D, with sides r and $2\pi r$. The area of the rectangle – which is the area of the two pies – is therefore $2\pi r^2$, so the area of one pie is πr^2.



Proof that the area of a circle = πr^2.

To square a circle we must construct (using just a compass and straightedge) a square that has the same area as a given circle. Now we know that a line with length r is the radius of a circle with area πr^2, and we also know that a square with area πr^2 must have a side length r $r\sqrt{\pi}$(since ($(r\sqrt{\pi})^2 = r^2(\sqrt{\pi})^2 = r^2\pi = \pi r^2$)). So squaring the circle can be reduced to the challenge of constructing the length $r\pi$ from the length r. Or, taking r as 1 for convenience, the length π from 1.

Using coordinate geometry, which I will cover later, it is possible to express the process of the construction of a line algebraically, as a finite equation. It can be shown that so long as x is the solution to a finite equation, then starting with a line of length 1 we can construct a line with length x. But if x is not the solution to a finite equation – in other words, if x is transcendental – it is impossible to construct a line with length x. Now, the fact that p is transcendental means that π is also transcendental. (You’re going to have to trust me on that.) So it is impossible to construct the length π. The transcendence of pi proves that the circle cannot be squared.

Lindemann’s proof of the transcendence of pi dashed what had been the dream, for thousands of years, of countless mathematicians. Perhaps the most eminent figure ever to have declared that he had squared the circle was Thomas Hobbes, the seventeenth-century English thinker whose book *Leviathan* founded political philosophy. Having become a keen amateur geometer in later life, Hobbes published his solution when he was 67. Even though circle-squaring was still an open question at the time, his proof was received with bemusement by the scientific community. John Wallis, professor at Oxford and the finest British mathematician before Isaac Newton, exposed Hobbes’s errors in a pamphlet, thus setting in motion one of the most entertaining – and pointless – feuds in the history of British intellectual life. Hobbes replied to Wallis’s comments with an addendum to his book entitled *Six Lessons to the Professors of Mathematics*. Wallis countered with *Due Correction for Mr Hobbes in School Discipline for not saying his Lessons right*. Hobbes followed this with *Marks of the Absurd Geometry, Rural Language, Scottish Church Politics and Barbarisms of John Wallis*. This led to Wallis’s *Hobbiani Puncti Dispunctio! or the Undoing of Mr Hobbes’s Points*. The quarrelling lasted almost a quarter of a century, until Hobbes’s death in 1679. Wallis rather enjoyed the hostilities, since it was a way of casting aspersions on Hobbes’s political and religious views, which he despised. And, of course, he was right. In many disputes truths are shared between both sides. Not in Hobbes vs Wallis. Hobbes could not square the circle because it is impossible to do so.

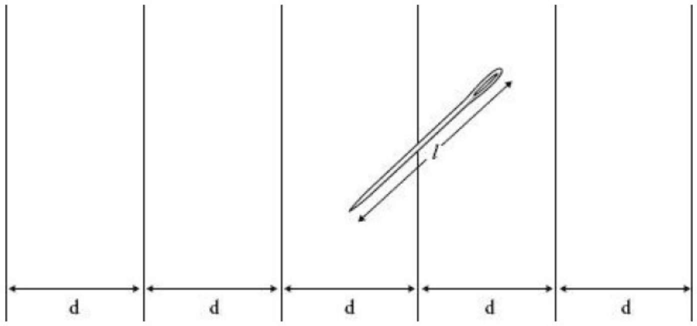
Proof that you cannot square the circle has not put people off trying. In 1897 the Indiana state legislature famously considered a bill containing a proof of squaring the circle by E.J. Goodwin, a country doctor, who offered it ‘as a gift to the State of Indiana’. He was, of course, misguided. Since Ferdinand von Lindemann in 1882, the phrase circle-squarer has been mathspeak for crank.

Pi’s enigmatic attributes were, in the eighteenth and nineteenth centuries, revealed not only to be at the heart of ancient geometrical problems but also deeply rooted in new fields of science that were not always obviously related to circles. ‘This mysterious 3.141592…which comes in at every door and window, and down every chimney,’ wrote the British mathematician Augustus De Morgan. For example, the time it takes a pendulum to swing is dependent on pi. The distribution of deaths in a population is a function of pi. If you toss a coin $2n$ times, the probability when n is very large of getting exactly 50 percent heads and 50 percent tails is $\frac{1}{\sqrt{(n\pi)}}$.

The man whose name is most associated with offbeat occurrences of pi was the French polymath Georges-Louis Leclerc, the Comte de Buffon (1707–88). Of Buffon's many colourful scientific endeavours, perhaps his most ambitious was the construction of a working version of Archimedes' weapon of mirrors, with which he was said to have set fire to ships. Buffon's contraption was made up of 168 flat mirrors, each six by eight inches, and it was able to ignite a wooden plank at a distance of 150 feet, a good effort, though on a different scale from setting a Roman fleet ablaze.

With regard to pi, Buffon is remembered for having devised an equation that led to a new method for calculating pi, though Buffon did not himself make the connection. Buffon arrived at his equation by studying an eighteenth-century gambling game called 'clean tile', in which you throw a coin on to a tiled surface and bet on whether it will touch the cracks between tiles or rest cleanly. Buffon came up with the following alternative scenario: imagine that a floor is marked with parallel lines spaced evenly apart and that a needle is thrown on it. He then correctly calculated that if the length of the needle is l and the distance between lines is d, then the following equation holds:

$$\text{Probability of the needle touching the line} = \frac{2l}{\pi d}$$



A few years after Buffon died, Pierre Simon Laplace realized that this equation could be used to estimate a value for pi. If you throw lots and lots of needles on the floor, then the ratio of the number of times that the needle hits the line to the total number of throws will be approximately equal to the mathematical probability of the needle touching the line. In other words, after many throws

$$\frac{\text{number of times needle touches a line}}{\text{number of total throws}} \approx \frac{2l}{\pi d}$$

or:

$$\pi \approx \frac{2l\,(\text{number of total throws})}{d\,(\text{number of times needle touches a line})}$$

(The symbol ≈ means ‘is approximately equal to’.)

Even though Laplace was the first to write about how pi could be estimated this way, his work followed from Buffon’s equation, so Buffon is the person remembered for it. His achievement put him in esteemed company as a member of the club of mathematicians, including Archimedes and Leibniz, who each found a new way to calculate pi.

The more throws of the needle that are taken, the better the approximation, and aiming needles at boards has become a standard diversion for mathematicians unable to think of more creative ways to pass the time. You need, however, to keep on going a fair while before any interesting result is achieved. An early adopter is said to have been a certain Captain Fox in the American Civil War, who, while recovering from battle wounds, threw a piece of wire eleven hundred times on a board of parallel lines and managed to derive pi to 2 decimal places.

Pi’s mathematical properties have made it a celebrity among numbers, and also a more general cultural icon. Because pi’s digits never repeat, they are perfect for feats of memorization. If remembering numbers is your thing, the *ne plus ultra* of digits is the digits in pi. This has been a pastime since at least 1838, when *The Scotsman* reported that a 12-year-old Dutch boy recited all the 155 digits that were known at the time to an audience of scientists and royals. Akira Haraguchi, a 60-year-old retired engineer, holds the current world record. In 2006 he was filmed in a public hall near Tokyo reciting pi to 100,000 decimal places. The performance took him 16 hours and 28 minutes, including five-minute breaks every two hours to eat rice balls. He explained to a journalist that pi symbolized life since its digits never repeated and followed no pattern. Memorizing pi, he added, was ‘the religion of the universe’.

Pi memorization gets a little dull, but pi memorization while juggling, now there’s a competitive sport! The record is held by Mats Bergsten, an actuary in Sweden in his late fifties, who has recited 9778 digits while juggling with three balls. He told me, however, that he is proudest of his achievements in the ‘erest test’, in which the first 10,000 digits of pi’s expansion are divided into 2000 groups of five, beginning with 14159. In the test 50 groups are randomly read out, and the contestant has to say from memory which five numbers precede and succeed each of them. Mats Bergsten is one of only four people in the world who can do this with no errors, and his time, 17min 39secs, is the fastest. It is much more mentally straining, he told me, to recall 10,000 digits randomly than merely remembering them in order.

When Akira Haraguchi recited 100,000 digits of pi by heart, he used a mnemonic technique, assigning syllables to each number from 0 to 9 and then translating pi’s decimals into words, which in turn formed sentences. The first fifteen digits sounded like: ‘the wife and children have gone abroad; the husband is not scared.’ Using words to remember the digits in pi this way is used by schoolchildren in cultures all over the world, but usually this is done not by assigning syllables, but by creating a phrase in which the number of letters in each word represents each consecutive digit in the decimal expansion of pi. A well-known English one is credited to the astrophysicist Sir James Jeans: *How I need a drink, alcoholic in nature, after the heavy lectures involving quantum mechanics. All of thy geometry, Herr Planck, is fairly hard*. ‘How’ has 3 letters, ‘I’ has 1, ‘need’ has 4, and so on.

Among numbers, only pi has inspired this type of fandom. No one wants to memorize the square root of two, which is just as challenging. Pi is also the only number to have inspired its own literary subgenre. Constrained writing is a technique in which some condition is adopted that imposes a pattern or forbids certain things in the text. Entire poems – or ‘piems’ – have been written under the constraint that the number of letters per word is determined by pi, usually with the convention that a 0 in the expansion requires a ten-letter word. The most ambitious piem is the *Cadaeic Cadenza* by Mike Keith, which follows pi for 3835 digits. It begins as a pastiche of Edgar Allan Poe:

> One; A poem
>
> A Raven
>
> Midnights so dreary, tired and weary,
>
> Silently pondering volumes extolling all by-now obsolete lore. During my rather long nap – the weirdest tap!
>
> An ominous vibrating sound disturbing my chamber’s antedoor. ‘This,’ I whispered quietly, ‘I ignore.’

Keith says that writing with a difficult constraint is an exercise both in discipline and discovery. Since the digits in pi are random, the constraint is, he said, ‘like bringing order out of chaos’. When I asked him ‘Why pi?’ he replied that pi was ‘a metaphor for all things infinite, or inscrutable, or unpredictable, or full of endless wonder’.

Pi has gone by this name only since 1706, when the Welshman William Jones introduced the symbol p in his book, the snappily titled *A New Introduction to the Mathematics, for the Use of some Friends who have neither Leisure, Convenience, nor, perhaps, Patience, to search into so many different Authors, and turn over so many tedious Volumes, as is unavoidably required to make but tolerable progress in the Mathematics*. The Greek letter, which was probably an abbreviation for the word periphery, did not immediately catch on, howeve, becoming standard notation for pi only 30 years later when Leonhard Euler adopted it.

Euler was the most prolific mathematician of all time (he published 886 books), and he is possibly the one who contributed most to an understanding of pi. It was his improved formulae for pi that enabled the eighteenth-and nineteenth-century digit-hunters to peel back more and more decimal places. In the beginning of the twentieth century the Indian mathematician Srinivasa Ramanujan devised many more Euler-style infinite series for pi.

Ramanujan was a largely self-taught mathematician who worked as a clerk in Madras before writing a letter to Cambridge university professor G.H. Hardy. Hardy was flabbergasted to see that Ramanujan had rediscovered results that had taken centuries to achieve, and invited him to England, where the men collaborated before Ramanujan died aged 32. His work showed an extraordinary intuition about the properties of numbers, including pi, and his most famous formula is the following:

$$\frac{1}{\pi} = \frac{2\sqrt{2}}{9801} \sum_{n=0}^{\infty} \frac{(4n)!(1103 + 26390n)}{(n!)^4 396^{4n}}$$

The $\sum_{n=0}^{\infty}$ symbol indicates a series of values all added up, starting with the value when *n* equals zero, added to the value when *n* equals one, and so on to infinity. Even without understanding the notation, however, one can appreciate the drama of such an equation. The Ramanujan formula races towards pi with remarkable speed. From the very start, when *n* is 0 the formula has one term and gives a value of pi accurate to six decimal places. For each increase in the value of *n*, the formula adds roughly eight new digits to pi. It is an industrial-strength pi-making machine.

Inspired by Ramanujan, in the 1980s the Ukrainian-born mathematicians Gregory and David Chudnovsky devised an even more ferocious formula. Each new term adds roughly 15 digits.

$$\frac{1}{\pi} = \sum_{n=0}^{\infty} (-1)^n \times \frac{(6n)!}{(3n)!\, n!^3} \times \frac{163096908 + 6541681608n}{(262537412640768000)^{n+½}}$$

The first time I saw the Chudnovsky formula I was standing on it. Gregory and David are brothers and they share an office at the Polytechnic University in Brooklyn. It consists of an open-plan space with a sofa in the corner, a couple of chairs and a blue floor decorated with dozens of formulae for pi. ‘We wanted to put something on the floor and what else can you put on the floor other than stuff which relates to mathematics?' explained Gregory.

In fact, the pi floor pattern was their second choice. The original plan was to lay down a giant reproduction of *Melencolia I* by Albrecht Dürer (reproduced on chapter 6). The sixteenth-century woodcut is beloved of mathematicians since it is full of playful references to numbers, geometry and perspective.

'One night, when there was nothing on the surface, we printed 2000 or more pages of [*Melencolia I*] and we laid it on the floor,' said David. 'But if you walked around it, you wanted to throw up! Because your point of view changes extremely abruptly.' David began to study the floors of the cathedrals and castles of Europe in order to work out how he could decorate the office without inducing nausea in anyone walking through. 'I discovered they are mostly laid out in a –'

'Simple geometric style,' interrupted Gregory.

'Black, white, black, white squares…#8217; said David.

'You see, if you really have a complex picture and you try to walk on it, the angle changes so abruptly that your eyes don't like it,' added Gregory. 'So the only way you can do something like that is to –'

'Hang from the ceiling!' David shouted in my left ear, and both men lost themselves in guffaws.

Talking to the Chudnovskys was like wearing stereo headphones with an erratically alternating connection to both ears. They sat me on their sofa and sat on either side of me. Constantly interrupting each other, they finished each other's sentences, speaking in a highly melodic English thick with Slavic tones. The brothers were born in Kiev, when it was in the Soviet Republic of Ukraine, although they have lived in the United States since the late 1970s and are American citizens. They have collaborated on so many papers and books together that they encourage you to think of them as one mathematician, not two.

For all their genetic, conversational and professional homogeneity, however, the men look very different. This is mostly because Gregory, who is 56, suffers from *myasthenia gravis*, an auto-immune disorder of the muscles. He is so thin and frail that he spends most of his time lying down. I never saw him get up off the sofa. Still, the energy his limbs lacked was compensated for by a brilliantly expressive face that burst into life as soon as he talked about maths. He has pointed features, large brown eyes, a white beard and wispy unkempt hair. David, who has blue eyes, is five years older, rounder of body and fuller of face.

He was clean-shaven and his short hair was hidden under an olive-green baseball cap.

The Chudnovskys are arguably the mathematicians who have done the most to popularize pi in recent years. In the early 1990s they built a supercomputer in Gregory's Manhattan apartment out of mail-order parts that, using their own formula, calculated the number to more than two billion decimal places – a record at the time.

This amazing achievement was chronicled in a *New Yorker* article, which in turn inspired the 1998 film *Pi*. The main protagonist was an unruly-haired maths genius looking for hidden patterns in stock-market data on a homemade supercomputer. I was curious to discover if the Chudnovskys had seen the film, which garnered favourable reviews and has become a reference for low-budget, black-and-white psycho-mathematical thrillers. 'No, no, we haven't seen it,' said Gregory.

'You have to realize, usually movie-makers repeat their internal state,' added David sarcastically.

I tell them I thought they might have been flattered by the attention.

'No, no,' grinned Gregory.

'Let me tell you another thing,' David cut in. 'Two years ago I came back from France. A couple of days before I left, there was a huge book fair. I stopped at a stand where there was a book that had a detective story on it. It was written by an engineer. It was a murder mystery, you know. A lot of dead bodies, mostly mistress in hotel, and the source that determined everything he did was pi.'

Gregory was smiling from ear to ear and said under his breath: 'OK, I am not going to read this book, *zat's* for sure.'

David carried on: 'So I talked to the guy. He is a very eucated man.' He paused, shrugged his shoulders and raised his pitch by an octave: 'As I say, I bear no responsibility!'

David said that he was taken aback the first time that he saw billboards advertising the Givenchy perfume. 'All the way down the street was pi…pi…pi…' He was wailing now: '*Pi…pi…pi!* Do I bear any responsibility?'

Gregory glanced at me and said: 'For some reason, the general public is fascinated with this stuff. They get kind of the wrong inference.' There are many professional mathematicians, he said, who study pi. He added wryly: 'Usually these people are not allowed to see the light of day.’

In the 1950s and 1960s advances in computer technology were reflected in the number of new digits found in pi. By the end of the 1970s the record had been broken nine times and stood at just over a million decimal places. In the 1980s, however, a combination of even faster computers and brand-new algorithms led to a frenetic new era of digit-hunting. Yasumasa Kanada, a young computer scientist at Tokyo University, was first off the block in what became a two-way pi race between Japan and the United States. In 1981 he used an NEC computer to calculate pi to 2 million digits in 137 hours. Three years later he was up to 16 million. William Gosper, a mathematician in California, then nudged into the lead with 17.5 million, before David H. Bailey, at NASA, bettered him with 29 million. In 1986 Kanada overtook them both with 33 million and broke his own record three times in the next two years to reach 201 million with a new machine, the S-820, which did the calculation in just under six hours.

Away from the digit-hunting spotlight, the Chudnovskys were also beavering away on pi. Using a new method of communication called the internet, Gregory connected the computer at his bedside to two IBM supercomputers at different sites in the US. The brothers then devised a program to calculate pi based on the new superfast pi formula they had discovered. They were allowed on to the computers only when no one else was using them, at nights and weekends.

‘It was a great thing,’ remembered Gregory nostalgically. In those days there was no computer capacity to store the numbers that the brothers were calculating. ‘They kept the pi on magnetic tape,’ he said.

‘Mini-tape. And you had to call the guy and ask…’ added David.

‘And say tape number such and such,’ continued Gregory. ‘And sometimes if somebody else is more important your tapes are dismounted in the middle of computation.’ His eyes rolled as if to throw his hands in the air.

Despite the obstacles, the Chudnovskys kept on going, pushing beyond a billion digits. Kanada then nudged ahead of them briefly, before the Chudnovskys retook the lead with 1.13 billion. David and Gregory then decided that if they were serious about calculating pi they needed their own machine.

The Chudnovskian supercomputer lived in a room in Gregory’s apartment.

Made up of processors linked by cables, the whole thing cost, according to their estimates, about $70,000. It was a steal, compared to the millions of dollars that would have bought a machine of similar capacity; although it came with its own complications to their lifestyles. The computer, which they called *m zero*, was switched on at all times, just in case switching it off was irreversible, and keeded 25 fans in the room to keep it cool. The brothers were careful not to switch on too many lights in the apartment just in case the added demand blew the wiring.

In 1991 David and Gregory's homemade contraption calculated pi to more than two billion places. Then they got distracted by other problems. By 1995 Kanada was ahead once again, and he reached 1.2 trillion digits in 2002, a record that lasted only until 2008, when compatriots at the University of Tsukuba revealed 2.6 trillion. In December 2009 the Frenchman Fabrice Bellard claimed a new record using the Chudnovsky formula: almost 2.7 trillion places. The calculation had taken 131 days on his desktop PC.

If you wrote a trillion digits in small type, the distance would cover from here to the sun. If you put 5000 digits on a page (which is very small type) and stacked the pages on top of each other, the pi in the sky would be 10km high. What is the point of calculating pi to such absurd lengths? One reason is very human: records exist to be broken.

But there is another, more important motivation. Finding new digits in pi is ideal for testing the processing capacity and reliability of computers. 'I have no interest as a hobby for extending the known value of pi itself,' Kanada once said. 'I have a major interest for improving the performance of the computation.' Pi calculation is now essential for quality-testing supercomputers because it is a 'high-duty job which requires large main memory, operates huge number-crunching and gives [an] easy [way] to check [the] correct answer. Mathematical constants like the square root of two, *e*[*] [and] gamma are some of the candidates, but pi is most effective.'

The story of pi has wonderful circularity. It is the simplest and most ancient ratio in maths, which has been reinvented as a massively important tool on the frontline of computer technology.

In fact, the Chudnovskys' interest in pi came primarily from their desire to build supercomputers, a passion that still burns brightly. The brothers are currently designing a chip that they claim will be the fastest in the world, only 2.7cm wide but containing 160,000 smaller chips and 1.75km of wire.

On discussion of their new chip, Gregory became very high-spirited:

‘Computers double their power every 18 months, not because they are faster but because they can pack more stuff in. But there is a catch,’ he said. The mathematical challenge was how to partition the smaller pieces so that they can talk to each other in the most efficient way. His laptop showed the chip’s circuitry. ‘I’d say the problem with this chip is that it is a capitalist chip!’ he exclaimed. ‘The problem is that most of the stuff here is not doing anything. There are not too much proles here.’ He pointed at one section. ‘This is just management of the stores inside the chip,’ he lamented. ‘The majority of these guys just do warehousing and accounting. This is awful! Where is the manufacturing sector?’

In Carl Sagan’s bestselling book *Contact*, an extraterrestrial informs a woman on Earth that after a certain amount of digits the randomness in pi stops and there is a message written in 0s and 1s. This message occurs after 10^{20} decimal places – which is the number described by 1 followed by 20 zeros. Since we currently know pi to ‘only’ 2.7 trillion places (27 followed by 11 zeros), we have a little way to goe s to check that he was making it up. Actually, we have further to go since the message is apparently written in base 11.

The idea that there is a pattern in pi is an exhilarating one. Mathematicians have been looking for signs of order in the decimal expansion of pi for as long as there have been decimal expansions. The irrationality of pi means that the numbers keep on spewing out with no repeated pattern, but this does not eliminate the possibility of patches of order – such as a message written in 0s and 1s. So far, however, no one has found anything significant. The number, does, though, have its quirks. The first 0 comes in position 32, which is much later than expected if the digits are randomly distributed. The first time a digit is repeated six times consecutively is 999999 at the 762nd decimal place. The likelihood of six 9s occurring so early if they occur randomly is less than 0.1 percent. This sequence is known as the Feynman point, since physicist Richard Feynman once remarked that he wanted to memorize pi until that point and finish by saying ‘nine, nine, nine, nine, nine, nine, and so on’. The next time pi throws up six consecutive identical digits happens in position 193,034 and they are also 9s. Is this a message from beyond, and if so what is it saying?

A number is considered *normal* if each of the digits 0 to 9 occurs equally often in the number’s decimal expansion. Is pi normal? Kanada looked at the first 200 billion digits of pi and found that the digits occurred with the following frequencies:

0	20,000,030,841	5	19,999,917,053
1	19,999,914,711	6	19,999,881,515
2	20,000,136,978	7	19,999,967,594
3	20,000,069,393	8	20,000,291,044
4	19,999,921,691	9	19,999,869,180

Only the digit 8 seems a little overabundant, yet the difference is statistically insignificant. It would appear that pi is normal, yet no one has been able to prove it. And neither has anyone been able to prove that such a proof is impossible. There is a chance, therefore, that pi is *not* normal. Maybe after 10^{20} there really are just 0s and 1s?

A different, but related issue, is the positioning of the numbers. Are they distributed randomly? Stan Wagon analysed the first ten million digits of pi with a 'poker test': take five consecutive digits and consider them as if they are a poker hand.

Type of hand	**Actual occurrence**	**Expected occurrence**
All digits different	604,976	604,800
One pair, three different	1,007,151	1,008,000
Two pairs	216,520	216,000
Three of a kind	144,375	144,000
Full house	17,891	18,000
Four of a kind	8887	9000
Five of a kind	200	200

The right column is how many times we would expect to see the poker hands if pi was normal and each decimal place had an equal chance of being occupied by any digit. The results are well within the boundaries of what we would expect. Each pattern of numbers seems to appear with the frequency it would had each decimal place been randomly generated.

There are websites that can find you the first occurrence in pi of the numbers of your birthday. The first time the sequence 0123456789 occurs is at the 17,387,594,880th place – which was discovered only when Kanada got that far in 1997.

I asked Gregory if he ever believed an order would be found in pi. ‘There is no order,’ he replied dismissively. ‘And if there would be an order, it would be weird and not right. So there is no point wasting the time.’

Instead of focusing on patterns in pi, some see its very randomness as a tremendous expression of mathematical beauty. Pi is predetermined but it seems to mimic randomness extraordinarily well.

‘It is a very good random number,’ agreed Gregory.

Shortly after the Chudnovskys started computing pi they got a call from the United States government. David squealed an impersonation of the voice at the end of the line: ‘Could you please send pi?’

Random numbers are needed in industry and commerce. For example, just say a market-research company needs to poll a representative sample of a thousand people from a population of a million. The company will use a random-number generator to select the sample group. The better the generator is at providing random numbers, the more representative the sample will be – and the poll will be more accurate. Likewise, streams of random numbers are needed to simulate unpredictable scenarios when testing computer models. The more random the numbers, the more robust the testing will be. In fact, projects can fail if the random numbers used to test them are not random enough. ‘You are only as good as your random number,’ remarked David. ‘If you use terrible random numbers, you will end up in a terrible condition,’ concluded Gregory. Of all sets of available random numbers, the decimal expansion of pi is the best.

Yet there is a philosophical paradox. Pi is self-evidently not random. Its digits may behave like random digits, but they are fixed. For example, if the digits in pi were truly random then there would be only a 10 percent chance that the first digit after the decimal point is a 1, yet we know that it is 1 with absolute certainty. Pi exhibits randomness non-randomly – which is fascinating, and weird.

Pi is a mathematical concept that has been studied for thousands of years, yet it holds many secrets. There have been no great advances in understanding its nature since transcendence was proved almost a century and a half ago.

‘We actually don’t know about most of this stuff,’ said Gregory.

I asked if there would ever be a new advance in understanding pi.

‘Of course, of course,’ said Gregory, ‘There are always advances. Mathematics moves forward.’

‘It will be more miraculous but it won’t be nice,’ David said.

Nineteen sixty-eight was a year of counter-cultural uprisings around the world, and Britain was not immune to such generational upheaval. In May the Treasury announced the introduction of a revolutionary new coin.

The 50p piece was designed to replace the old ten-shilling note as part of the switch from imperial to decimal currency. Yet what set the coin apart was not its denomination, but its unorthodox shape.

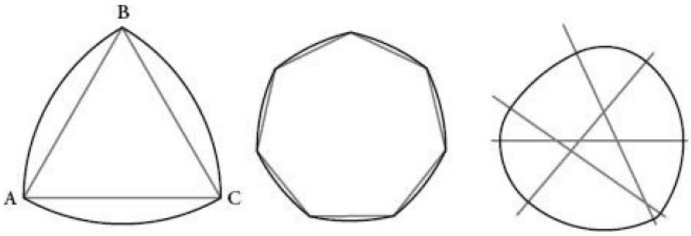
‘It’s no ordinary coin,’ exhorted the *Daily Mirror*. ‘Why, the Decimal Currency Board even go so far as to call it a “multilateral-curve heptagon”.’ Never before had a country introduced a seven-sided coin. And never before had a nation been so outraged over the aesthetics of a geometric shape. Leading the foment was retired army colonel Essex Moorcroft, of Rosset, Derbyshire, who formed the Anti-Heptagonists. ‘We take our motto from Cromwell’s heartfelt cry, “Take away this bauble”. I have founded the society because I believe our Queen is insulted by this heptagonal monstrosity,’ he said. ‘It is an ugly coin and an insult to our Sovereign, whose image it bears.’

Nonetheless, the 50p entered circulation in October 1969, and Colonel Moorcroft did not take to the barricaes. Indeed, by January 1970 *The Times* reported that ‘the curvaceous heptagon seems to have won for herself some affection’. Today the 50p piece is considered a distinctive and cherished part of British heritage. When a 20p piece was introduced in 1982, it too was heptagonal.

The 50p and 20p pieces are, in fact, design classics. Their seven-sided shape means that they are easily distinguished from circular coins, helping in particular the blind and partially sighted. They are also the most thought-provoking coins in circulation. The circle is not the only interesting round shape in mathematics.

A circle can be defined as a curve for which every point is equidistant from a fixed point, the centre. This property has many practical applications. The wheel – generally trumpeted as humanity’s first great invention – is the most obvious. An axle attached to the centre of a wheel will stay at a fixed point above the ground when the wheel rotates smoothly along a surface, which is why carts, cars and trains run smoothly without bobbing up and down.

For the transportation of very heavy loads, however, an axle might not take the weight. One alternative is to use rollers. A roller is a long tube with a circular cross-section, laid out on the ground. If a heavy object with a flat base (such as a giant cuboidal piece of stone intended for a pyramid) is put on several rollers, then it can be pushed smoothly over the rollers, with new rollers being put in front as it inches forward.



Curves of constant width include the Reuleaux triangle (left) and the multilateral-curve heptagon, better known as the 50p piece (centre).

The crucial feature of a roller is that the distance between the ground and the top of the roller is always the same. This is obviously the case with a circular cross-section, since the width of a circle (the diameter) is always the same.

Do all rollers have to have a circular cross-section? Are there any other shapes that will work? It may appear counter-intuitive, but there are, in fact, a variety of shapes that will make perfect rollers. An example is the 50p piece.

If you welded coins together to form rollers that had a 50p piece as a cross-section and then placed this book on these rollers, the book would not wobble up and down as you pushed it along. It would ride as smoothly as if on circular cylinders.

The reason this happens is because the 50p piece is a *curve of constant width*. Wherever you measure it around its perimeter, the 50p has the same breadth. So, when a 50p rolls along the floor, the distance from the floor to the top of the coin is always equal. A book lying atop a set of 50p rollers therefore stays at the same height.

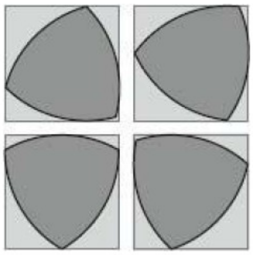
Surprisingly, there are many, many curves of constant width. The simplest is the Reuleaux triangle. It is constructed from an equilateral triangle by putting the point of a compass at each vertex and drawing the arc that goes between the other two vertices. In the diagram above, put the compass at A and move the pencil from B to C, and then repeat with the other vertices. The multilateral-curve heptagon is constructed the same way. Curves of constant width do not need to be symmetrical. It is possible to construct them from any number of lines crossing, as shown above right. The sections of perimeter are always arcs of a circle centred in the opposing vertex.

The curvilinear triangle owes its name to Franz Reuleaux, a German engineer who first wrote about its applications in his 1876 book *Kinematics of Machinery*. This was read many years later by H.G. Conway, a former president of the Institution of Mechanical Engineers, who sat on the British Treasury's Decimal Currency Board. Conway suggested a non-circular curve of constant breadth for the 50p piece since this property made it suitable for use in coin-operated machines. Machines distinguish coins by measuring diameter, and the 50p piece has the same width whichever position it is in. (A square coin, even with rounded sides, can never have constant width, which is why there are no four-sided coins.) Seven sides were chosen since it was considered the most aesthetically pleasing.

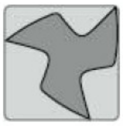
While the Reuleaux triangle reinvented the roller, it didn't reinvent the wheel. Wheels cannot be made of Reuleaux triangles because non-circular curves of constant width do not have a 'centre' – a fixed point that is equidistant from every point on the perimeter. If you put an axle on a Reuleaux triangle and rolled it, the height of the shape would stay the same but the axle would judder around.

One useful property of a Reuleaux triangle is that it can be rotated inside a square so that it touches all four sides of the square at all times. This property was exploited by Harry James Watts, an English engineer living in Pennsylvania, in 1914, when he designed one of the most bizarre tools in existence: a drill that can drill square holes. (The corners are rounded, rather than sharp, so, strictly speaking, the hole is a modified square.)

The cross-section of Watts's invention is simply a Reuleaux triangle, with three portions removed to make a cutting edge. It comes with a special chuck to compensate for the wobble of the drill bit's centre as it rotates. The Watts square-hole drill is still used today.



Reuleaux triangle rotating in square.



Cross-section of Watts's square drill.

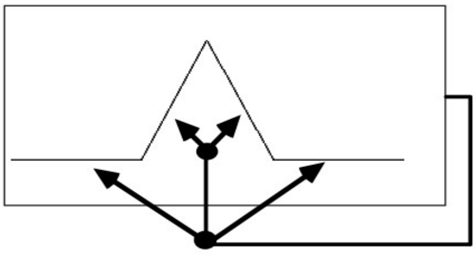
reentry as shown in the figure above. The recursion corresponding to the Koch eigenform is illustrated in the next figure (Fig. 8). Here we see the sequence of approximations leading to the infinite self-reflecting eigenform that is known as the Koch snowflake fractal.



K = K { K K } K

Figure 7.

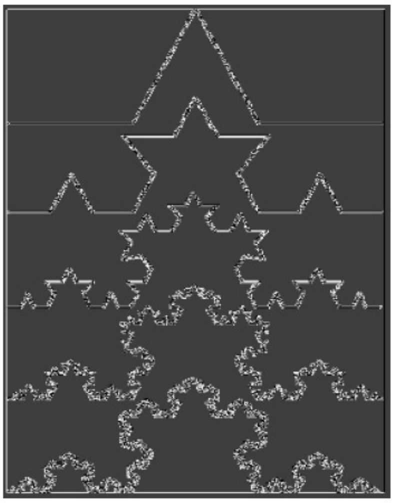


Figure 8.

Five stages of recursion are shown. To the eye, the last stage vividly illustrates how the ideal fractal form contains four copies of itself, each one-third the size of the whole. The abstract schema

K = K { K K } K

for this fractal can itself be iterated to produce a skeleton of the geometric recursion:

K = K { K K } K

= K { K K } K { K { K K } K K { K K } K } K { K K } K

= ...

We have only performed one line of this skeletal recursion. There are sixteen **K**'s in this second expression just as there are sixteen line segments in the second stage of the geometric recursion. Comparison with this symbolic recursion shows how geometry aids the intuition. The interaction of eigenforms with the geometry of physical, mental, symbolic and spiritual landscapes is an entire subject that is in need of deep exploration.

It is usually thought that the recognition of an object arises in some simple way from the assumed existence of the object and the action of our perceiving systems. This is a fine tuning to the point where the action of the perceiver and the perception of the object are indistinguishable. Such tuning requires an intermixing of the perceiver and the perceived that goes beyond description. Yet in the mathematical levels, such as number or fractal pattern, part of the process is slowed down to the point where we can begin to apprehend the process. There is a stability in the comparison, in the correspondence that is a process happening at once in the present time. The closed loop of perception occurs in the eternity of present individual time. Each such process depends upon linked and ongoing eigenbehaviors and yet is seen as simple by the perceiving mind. The perceiving mind is itself an eigenform.

3. The Square Root of Minus One and the Algebra of Iterants

The purpose of this section is to place **i**, square root of minus one, and its algebra in a process context. We then see that the square root of minus one is intimately related to time and the mathematical expression of time. The main point is that **i** can be interpreted as a primitive dynamical system that undergoes oscillation and nevertheless has a significant algebraic form associated with this iteration.

Traditionally **i**, the square root of minus one, arises from the fact that it is suggested by the solutions to quadratic equations. The simplest instance is the equation $\mathbf{x^2 + 1 = 0}$. A solution to this equation must have square equal to **-1**, but there are no real numbers whose square is **-1**. The square of a negative number is positive and the square of a positive number is positive and the square of zero is zero. Thus mathematicians (reluctantly at first) introduced an ideal number **i** such that $\mathbf{i^2 = -1}$. This number can be used to find solutions to other quadratic equations. For example **1+i** and **1-i** are the roots of $\mathbf{x^2 - 2x + 2 = 0}$.

The use of such complex numbers became indispensable when it was realized that they could be used in the solution of cubic equations in such a way that the real solution of a cubic was expressed naturally as a combination of two complex numbers such that the imaginary parts canceled out and all that was left was the real solution. Mathematicians began to seriously use complex numbers in the 1500's. It was not until around 1800 that Gauss and Argand discovered a geometric interpretation that opened up the subject to genuinely deep explorations.

The geometric interpretation of the complex numbers is well-known and we shall not repeat it here except to remark that **i** seen as a vector of unit length in the plane, and perpendicular to the horizontal axis. The horizontal axis is taken to be the real numbers. Multiplication by **i** is interpreted geometrically as rotation by **90** degrees. Thus **ii** is rotation by **180** degrees. Indeed the **180** degree rotate of **+1** is **-1**, and so **ii = -1**.

We now describe a process point of view for complex numbers. Think of the oscillatory process generated by

$$\mathbf{R(x) = -1/x.}$$

The fixed point would satisfy $\mathbf{i = -1/I}$ and multiplying, we get that $\mathbf{ii = -1}$. On the other hand the iteration of **R** on **1** yields $\mathbf{+1, R(1) = -1, R(R(1)) = +1, -1, +1, ...}$

Thus there must be a linkage between this ideal number **i** whose square is **-1** and the recursion that leads to an oscillation. The square root of minus one is a perfect example of an eigenform that occurs in a new and wider domain than the original context in which its recursive process arose. The process has no fixed point in the original domain.

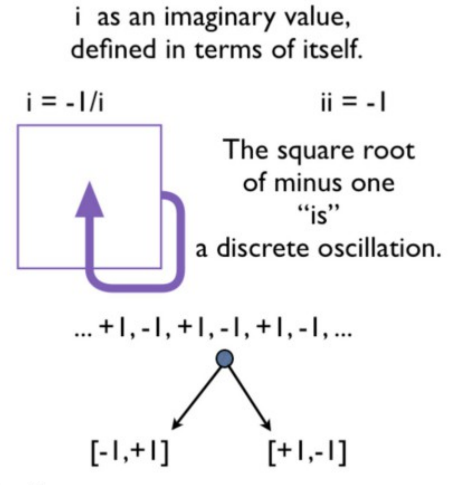

Figure 9.

Looking at the oscillation between **+1** and **-1**, we see that there are naturally two viewpoints that we denote by **[+1,-1]** and **[-1,+1]**. These viewpoints correspond to whether one regards the oscillation at time zero as starting with **+1** or with **-1**. We shall let **I{+1,-1}** stand for an undisclosed alternation or ambiguity between **+1** and **-1** and call **I{+1,-1}** an *iterant*. There are two *iterant views*: **[+1,-1]** and **[-1,+1]**.

Given an iterant **[a,b]**, we can think of **[b,a]** as the same process with a shift of one time step. These two iterant views, seen as points of view of an alternating process, will become the square roots of negative unity, **i** and **-i.** We introduce a *temporal shift operator* η such that

$$\mathbf{[a,b]}\eta = \eta\,\mathbf{[b,a]} \text{ and } \eta\,\eta = \mathbf{1}$$

for any iterant **[a,b]**, so that concatenated observations can include a time step of one-half period of the process **...abababab...** .

We combine iterant views term-by-term as in

$$\mathbf{[a,b][c,d] = [ac,bd]}.$$

We now define i by the equation, $\mathbf{i = [1,-1]}\eta$.

This makes **i** both a view of the iterant process and an operator that takes into account a step in time.

We calculate

$$\mathbf{ii = [1,-1]}\eta\,\mathbf{[1,-1]}\eta = \mathbf{[1,-1][-1,1]}\eta\,\eta = \mathbf{[-1,-1] = -1.}$$

Thus we have constructed the square root of minus one by using an iterant viewpoint. The key to rethinking the complex numbers in these terms is to understand that **i** represents a discrete oscillating temporal process and it is an eigenform participating in the algebraic structure of the complex numbers.

The Temporal Nexus

*We take as a matter of principle that the usual real variable **t** for time is better represented as **it** so that time is seen to be a process, an observation and a magnitude all at once.* This principle of imaginary time is justified by the eigenform approach to the structure of time and the structure of the square root of minus one. An example of the use of the Temporal Nexus, consider the expression $\mathbf{x^2 + y^2 + z^2 + t^2}$, the square of the Euclidean distance of a point **(x,y,z,t)** from the origin in Euclidean four-dimensional space. Now replace **t** by **it**, and find

$$\mathbf{x^2 + y^2 + z^2 + (it)^2 = x^2 + y^2 + z^2 - t^2,}$$

the squared distance in hyperbolic metric for special relativity. By replacing **t** by its process operator value **it** we make the transition to the physical mathematics of special relativity. We will discuss this theme further and relate the Temporal Nexus, the role of complex numbers in quantum mechanics and the role of temporal shift operators in discrete physics.

4. Quantum Physics, Eigenvalue, and Eigenform

Quantum is inextricably related to the complex numbers and in particular to the square root of minus one. We wish to show that the process view of the square root of minus one and the Temporal Nexus inform the epistemology of quantum theory. The reader should recall the Temporal Nexus from the previous section. *We take as a matter of principle that the usual real variable* ***t*** *for time is better represented as* ***it*** *so that time is seen to be a process, an observation and a magnitude all at once.* This principle of imaginary time is justified by our approach to the structure of time and the structure of the square root of minus one.

In quantum physics [11], the state of a physical system is modeled by a vector in a high-dimensional space, called a Hilbert space. As time goes on the vector rotates in this high dimensional space. Observable quantities correspond to Hermitian operators H on this vector space. Linearity is usually a simplifying assumption in mathematical models, but it is an essential feature of quantum mechanics. *In quantum mechanics observation is founded on the production of eigenvectors,* ***v*** *with* ***Gv = v*** *where* ***v*** *is a vector in a Hilbert space and* ***G*** *is a linear operator on that space.*

Many of the strange and fascinating properties of quantum mechanics emanate directly from this model of observation. In order to observe a quantum state, its vector is projected into an eigenvector for that particular mode of observation. By projecting the vector into that mode and not another, one manages to make the observation, but at the cost of losing information about the other possibilities inherent in the vector. This is the source, in the mathematical model, of the complementarities that allow exact determination of the position of a particle at the expense of nearly complete uncertainty about its momentum (or vice versa the determination of momentum at the expense of knowledge of the position).

Observation and quantum evolution (the determinate rotation of the state vector in the high dimensional Hilbert space) are interlocked. Each observation discontinuously projects the state vector to an eigenvector. The intervals between observations allow the continuous evolution of the state vector. This tapestry of interaction of the continuous and the discrete is the basis for the quantum mechanical description of the world. Is the quantum model, in its details, a consequence of general principles about systems? This is an exploration that needs to be made. We can only ask the question here. But the mysteries of the interpretation of quantum mechanics all hinge on an assumption of a world external to the quantum language. Thinking in terms of eigenform we can begin to look at how the physics of objects emerges from the model itself.

Where are the eigenforms in quantum physics? They are in the mathematics itself. For example, we have the simplest wave-function

$$\psi(x,t) = e^{i(kx - wt)}.$$

Since we know that the function $E(x) = e^x$ is an eigenform for operation of differentiation with respect to x, $\psi(x,t)$ is a special multiple eigenform from which the energy can be extracted by temporal differentiation, and the momentum can be extracted by spatial differentiation. We see in $\psi(x,t)$ the complexity of an individual who presents many possible sides to the world. $\psi(x,t)$ is an eigenform for more than one operator and it is a composition of e^x and **i**, the square root on minus one, a primordial eigenvalue related to time. It is this internal complexity that is mirrored in the uncertainty relations of Heisenberg and the complementarity of Bohr. The eigenforms themselves, as wavefunctions, are *inside* the mathematical model, on the *other side* of that which can be observed by the physicist.

We have seen eigenforms as the constructs of the observer, and in that sense they are on the side of the observer, even if the process that generates them is outside the realm of his perception. This suggests that we think again about the nature of the wave function in quantum mechanics. Is it also a construct of the observer? To see quantum mechanics and the world in terms of eigenforms requires a turning around, a shift of perception where indeed we shall find that the distinction between model and reality has disappeared into the world of appearance.

This is a reversal of epistemology, a complete turning of the world upside down. Eigenform has tricked us into considering the world of our experience and we find that it is our world, generated by our actions. The world has become objective through the self-generated stabilities of those actions.

A Quick Review of Quantum Mechanics

De Broglie hypothesized two fundamental relationships: between energy and frequency, and between momentum and wave number. These relationships are summarized in the equations

$$E = \hbar\omega,$$

$$p = \hbar k,$$

where **E** denotes the energy associated with a wave and **p** denotes the momentum associated with the wave**.** Here $\hbar = h/2\pi$ where **h** is Planck's constant. Schrödinger answered the question: *Where is the wave equation for De Broglie's waves?* Writing an elementary wave in complex form

$$\psi = \psi(x,t) = \exp(i(kx - wt)),$$

we see that we can extract De Broglie's energy and momentum by differentiating:

$$i\hbar\partial\psi/\partial t = E\psi \quad \text{and} \quad -i\hbar\partial\psi/\partial x = p\psi\,.$$

This led Schrödinger to postulate *the identification of dynamical variables with operators* so that the first equation, $i\hbar\partial\psi/\partial t = E\psi$, is promoted to the status of an equation of motion while the second equation becomes the definition of momentum as an operator:

$$p = -ih\partial/\partial x\,.$$

Once **p** is identified as an operator, the numerical value of momentum is associated with an eigenvalue of this operator, just as in the example above. In our example $py = \hbar k\psi$**.** In this formulation, the position operator is just multiplication by **x** itself. Once we have fixed specific operators for position and momentum, the operators for other physical quantities can be expressed in terms of them. We obtain the energy operator by substitution of the momentum operator in the classical formula for the energy:

$$E = (1/2)mv^2 + V$$
$$E = p^2/2m + V$$
$$E = -(\hbar^2/2m)\partial^2/\partial x^2 + V.$$

Here **V** is the potential energy, and its corresponding operator depends upon the details of the application. With this operator identification for **E**, Schrödinger's equation

$$i\hbar\partial\psi/\partial t = -(\hbar^2/2m)\partial^2\psi/\partial x^2 + V\psi$$

or equivalently,

$$\partial y/\partial t = i(\hbar/2m)\partial^2\psi/\partial x^2 - (i/\hbar)V\psi$$

is an equation in the first derivatives of time and in second derivatives of space. In this form of the theory one considers general solutions to the differential equation and this in turn leads to excellent results in a myriad of applications. It is useful to point out that Schrödinger's equation without the potential term has the form

$$\partial y/\partial t = i(\hbar/2m)\partial^2\psi/\partial x^2.$$

It is in this form that we shall compare it with discrete processes in the next section. There we shall use the Temporal Nexus to obtain new insight into the role of **i** in this equation.

In quantum theory, observation is modeled by the concept of eigenvalues for corresponding operators. *The quantum model of an observation is a projection of the wave function into an eigenstate.* An energy spectrum, **{Ek}** corresponds to wave functions, **y** satisfying the Schrödinger equation, such that there are constants Ek with $E\psi = Ek\psi$. An *observable* (such as energy) **E** is a Hermitian operator on a Hilbert space of wavefunctions. Since Hermitian operators have real eigenvalues, this provides the link with measurement for the quantum theory.

It is important to notice that there is no mechanism postulated in this theory for how a wave function is sent into an eigenstate by an observable. Just as mathematical logic need not demand causality behind an implication between propositions, the logic of quantum mechanics does not demand a specified cause behind an observation. This absence of an assumption of causality in logic does not obviate the possibility of causality in the world. Similarly, the absence of causality in quantum observation does not obviate causality in the physical world. Nevertheless, the debate over the interpretation of quantum theory has often led its participants into asserting that causality has been demolished in physics.

Note that the operators for position and momentum satisfy the equation $xp - px = \hbar i$. This corresponds directly to the equation obtained by Heisenberg, on other grounds, that dynamical variables can no longer necessarily commute with one another. In this way, the points of view of De Broglie, Schrödinger and Heisenberg came together, and quantum mechanics was born. In the course of this development, interpretations varied widely. Eventually, physicists came to regard the wave function not as a generalized wave packet, but as a carrier of information about possible observations. In this way of thinking y^*y (y^* denotes the complex conjugate of **y**) represents the probability of finding the particle (A particle is an observable with local spatial characteristics.) at a given point in spacetime. Strictly speaking, it is the spatial integral of $\psi^*\psi$ that is interpreted as a total probability with $\psi^* \psi$ the probability density. This way of thinking is supported by the fact that the total spatial integral is time-invariant as a consequence of Schrödinger's equation!

5. Iterants, Complex Numbers, and Quantum Mechanics

We have seen that there are indeed eigenforms in quantum mechanics. *The eigenforms in quantum mechanics are the mathematical functions such as* e^x *that are invariant under operators such as* $D = d/dx$.

But we wish to examine the relationship between recursion, reflexive spaces and the properties of the quantum world. The hint we have received from quantum theory is that we should begin with mathematics which is replete with eigenforms. In fact, this hint seems very rich when we consider that **i**, the square root of minus one, is a key eigenform in our panoply of eigenforms and it is a key ingredient in quantum mechanics intimately related to the role of time.

Revisiting the Temporal Nexus

If we define

$$R(A) = -1/A$$

then **R(i) = i** since $i^2 = -1$ is equivalent to **i = -1/i.** Using the infinite recursion we would then write

$$i = -1/-1/-1/-1/-1/... ,$$

making **i** an infinite reentry form for the operator **R.** We will write

$$i = [-1/*]$$

where * denotes the reentry of the whole form into that place in the right-hand part of the expression. Similarly, if **F(x) = 1 + 1/x,** then the eigenform would be **[1 + 1/*]** and we could write $(1+\sqrt{5})/2 = [1 + 1/*]$. With this in place we can now consider wave functions in quantum mechanics such as

$$y(x,t) = \exp(i(kx - wt)) = \exp([-1/*] (kx - wt))$$

and we can consider classical formulas in mathematics such as *Euler's formula*

$$\exp([-1/*]j) = \cos(j) + [-1/*] \sin(j)$$

in this light. We start here with Euler's formula, for this formula is the key relation between complex numbers, **i**, waves and periodicity.

We return to the finite nature of **[-1/*]**. This eigenform is an oscillator between **-1** and **+1**. It is only **i** in its idealization. In its appropriate synchronization it has the property that **i = -1/i**. As a real oscillator, the equation **R(i) = -1/i** tells us that when **i** is **1**, then i is transformed to **-1** and when **i** is **-1** then **i** is transformed to **+1**. There is no fixed point for **R** in the real domain. The eigenform is achieved by leaving the real domain for a new and larger domain.

We know that this larger domain can be conceptualized as the plane with Euclidean rotational geometry, but here we explore the larger domain in terms of eigenforms. *We find that* **i** *itself is a fundamental discrete process, and it is in the microworld of such discrete physical processes that not only quantum mechanics, but also classical mechanics is born.*

Iterants and Iterant Views

In order to think about i, consider an infinite oscillation between **+1** and **-1**:

... -1,+1,-1,+1,-1,+1,-1,+1,...

This oscillation can be seen in two distinct ways. It can be seen as **[-1,+1]** (a repetition in this order) or as **[+1,-1]** (a repetition in the opposite order). This suggests regarding an infinite alternation such as

... a,b,a,b,a,b,a,b,a,b,a,b,a,b,...

as an entity that can be seen in two possible ways, indicated by the ordered pairs **[a,b]** and **[c,d]**. We shall call the infinite alternation of **a** and **b** the *iterant* of **a** and **b** and denote it by **I{a,b}**. Just as with a set **{a,b}**, the iterant is independent of the order of **a** and **b**.

We have **I{a,b} = I{b,a}**, but there are two distinct views of any iterant and these are denoted by **[a,b]** and **[b,a]**. The key to iterants is that two representatives of an iterant can *by themselves* appear identical, but *taken together* are seen to be different. For example, consider

... a,b,a,b,a,b,a,b,a,b,a,b,a,b,...

and also consider

...b,a,b,a,b,a,b,a,b,a,b,a,b,a,...

There is no way to tell the difference between these two iterants except by a direct comparison as shown below

... a,b,a,b,a,b,a,b,a,b,a,b,a,b,...
... b,a,b,a,b,a,b,a,b,a,b,a,b,a,...

In the direct comparison we see that if one of them is **[a,b]**, then the other one should be **[b,a]**. Still, there

The Poincaré transformations

In this Chapter, we examine the general properties of the Poincaré group, i.e. the group of inhomogeneous Lorentz transformations, which are space-time coordinate transformations between any two inertial frames of reference. Then we consider those unitary irreducible representations of this group which are the most suitable for the description of the quantum mechanical states of one or more particles.

It is well known from special relativity that all inertial frames of reference are completely equivalent for the description of the physical phenomena; in fact, the physical laws are the same in all inertial frame or, in other words, they are *invariant* under the Poincaré transformations. The importance of the Poincaré group is related to this invariance principle. We refer to Section 9.2 for a brief discussion on *invariance principles*, symmetries and conservation laws.

4.1 Group properties

The inhomogeneous Lorentz transformations, or Poincaré transformations, connect the space-time coordinates of any two frames of reference whose relative velocity is constant.

A general Poincaré transformation can be written, as a generalization of a homogeneous Lorentz transformation (3.1), in the form

$$x'^{\mu} = \Lambda^{\mu}{}_{\nu} x^{\nu} + a^{\mu} \,, \tag{4.1}$$

where a^{μ} $(\mu = 0, 1, 2, 3)$ stand for the components of a vector in $\mathcal{R}^4$. We shall denote the above transformation by (a, Λ).

It is easy to see that the transformations (a, Λ) form a group: the so-called *Poincaré group*, denoted in the following by $\mathcal{P}$. In particular, the application of two successive transformations (a_1, Λ_1), (a_2, Λ_2) gives

$$x' = \Lambda_1 x + a_1 \,, \qquad x'' = \Lambda_2 x' + a_2 = \Lambda_2 \Lambda_1 x + \Lambda_2 a_1 + a_2 \,, \tag{4.2}$$

G. Costa and G. Fogli, *Symmetries and Group Theory in Particle Physics*,
Lecture Notes in Physics 823, DOI: 10.1007/978-3-642-15482-9_4,

© Springer-Verlag Berlin Heidelberg 2012

so that the product of the two transformations is

$$(a_2, \Lambda_2)(a_1 \Lambda_1) = (a_2 + \Lambda_2 a_1, \Lambda_2 \Lambda_1) \ . \tag{4.3}$$

Clearly the unit element is $(0, I)$; then from Eq. (4.3) one gets the inverse element

$$(a, \Lambda)^{-1} = (-\Lambda^{-1} a, \Lambda^{-1}) \ . \tag{4.4}$$

The group $\mathcal{P}$ is characterized by 10 parameters: the 6 parameters of the homogeneous Lorentz group plus the 4 parameters a^μ.

Obviously, the Poincaré group contains, as a subgroup, the homogeneous Lorentz group $\mathcal{L}$ of the transformations $(0, \Lambda)$; it contains also the subgroup $\mathcal{S}$ of the four dimensional translations(a, I), which is an Abelian invariant subgroup of $\mathcal{P}$. Any Poincaré transformation can be written in a unique way as the product of a pure translation and a homogeneous Lorentz transformation

$$(a, \Lambda) = (a, I)(0, \Lambda) \ , \tag{4.5}$$

$$(a, \Lambda) = (0, \Lambda)(\Lambda^{-1} a, I) \ . \tag{4.6}$$

This shows that the Poincaré group is the semi-direct product of the two subgroups:

$$\mathcal{P} = \mathcal{S} \ \circledS \ \mathcal{L} \ . \tag{4.7}$$

We note that the order of the transformations in Eqs. (4.5), (4.6) is important, since the translations do not commute with the Lorentz transformations. From the above relations one gets easily the useful result

$$(0, \Lambda^{-1})(a, I)(0, \Lambda) = (\Lambda^{-1} a, I) \ . \tag{4.8}$$

We know that the group $\mathcal{L}$ consists of four disjoint components $\mathcal{L}_+^\uparrow$, $\mathcal{L}_-^\uparrow$, $\mathcal{L}_+^\downarrow$, $\mathcal{L}_-^\downarrow$, corresponding to the possible choices of the signs of $\det \Lambda$ and $\Lambda^0{}_0$ listed in Table 3.1. Similarly, the group $\mathcal{P}$ consists of four disjoint components $\mathcal{P}_+^\uparrow$, $\mathcal{P}_-^\uparrow$, $\mathcal{P}_+^\downarrow$, $\mathcal{P}_-^\downarrow$, each of which contains the corresponding component of the subgroup $\mathcal{L}$.

In this Chapter, we shall limit ourselves to the transformations of $\mathcal{P}_+^\uparrow = \mathcal{S} \ \circledS \ \mathcal{L}_+^\uparrow$, which form the proper orthochronous inhomogeneous Lorentz group. We briefly mention the topological properties of $\mathcal{P}_+^\uparrow$, which are easily derived from those of its subgroups:

a) The group $\mathcal{P}_+^\uparrow$ is *non-compact*; in fact, it contains the subgroups $\mathcal{L}_+^\uparrow$ and $\mathcal{S}$ which are both non-compact (the translation group $\mathcal{S}$ is clearly non-compact, since $\mathcal{R}^4$ is not compact);
b) The group $\mathcal{P}_+^\uparrow$ is *doubly-connected*: it has the same connectedness of its subgroup $\mathcal{L}_+^\uparrow$ (specifically of $SO(3)$). Its *universal covering group* is defined by the transformations (a, A), where A is an element of $SL(2, C)$;
c) The group $\mathcal{P}_+^\uparrow$ is neither simple nor semi-simple, in fact, the translation group $\mathcal{S}$ is an invariant subgroup of $\mathcal{P}_+^\uparrow$.

Next we consider the Lie algebra of the group $\mathcal{P}_+^\uparrow$; its basic elements are the infinitesimal generators of $\mathcal{L}_+^\uparrow$ and $\mathcal{S}$.

In general, an infinitesimal translation is given by

$$(\delta a, I) = I - i\delta a_\mu P^\mu \ , \tag{4.9}$$

introducing four operators P^μ, which are the infinitesimal generators of the translations. A finite translation is given by exponentiation, as

$$(a, I) = e^{-ia_\mu P^\mu} \ . \tag{4.10}$$

The commutation relations of the infinitesimal generators are easily obtained giving a specific representation of the Lie algebra of $\mathcal{P}_+^\uparrow$. For this purpose it is convenient to write (a, Λ) as a 5×5 matrix

$$\begin{pmatrix} \Lambda & a \\ 0 & 1 \end{pmatrix} , \tag{4.11}$$

where the four vector a is written as a column matrix. Eq. (4.2) is then obtained by matrix product, and Eq. (4.1) can be considered as the transformation of a vector

$$y = \begin{pmatrix} x \\ 1 \end{pmatrix} \tag{4.12}$$

in a five-dimensional space. In fact, it can be re-written as

$$\begin{pmatrix} x' \\ 1 \end{pmatrix} = \begin{pmatrix} \Lambda & a \\ 0 & 1 \end{pmatrix} \begin{pmatrix} x \\ 1 \end{pmatrix} = \begin{pmatrix} \Lambda x + a \\ 1 \end{pmatrix} . \tag{4.13}$$

Expressing in similar way the infinitesimal transformation (4.9), one can obtain explicitly

$$P_0 = \begin{pmatrix} 0 & 0 & 0 & 0 & i \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \end{pmatrix} , \qquad P_1 = \begin{pmatrix} 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & i \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \end{pmatrix} , \tag{4.14}$$

and similarly for P_2, P_3.

In the same representation, the generators J_i and K_i are replaced by 5×5 matrices, obtained from (3.50) and (3.54) by adding a fifth row and a fifth column of zeros.

One can check that the following commutation relations hold:

$$\begin{aligned} [P_\mu, P_\nu] &= 0 \ , \\ [J_i \ , P_0] &= 0 \ , \\ [J_i \ , P_i\,] &= 0 \ , \\ [J_i \ , P_j] &= i\epsilon_{ijk} P_k \ , \\ [K_i, P_0] &= -iP_i \ , \\ [K_i, P_i\,] &= -iP_0 \ , \\ [K_i, P_j] &= 0 \ . \end{aligned} \tag{4.15}$$

In terms of the antisymmetric tensor $M_{\mu\nu}$ given by (3.59), the above commutators become:

$$\begin{aligned} [P_\mu, P_\nu] &= 0 \,, \qquad (4.16)\\ [M_{\mu\nu}, P_\rho] &= -i(g_{\mu\rho}P_\nu - g_{\nu\rho}P_\mu) \,, \qquad (4.17) \end{aligned}$$

and, together with the commutators

$$[M_{\lambda\rho}, M_{\mu\nu}] = -i(g_{\lambda\mu}M_{\rho\nu} + g_{\rho\nu}M_{\lambda\mu} - g_{\lambda\nu}M_{\rho\mu} - g_{\rho\mu}M_{\lambda\nu}) \,, \qquad (3.60)$$

they define the Lie algebra of $\mathcal{P}_+^\uparrow$.

One can check that the operator

$$P^2 = P_\mu P^\mu \qquad (4.18)$$

commutes with all the generators P_μ, $M_{\mu\nu}$ of the Lie algebra; hence P^2 is an invariant operator under the Poincaré transformations.

Let us introduce the operator

$$W_\mu = \epsilon_{\mu\nu\sigma\tau} M^{\nu\sigma} P^\tau \,; \qquad (4.19)$$

it follows immediately that

$$W_\mu P^\mu = 0 \,. \qquad (4.20)$$

Moreover, making use of Eqs. (3.60), (4.17), one can obtain the following commutators

$$\begin{aligned} [P_\mu, W_\nu] &= 0 \,, \\ [M_{\mu\nu}, W_\sigma] &= -i(g_{\nu\sigma}W_\mu - g_{\mu\sigma}W_\nu) \,, \qquad (4.21)\\ [W_\mu, W_\nu] &= i\epsilon_{\mu\nu\sigma\tau} W^\sigma P^\tau \,. \end{aligned}$$

Finally, one can prove that the operator

$$W^2 = W_\mu W^\mu \qquad (4.22)$$

commutes with all the P_μ and $M_{\mu\nu}$ and hence it is an invariant operator.

The eigenvalues of the invariant operators P^2 and W^2 are used to label the IR's of the group; for some classes of IR's one can have additional invariants.

4.2 Unitary representations of the proper orthochronous Poincaré group

In the previous Section, we have exhibited a 5-dimensional representation of the proper orthochronous Poincaré group $\mathcal{P}_+^\uparrow$, which is not unitary, since both the generators P_μ and K_i are expressed by non-hermitian matrices. In fact, as pointed out in Subsection 1.2.1, since the group $\mathcal{P}$ and its subgroup $\mathcal{P}_+^\uparrow$ are not compact, no finite-dimensional unitary IR's exists.

We recall from quantum mechanics[1] the well known fact that the infinitesimal generators of translations P_μ can be identified with the *energy-momentum operators*. Moreover, the infinitesimal generators $M_{\mu\nu}$ can be identified with the components of the *angular momentum tensor*. For physical applications, we are interested in those IR's in which the operators P_μ and $M_{\mu\nu}$ are *hermitian*, since they correspond to dynamical variables, i.e. in the *unitary*, and hence infinite-dimensional, IR's of the Poincaré group $\mathcal{P}$. Here we are mainly concerned with the IR's of the restricted group $\mathcal{P}_+^\uparrow$.

Before going to the IR's of $\mathcal{P}_+^\uparrow$, we want to review briefly some general properties of the invariance principles for a quantum mechanical system. Each state of the system is represented by a vector $|\Phi>$ in a Hilbert space. The state vectors are normalized to unity, to allow the probability interpretation; two vectors that differ only by a phase represent the same physical state. In fact, the results of experiments are expressed in terms of transition probabilities

$$|<\Psi|\Phi>|^2 \tag{4.23}$$

between the states $|\Phi>$ and $|\Psi>$, which depend only on the absolute value of the scalar product between the two states. This shows that each vector in the set $e^{i\alpha}|\Phi>$, where α is a real number, corresponds to the same physical state. The collection of all the state vectors of the form $e^{i\alpha}|\Phi>$ is called a *ray*, which we denote simply by Φ.

An *invariance principle*, or *symmetry operation*, of a physical system is a one-to-one correspondence between two rays Φ and Φ' (and similarly between Ψ and Ψ'), representing physically realizable states, such that the transition probabilities remain unchanged:

$$|<\Psi'|\Phi'>|^2 = |<\Psi|\Phi>|^2 \ . \tag{4.24}$$

An important theorem due to Wigner[2] states that, if $\Phi \to \Phi'$ is a symmetry operation of a physical theory, there exists a *linear unitary* or *antilinear unitary*[3] (antiunitary) operator U, determined up to a phase, such that:

$$\Phi' = U\Phi \ . \tag{4.25}$$

---

[1] See e.g. S. Weinberg, *The Quantum Theory of Fields, Vol. I, Foundations*, Cambridge University Press (1995).

[2] See e.g. F.R. Halpern, *Special Relativity and Quantum Mechanics*, Prentice-Hall (1968).

[3] An antilinear unitary operator U is defined by

$$\begin{aligned} <U\Psi|U\Phi> &= <\Psi|\Phi>^*, \\ U|\alpha\Psi + \beta\Phi> &= \alpha^* U|\Psi> + \beta^* U|\Phi> \ . \end{aligned}$$

In particular, if a physical system is invariant under the transformations of the Poincaré group, to each element (a, Λ) of $\mathcal{P}$ there corresponds a linear operator $U(a, \Lambda)$ which transforms the state Φ into

$$\Phi' = U(a, \Lambda)\,\Phi\ , \tag{4.26}$$

leaving Eq. (4.24) invariant. The operator $U(a, \Lambda)$ is determined up to a phase; however, for those Poincaré transformations which are connected with the identity, such as the transformations of the subgroup $\mathcal{P}_+^\uparrow$, it can be shown that it is possible to choose a phase convention such that the product of any two elements of $\mathcal{P}_+^\uparrow$ is always given by[4]:

$$U(a_1, \Lambda_1)U(a_2, \Lambda_2) = \pm U(a_3, \Lambda_3)\ . \tag{4.27}$$

The sign ambiguity is related to the fact that the group $\mathcal{P}$ is doubly connected, and it can have double-valued representations.

We stress the fact that the operators $U(a, \Lambda)$ of $\mathcal{P}_+^\uparrow$ are *unitary*. In fact, for any element (a, Λ) of $\mathcal{P}_+^\uparrow$ one can find an element (a', Λ') such that

$$(a, \Lambda) = (a', \Lambda')(a', \Lambda')\ . \tag{4.28}$$

Then, from Eq. (4.27):

$$U(a, \Lambda) = \pm U(a', \Lambda')U(a', \Lambda')\ . \tag{4.29}$$

According to Wigner's theorem, $U(a', \Lambda')$ could be either unitary or antiunitary, but in both cases, since the square of an antiunitary operator is unitary, $U(a, \Lambda)$ can only be unitary. Since $U(a, \Lambda)$ is an arbitrary element of $\mathcal{P}_+^\uparrow$, it follows that all the linear operator $U(a, \Lambda)$ are unitary.

We have thus obtained a representation of the group $\mathcal{P}_+^\uparrow$ in the Hilbert space of the state vectors $|\Phi>$ in terms of the unitary operators $U(a, \Lambda)$.

The unitary representation realized by the operators $U(a, \Lambda)$ is, of course, *infinite-dimensional*, since the Hilbert space of the state vectors $|\Phi>$ is infinite-dimensional, but it is, in general, reducible. To obtain the *unitary irreducible representations*, one has to find the invariant subspaces, i.e. invariant under the transformations (a, Λ).

To make this point clear, let us consider a given set of vectors $|\Phi>$ in the Hilbert space. Since the P_μ commute among themselves (see eq. (4.16)), it would be convenient to start from the vectors $|p, \zeta>$, labelled by the eigenvalues p_μ of P_μ and by other, for the moment unspecified, quantum number ζ:

$$P_\mu|p, \zeta> = p_\mu|p, \zeta>\ . \tag{4.30}$$

Now we are facing the following problem: the vectors $|p, \zeta>$ correponding to particular points p_μ in the momentum space are not normalizable, so that they do not belong to the Hilbert space. One can obtain normalizable vectors by convenient linear superposition of $|p,\zeta>$[5]. However, for the sake of simplicity, we shall adopt the normalization in terms of the Dirac delta function, widely used in the physics literature[6] and, with the inclusion of the convenient factor $2p_0$, define:

---

[4] F.R. Halpern, quoted ref.

$$<p',\zeta'|p,\zeta> = 2p_0\,\delta^3(\mathbf{p}'-\mathbf{p})\delta_{\zeta'\zeta}\;. \tag{4.31}$$

For a pure translation, from Eq. (4.10), we get

$$U(a,I)\,|p,\zeta> = e^{-ia_\mu p^\mu}|p,\zeta>\;, \tag{4.32}$$

while, for a homogeneous Lorentz transformation $(0,\Lambda)$, we obtain

$$U(0,\Lambda)\,|p,\zeta> = \sum_{\zeta'} Q_{\zeta'\zeta}|p',\zeta'>\;, \tag{4.33}$$

where Q is a unitary matrix and

$$p'^\mu = \Lambda^\mu{}_\nu p^\nu\;. \tag{4.34}$$

Eq. (4.34) is obtained from eq. (4.30) and from the relation

$$U^{-1}(0,\Lambda)P^\mu U(0,\Lambda) = \Lambda^\mu{}_\nu P^\nu\;, \tag{4.35}$$

which can be derived from Eqs. (4.8) and (4.9). This shows that the four operators P^μ transform as the components of a four-vector.

Once more we see that $P^2 = P_\mu P^\mu$ is invariant; in fact, we know that P^2 is one of the Casimir operators of the Poincaré group. Its eigenvalues p^2, when $p^2 = m^2 > 0$, correspond to the squared total energy in the c. m. system. If the physical system is a particle, m is the *mass of the particle*.

The subspace spanned by the vectors $|p,\zeta>$ with a given value of p^2 is then *invariant* under the transformations (a,Λ), so that the representation $U(0,\Lambda)$ given by (4.33) is, in general, reducible and can be decomposed into an (infinite) direct sum of representations corresponding to different eigenvalues m^2.

To reduce further the representation, we need to consider also the operator W_μ (Eq. (4.19)), whose square W^2 is the other Casimir operator of the Poincaré group. Since the components W_μ commute with P_μ but not among themselves (Eq. (4.21)), we can diagonalize W^2 and *one* component, say W_3. Among the quantum numbers ζ labelling the eigenstates $|p,\zeta>$ one can then single out the eigenvalues w_3 of W_3. For the sake of simplicity, we shall neglect in the following the other unspecified quantum numbers which should be added to make the set of observables complete.

---

[5] See, e.g., A. Messiah, *Quantum Mechanics*, North Holland (1962).

[6] See e.g. M.E. Peskin, D.V. Schroeder, *An Introduction to Quantum Field Theory*, Addison-Wesley (1995); S. Weinberg, *The Quantum Theory of Fields, Vol. I, Foundations*, Cambridge University Press (1995)

Let us first consider those representations for which $p^2 = m^2 > 0$. In that case $p_0/|p_0|$, i.e. the sign of the energy, is also an invariant of the group $\mathcal{P}_+^\uparrow$. In the four-momentum space, the eigenstates of $p^2 = m^2 > 0$ with $p_0 > 0$, which correspond to physical states, are represented by the points in the upper branch of the hyperboloid shown in Fig. 4.1. Under a transformation of $\mathcal{P}_+^\uparrow$ the representative point moves on the *same* branch of the hyperboloid.

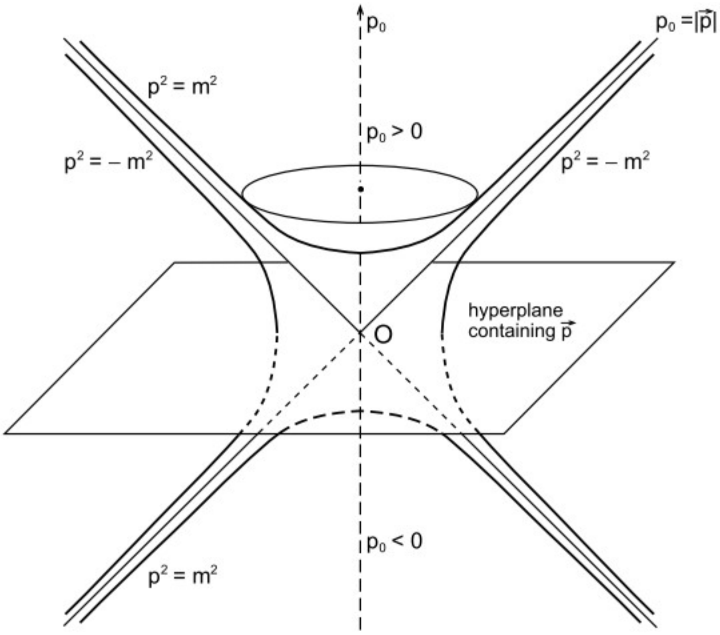

Fig. 4.1. *Hyperboloid $p^2 = m^2$ in the four-momentum space.*

An irreducible representation is characterized by the eigenvalues of P^2, W^2 and the sign of $p_0/|p_0|$; an IR with $p_0 > 0$ is then spanned by the vectors $|p, w_3>$ with $p^2 = m^2 = \text{const.}$, and $p_0 = +\sqrt{\mathbf{p}^2 + m^2}$.

The physical meaning of W^μ is made clear by considering explicitly its components. Using the definitions (3.59), one gets from (4.19)

$$W_0 = \mathbf{P} \cdot \mathbf{J}\,, \tag{4.36}$$

$$\mathbf{W} = P_0\, \mathbf{J} - \mathbf{P} \times \mathbf{K}\,. \tag{4.37}$$

It is convenient to go to the rest frame, in which $\mathbf{p} = 0$. In this frame Eqs. (4.36), (4.37) are equivalent to

$$W^\mu = m(0, J^1, J^2, J^3)\,, \tag{4.38}$$

i.e. W^μ reduces essentially to the components of the total angular momentum $\mathbf{J}$, which is the *spin* in the case of a particle. A rest frame can then be specified by $|\tilde{p}, j_3\rangle$, where $\tilde{p} = (m, \mathbf{0})$. According to Eq. (4.38), one gets

$$\begin{aligned} W_3|\tilde{p}, j_3\rangle &= mj_3|\tilde{p}, j_3\rangle \ , \\ (W)^2|\tilde{p}, j_3\rangle &= -m^2 j(j+1)|\tilde{p}, j_3\rangle \ . \end{aligned} \tag{4.39}$$

If $p^2 = 0$, one cannot apply the above arguments, since one cannot go to the rest frame. Since we are interested in the physical case of a massless particle, we take also $w^2 = 0$ ($w^2 \neq 0$ would represent continuous spin values, as we will see in Section 5.3). However, these two null quantum numbers are not sufficient to characterize an IR. Taking into account also Eq. (4.20) we have: $p^2 = 0$, $w^2 = 0$ and $w_\mu p^\mu = 0$. These conditions are satisfied only if the two four-vectors w_μ and p_μ are parallel: $w_\mu = \lambda p_\mu$. In terms of operators we can write[7]:

$$W_\mu = \lambda P_\mu \ , \tag{4.40}$$

where λ is an *invariant*. The physical interpretation of λ becomes evident making use of Eq. (4.36) and of the relation $\mathbf{p}^2 = p_0^2$:

$$\lambda = \frac{W_0}{P_0} = \frac{\mathbf{P} \cdot \mathbf{J}}{P_0} = \frac{\mathbf{P} \cdot \mathbf{J}}{|\mathbf{P}|} \ . \tag{4.41}$$

This shows that λ represents the component of the spin along the direction of motion, which is usually called *helicity*. In the case $p^2 = 0$, we label the state vector with the eigenvalues of λ; i.e. by $|p, \lambda\rangle$.

The above examples show that the operator W_μ describes the polarization states of both massive and massless particles; it represent the covariant generalization of the spin, and it is called, in fact, *covariant spin*.

We have considered only two kinds of IR's of $\mathcal{P}_+^\uparrow$ of physical interest. To summarize and complete the preceding discussion, we list in the following all the IR's of $\mathcal{P}_+^\uparrow$[8]:

a) $p^2 = m^2 > 0$.
For each pair of values of p^2 and w^2, there are two IR's, one for each value of $p_0/|p_0|$. The vector basis of an IR is given by $|p, w_3\rangle$; in the rest frame it reduces to the $(2j+1)$-dimensional basis of the IR of the rotation group, which corresponds to the $(2j+1)$ states of polarization.

b) $p^2 = 0$, $p_\mu \neq 0$, $w^2 = 0$.
Each IR is characterized by the sign of p_0 and by the value (integer or half-integer) of the helicity λ. For a given momentum p_μ and given $\lambda \neq 0$, there exist two independent states (they belong to two independent IR's), which correspond to the two different helicities $\pm\lambda$.

---

[7] Usually we denote operators by capital letters (P_μ, W_μ...) and the corresponding eigenvalues by small letters (p_μ, w_μ...).

[8] I.M. Gel'fand, R.A. Minlos, Z.Ya. Shapiro, *Representations of the Rotations and Lorentz Groups and Their Applications*, Pergamon Press (1963); M.A. Naimark, *Linear Representations of the Lorentz Group*, Pergamon Press (1964).

c) $p^2 = 0$, $p_\mu \neq 0$, $w^2 < 0$.
The IR's are infinite-dimensional also in the spin variable and would correspond to particles with continuous spin.

d) $p^2 = 0$, $p_\mu = 0$, $w^2 < 0$.
The unitary IR's coincide with those of the homogeneous Lorentz group, and they will not be considered further (they provide a powerful tool for the study of the analytic properties of the forward scattering amplitude in the angular momentum variable).

e) $p^2 < 0$.
These IR's correspond to space-like vectors p_μ, so they cannot be used in the description of physical states (they can be useful, however, in the study of the analytic properties of the scattering amplitude).

Problems

4.1. Show that the Poincaré transformations (a, Λ) form a group and give the explicit proof that the translation group $\mathcal{S}$ is an invariant subgroup.

4.2. Prove that P^2 and W^2 are invariant operators of the group $\mathcal{P}_+^\uparrow$.

4.3. Derive the transformation properties of the generators P_μ under $\mathcal{L}_+^\uparrow$ and the commutation relations (4.17), making use of the general form

$$U(a, \Lambda) = e^{-ia_\mu P^\mu} e^{-\frac{1}{2}i\omega_{\mu\nu}M^{\mu\nu}}$$

of the unitary IR's of $\mathcal{P}_+^\uparrow$.

4.4. Derive the transformation properties of the generators $M^{\mu\nu}$ under $\mathcal{L}_+^\uparrow$ and the commutation relations (3.60) starting from the general form

$$U(0, \Lambda) = e^{-\frac{1}{2}i\omega_{\mu\nu}M^{\mu\nu}}$$

of the unitary IR's of $\mathcal{L}_+^\uparrow$.

4.5. Making use of the Lorentz transformation which brings the state $|p, \zeta>$ at rest, show that the commutators $[W_\mu, W_\nu] = i\epsilon_{\mu\nu\sigma\tau}W^\sigma P^\tau$ reduce to $[J_i, J_j] = i\epsilon_{ijk}J_k$.

4.6. Show that the Lorentz transformations of the form

$$U(0, \Lambda) = e^{-in_\mu W^\mu} ,$$

where n is an arbitrary four-vector, leave the eigenvalues p_μ of P_μ invariant.

8.1.4 Tangent Plane Maneuvers

A general maneuver changes the shape of an orbit, a, e, its orientation ω within the orbital plane, and the orientation of the plane, i, Ω. Practically, the orientation ω of the orbital plane is largely irrelevant, because most of the spacecraft are in a circular orbit having no ω. In addition, for orbit transitions a Hohmann transfer altering a, e jointly with a plane change i, Ω is essential. We read from Eq. (8.1.1) that to solely change a, e and i, Ω only $\delta v_{||}$ and $\delta v_{\perp\perp}$ kick-burns are relevant. This implies that $\boldsymbol{v}_1$ and $\boldsymbol{v}_2$ span a plane, tangent to the orbit at the kick-burn location. This important class of orbit maneuvers is therefore called *tangent plane maneuvers*. Figure 8.4 shows a tangent change maneuver with $v_1 = v_2 =: v$, that is, without a, e changes. Such a particular tangent plane maneuver is hence called *genuine plane change maneuver* (see next section).

Transition Angle in Terms of Orbital Elements
The important property of a tangent plane maneuver is that because the plane spaned by $\boldsymbol{v}_1$ and $\boldsymbol{v}_2$ is vertical to the initial and final plane, the maneuver causes a tilt of the initial (index 1) to the final (index 2) orbit about a mutual nodal line, for which $\phi = \angle(\boldsymbol{v}_1, \boldsymbol{v}_2) = \angle(\boldsymbol{I}_1, \boldsymbol{I}_2)$ holds. Here $\boldsymbol{I}$ is the three-dimensional inclination vector (see Eq. (7.3.25)) given as

$$\boldsymbol{I} = \begin{pmatrix} \sin\Omega \sin i \\ -\cos\Omega \sin i \\ \cos i \end{pmatrix}_{IJK}$$

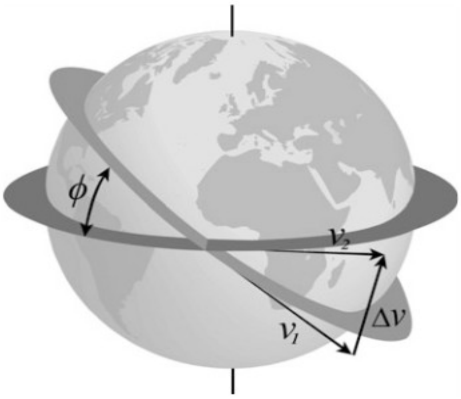

Fig. 8.4 A tangent plane maneuver with $v_1 = v_2$ (a.k.a. genuine plane change maneuver) in a circular orbit. The point where the maneuver takes place is the node of the mutual nodal line between the initial and final orbit plane

With this the transition angle is determined by

$$\cos\phi = \hat{\boldsymbol{v}}_1\hat{\boldsymbol{v}}_2 = \boldsymbol{I}_1\boldsymbol{I}_2 = \sin i_1 \sin i_2 \cos\Delta\Omega + \cos i_1 \cos i_2$$

or after some trigonometric modifications alternatively

$$\sin^2\frac{\phi}{2} = \sin^2\frac{\Delta i}{2} + \sin i_1 \sin i_2 \sin^2\frac{\Delta\Omega}{2} \tag{8.1.18}$$

where $\Delta i := i_2 - i_1$ and $\Delta\Omega := \Omega_2 - \Omega_1$. Obviously, the vector $\boldsymbol{N}$ of the nodal line between the initial and final orbit is given by

$$\boldsymbol{N} = \boldsymbol{I}_1 \times \boldsymbol{I}_2 \tag{8.1.19}$$

Maneuvers with either Inclination Change or RAAN Change

There are two special plane change maneuvers, which are of practical interest. One, in which the RAAN is kept constant, $\Delta\Omega = 0$. We thus obtain from Eq. (8.1.18)

$$\begin{aligned} &\phi = \Delta i \\ &\Delta v = \sqrt{v_1^2 + v_2^2 - 2v_1v_2\cos\Delta i} \end{aligned} \quad @\ \Delta\Omega = 0 \quad \textbf{nodal transfer} \tag{8.1.20}$$

According to Table 8.1 this plane tilt is achieved for a $\Delta\boldsymbol{v}$ that lies in either plane tangent to the two nodes of the initial orbit with the reference plane. Such transfers are therefore called *nodal transfers* and are the most frequently used plane change maneuvers.

The other special case is achieved if the inclination is kept constant, $\Delta i = 0$. We thus have from Eq. (8.1.18)

$$\begin{aligned} &\sin(\phi/2) = \sin i \cdot |\sin(\Delta\Omega/2)| \\ &\Delta v = \sqrt{(v_1 - v_2)^2 + 4v_1v_2\sin^2 i\,\sin^2(\Delta\Omega/2)} \end{aligned} \quad @\ \Delta i = 0 \tag{8.1.21}$$

According to Table 8.1 $\Delta i = 0$ is achieved for a $\Delta\boldsymbol{v}$ that lies in either plane tangent to the two points at 90° abeam from the nodes of the initial orbit with the reference plane.

8.1.5 Genuine Plane Change Maneuvers

We finally study just plane change maneuvers without a change in orbital velocity, $v_1 = v_2 =: v$ as depicted in Fig. 8.4. Because we now apply only a $\delta v_{\perp\perp}$ kick-burn, genuine plane change maneuvers are a subset of tangent plane maneuvers, which according to Eq. (8.1.1) only change i, Ω, ω. From Eq. (8.1.17) we derive for $v = v_1 = v_2$ quite generally

$$\boxed{\Delta v = 2v \cdot \left|\sin\frac{\phi}{2}\right|} \quad @ \quad v := v_1 = v_2 \tag{8.1.22}$$

Because $\Delta v \propto v$ we find the general rule of thumb

Plane Change Rule
An orbit plane change should be performed at the smallest possible orbital velocity, i.e. at best at the apoapsis.

For this reason it might be even preferable to bring the vehicle first into a higher orbit, change the plane there at apoapsis at low speed and low budget, and finally take it back to its original orbit. It is this principle, that the bi-elliptic transfer (Sect. 8.4.2) and the super-synchronous transfer (Sect. 8.4.3) make use of.

Genuine Inclination Change Maneuver
For $\Omega_1 = \Omega_2$ we have from Eq. (8.1.20) $\phi = \Delta i$. We hence obtain from Eq. (8.1.22)

$$\boxed{\Delta v = 2v \cdot \left|\sin\frac{\Delta i}{2}\right|} \quad @ \; v := v_1 = v_2,\; \Delta\Omega = 0 \tag{8.1.23}$$

According to Table 8.1 this tilt is achieved for a $\Delta \boldsymbol{v}$ that lies in either plane tangent to the two nodes of the initial orbit with the reference plane and is orthogonal to the plane bisecting the old and new orbit plane.

Genuine RAAN Change Maneuver
For $\Delta i = 0$ we have from Eq. (8.1.21)

$$\boxed{\Delta v = 2v \cdot \sin i \cdot \left|\sin\frac{\Delta\Omega}{2}\right|} \quad @ \; v := v_1 = v_2, \Delta i = 0 \tag{8.1.24}$$

This is the effort to rotate the inclination vector by $\Delta\Omega$ about the *K*-axis in the geocentric equatorial reference frame. According to Table 8.1 this rotation is achieved for a $\Delta \boldsymbol{v}$ that lies in either plane tangent to the two points at 90° abeam from the nodes of the initial orbit with the reference plane. Obviously, a RAAN change by $\Delta\Omega = 180°$ is identical to an inclination change by $\Delta i = 2i$.

Because $\Delta v \propto v \sin i$ we find the general rule of thumb.

RAAN Change Rule
Adjust RAAN at the lowest inclination and/or orbital velocity possible.

8.1.6 Tangent Maneuver

Another quite special case of a tangent plane maneuver is $\phi = 0°$, i.e., the burn is along the direction of motion. We call this a *tangent maneuver* for which from Eq. (8.1.17) follows

$$\Delta v_{||} = |v_2 - v_1| \quad @ \quad \phi = 0° \tag{8.1.25}$$

From Eq. (8.1.1) we see that such a maneuver changes a, e, ω. As we will see in Sect. 8.3.1 this is the most efficient maneuver to increase the size of an orbit and hence to transfer to an outer orbit.

Let us assume we are in an initial orbit with a_1, e_1, ω_1 and perform at $r := r_1 = r_2$ a tangent maneuver $r, v_1, \theta_1 \to r, v_2, \theta_2$ with

$$v_2 = v_1 \pm \Delta v_{||} \tag{8.1.26}$$

We want to know what is a_2, e_2, ω_2? From the vis-viva Eq. (7.2.15) we immediately find

$$\frac{1}{a_2} = \frac{2}{r} - \frac{v_2^2}{\mu} \tag{8.1.27}$$

To determine the other modified orbital elements we make use of the fact that a tangent maneuver obviously does not change the flight path angle $\gamma := \gamma_1 = \gamma_2$ (see Sect. 7.3.3). From Eq. (7.3.16) we derive the relationships

$$\begin{aligned} v \cos \gamma &= \frac{h}{r} \\ \frac{1}{2} v^2 \sin 2\gamma &= \frac{\mu}{r} e \sin \theta \end{aligned}$$

Applying these equations to the orbits before and after the tangent maneuver we find

$$\frac{v_2}{v_1} = \frac{h_2}{h_1} = \frac{a_2\left(1 - e_2^2\right)}{a_1\left(1 - e_1^2\right)}$$

$$\frac{v_2^2}{v_1^2} = \frac{e_2 \sin \theta_2}{e_1 \sin \theta_1}$$

from which we derive

$$e_2 = \sqrt{1 - \frac{a_1 v_2}{a_2 v_1}\left(1 - e_1^2\right)} \tag{8.1.28}$$

$$\sin\,\theta_2 = \frac{v_2^2\,e_1}{v_1^2\,e_2}\sin\,\theta_1 \tag{8.1.29}$$

To finally determine ω_2 we make use of the fact that a tangent maneuver also does not change the argument of latitude $u = \omega + \theta$ (see Sect. 7.3.5). We hence obtain

$$\omega_2 = \omega_1 + \theta_1 - \theta_2 \tag{8.1.30}$$

Example (GEO Positioning)

Let us assume that a communication satellite is launched with an ATLAS rocket from Cape Canaveral with orbital inclination $i_L = 28^\circ$ after launch and needs to be positioned in GEO (see Berlin (2005)). As we will see in Sect. 12.6.1, due to lunisolar perturbations an optimum initial state in GEO would be $i_{GEO} = 3^\circ,\ \Omega_{GEO} = 280^\circ$. After launch and at the descending node the rocket will make an injection burn at $r_{LEO} = 6578.14\,\text{km}$ into the GTO with apoapsis at $r_{GEO} = 42{,}166\,\text{km}$. Because the descending node happens to coincide with the Greenwich meridian we have $\Omega_{GTO} = 180^\circ$.

To place the satellite in its final orbit position we have the choice of many different maneuver sequences for all of which are based on the following velocities before (−) and after (+) the kick-burns in LEO and GEO (see Eqs. (7.4.3) and (7.4.10)):

$$\begin{aligned} v_{LEO-} &= 7.784\,\text{km s}^{-1} \\ v_{LEO+} &= 10.239\,\text{km s}^{-1} \end{aligned} \quad \text{and} \quad \begin{aligned} v_{GEO-} &= 1.597\,\text{km s}^{-1} \\ v_{GEO+} &= 3.075\,\text{km s}^{-1} \end{aligned}$$

We now study exemplarily four different maneuvering sequences with the following total delta-v:

Sequence 1

- At the descending node after launch an inclination change maneuver ((Eq. (8.1.20) into Eq. (8.1.17)) is made that brings the satellite into a GTO with $i_{GEO} = 3^\circ,\ \Omega_{GTO} = 180^\circ$.
- At apogee a genuine RAAN change maneuver (see Eq. (8.1.24)) changes the orbit plane to $\Omega_{GEO} = 280^\circ$.
- Finally, a tangent maneuver (see Eq. (8.1.25)) brings the satellite into a circular GEO.

$$
\begin{aligned}
\Delta v = &\sqrt{v_{LEO-}^2 + v_{LEO+}^2 - 2v_{LEO-}v_{LEO+}\cos(28^\circ - 3^\circ)} \\
&\quad + 2v_{GEO-}\sin 3^\circ \cdot \sin[(280^\circ - 180^\circ)/2] + (v_{GEO+} - v_{GEO-}) \\
= &\, 4.578 + 0.128 + 1.478 = 6.184\,\text{km s}^{-1}
\end{aligned}
$$

Sequence 2

- At the descending node after launch a tangent maneuver transfers the satellite into a GTO, i.e., $i_{GTO} = 28^\circ,\ \Omega_{GTO} = 180^\circ$.
- At apogee a genuine RAAN change maneuver (see Eq. (8.1.24)) changes the orbit plane to $\Omega_{GEO} = 280^\circ$.
- Finally, a inclination change maneuver (Eq. (8.1.20) into Eq. (8.1.17)) is performed that circularizes the satellite into GEO at $i_{GEO} = 3^\circ$.

$$
\begin{aligned}
\Delta v = &(v_{LEO+} - v_{LEO-}) + 2v_{GEO-}\sin 28^\circ \cdot \sin[(280^\circ - 180^\circ)/2] \\
&\quad + \sqrt{v_{GEO-}^2 + v_{GEO+}^2 - 2v_{GEO-}v_{GEO+}\cos(28^\circ - 3^\circ)} \\
= &\, 2.455 + 1.149 + 1.762 = 5.366\,\text{km s}^{-1}
\end{aligned}
$$

Sequence 3

1. At the descending node after launch a tangent maneuver transfers the satellite into a GTO, i.e., $i_{GTO} = 28^\circ,\ \Omega_{GTO} = 180^\circ$.
2. At apogee a genuine inclination change maneuver (see Eq. (8.1.23)) changes the inclination to $i_{GEO} = 3^\circ$.
3. Still at apogee it is immediately followed by a genuine RAAN change maneuver (see Eq. (8.1.24)) that changes the orbit plane to $\Omega_{GEO} = 280^\circ$.
4. Finally, the orbit is circularized with an apogee kick-burn.

$$
\begin{aligned}
\Delta v = &(v_{LEO+} - v_{LEO-}) + 2v_{GEO-} \cdot \sin 12.5^\circ \\
&\quad + 2v_{GEO-}\sin 3^\circ \cdot \sin[(280^\circ - 180^\circ)/2] + (v_{GEO+} - v_{GEO-}) \\
= &\, 2.455 + 0.691 + 0.128 + 1.478 = 4.752\,\text{km s}^{-1}
\end{aligned}
$$

Sequence 4

- At the descending node the satellite is transferred into a GTO, i.e., $i_{GTO} = 28^\circ, \Omega_{GTO} = 180^\circ$.
- At apogee, an inclination-change maneuver (Eq. (8.1.20) into Eq. (8.1.17)) is performed such that the orbit is circularized at $i_{GEO} = 3^\circ$.
- Finally, a genuine RAAN change maneuver (see Eq. (8.1.24)) positions the satellite at $\Omega_{GEO} = 280^\circ$.

$$\begin{aligned}\Delta v &= (v_{LEO+} - v_{LEO-}) + \sqrt{v_{GEO-}^2 + v_{GEO+}^2 - 2v_{GEO-}v_{GEO+}\cos(28^\circ - 3^\circ)} \\ &\quad + 2v_{GEO+}\sin 3^\circ \cdot \sin[(280^\circ - 180^\circ)/2] \\ &= 2.455 + 1.762 + 0.247 = 4.464\,\text{km s}^{-1}\end{aligned}$$

The essence of comparing the four sequences is that for GEO positioning an inclination change should be combined with the orbit circularization at apoapsis and RAAN should be adjusted at the lowest possible inclination. This is how GEO positioning is actually performed.

This example corroborates the following rule of thumb, which is based on the fact (see Problem 8.1) that a tangent plane maneuver is always more efficient than a tangent maneuver and plane change maneuver performed sequentially at the same point in space:

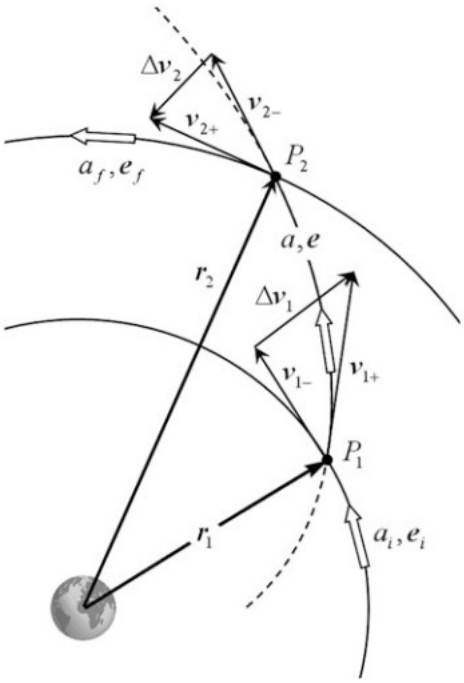
All-in-One Rule
If possible combine all orbital changes that need to be done into one kick-burn at one orbital position rather than making single burns at successive positions.

8.2 Lambert Transfer

Having explored the characteristics of one-impulse maneuvers between intersecting orbits we are now set to perform orbital transfers between two conic orbits that do not intersect and therefore require a transfer orbit with two orbital transition maneuvers at each end. The most general case is the so-called Lambert transfer, which we will investigate first. It played an important role in the 1960s for Gemini and Apollo orbital rendezvous. Today, Hohmann transfers are more common, which will be studied in Sect. 8.3.

8.2.1 Orbital Boundary Value Problem

Lambert Transfer
Let us assume that we have a S/C at point P_1 on an conic Earth orbit that needs to transfer to point P_2 on a coplanar conic target orbit, both of which do not intersect. (If they intersect we can perform an one-impulse maneuver at the intersection point, as described in Sect. 8.1, and move from there on the target orbit to point P_2.) Because the orbits and hence also the transfer orbit are coplanar they are fully characterized by their form and orientation to each other, i.e., by three orbital elements, namely $a_i, \boldsymbol{e}_i$ for the initial Earth orbit, $a, \boldsymbol{e}$ for the transfer orbit, and $a_f, \boldsymbol{e}_f$



$\Delta \boldsymbol{v}_2$
$\boldsymbol{v}_{2-}$
$\boldsymbol{v}_{2+}$
P_2
$a_f, \boldsymbol{e}_f$
$a, \boldsymbol{e}$
$\boldsymbol{r}_2$
$\Delta \boldsymbol{v}_1$
$\boldsymbol{v}_{1-}$
$\boldsymbol{v}_{1+}$
P_1
$\boldsymbol{r}_1$
$a_i, \boldsymbol{e}_i$

Fig. 8.5 A Lambert transfer (see text for details)

for the final target orbit. The most general description of this problem is that under the influence of a common central gravitational potential a S/C in the initial orbit at P_1 possesses the state vector $(\boldsymbol{r}_1, \boldsymbol{v}_{1-})$ and wants to transfer to P_2 with state vector $(\boldsymbol{r}_2, \boldsymbol{v}_{2+})$. This is a general two-impulse transfer, which we call a *Lambert transfer*, embracing a first impulse maneuver $\Delta \boldsymbol{v}_1$ at P_1 resulting in an unpowered conic coplanar Lambert transfer orbit with orbital elements $a, \boldsymbol{e}$ that ends at P_2 where the second impulse maneuver $\Delta \boldsymbol{v}_2$ takes place.

This can be shown as follows (see Fig. 8.5):

$$(a_i, \boldsymbol{e}_i)\, \underbrace{[\Delta \boldsymbol{v}_1]}_{P_1} \xrightarrow{a,\boldsymbol{e}} \underbrace{[\Delta \boldsymbol{v}_2]}_{P_2} (a_f, \boldsymbol{e}_f)$$

Lambert transfer

$$(\boldsymbol{r}_1, \boldsymbol{v}_{1-})\, \underbrace{{}_{-}[\Delta \boldsymbol{v}_1]_{+}}_{P_1} \xrightarrow{a,\boldsymbol{e}} \underbrace{{}_{-}[\Delta \boldsymbol{v}_2]_{+}}_{P_2} (\boldsymbol{r}_2, \boldsymbol{v}_{2+})$$

where the $+$ and $-$ signs indicate the situation just before or after an impulse maneuver. Since only the initial and final orbits and P_1 and P_2 are specified, while $\Delta \boldsymbol{v}_1$ and $\Delta \boldsymbol{v}_2$ remain unspecified, there in general exist many different Lambert transfer orbits connecting the two points P_1 and P_2.

Orbital Boundary Value Problem

The problem of finding a transfer orbit connecting two given points P_1 and P_2 is called the *orbital boundary value problem*, which is a special case of the general mathematical *two-point boundary value problem*.

Let us study the orbital boundary value problem by first assuming that just P_1 and P_2 are given through the position vectors $\boldsymbol{r}_1, \boldsymbol{r}_2$. With these we get from the orbit Eqs. (7.3.4) and (7.3.6) the two conditional equations for the three orbital elements $a, \boldsymbol{e}$

$$\begin{aligned} r_1 + \boldsymbol{e}\boldsymbol{r}_1 &= a\left(1 - e^2\right) \\ r_2 + \boldsymbol{e}\boldsymbol{r}_2 &= a\left(1 - e^2\right) \end{aligned}$$

Therefore, two orbital points are not sufficient to unequivocally define a Keplerian transfer orbit, but leave one orbital element undefined. We need a third position vector or an additional scalar specification to concretize the transfer orbit. Solving the orbital boundary value problem by three position vectors is accomplished by Gibbs' method, which will not be investigated here, but see e.g., Vallado (2001) or Curtis (2005). An additional scalar specification might be for instance the transfer time. This famous orbital boundary value problem is called *Lambert's problem* and will be discussed in Sect. 8.2.3.

As we will see in Sect. 8.2.2, even an additional scalar specification generally still leaves the alternative between two so-called *conjugate orbits*: a long path and a short path transfer orbit. Therefore the general orbital boundary value problem for a Lambert transfer to find the orbital elements $a, \boldsymbol{e}$ of the transfer orbit is uniquely defined only by providing the following boundary conditions:

$\boldsymbol{r}_1,\ \boldsymbol{r}_2$
+ an additional scalar specification
+ a specification for a long or short path transfer orbit

boundary conditions (8.2.1)

Given these boundary conditions we are able derive a unique solution $a, \boldsymbol{e}$ to the orbital boundary value problem in the following way. *Suppose we have found the unique transfer orbit by providing p.* According to Battin (1987), the terminal velocities at P_1 and P_2 are then determined as

$$\begin{aligned} \boldsymbol{v}_{1+} &= \frac{\sqrt{\mu p}}{r_1 r_2 \sin(\Delta\theta)}\left[(\boldsymbol{r}_2 - \boldsymbol{r}_1) + \frac{r_2}{p}(1 - \cos\,\Delta\theta)\boldsymbol{r}_1\right] \\ \boldsymbol{v}_{2-} &= \frac{\sqrt{\mu p}}{r_1 r_2 \sin(\Delta\theta)}\left[(\boldsymbol{r}_2 - \boldsymbol{r}_1) - \frac{r_1}{p}(1 - \cos\,\Delta\theta)\boldsymbol{r}_2\right] \end{aligned} \tag{8.2.2}$$

where $\Delta\theta = \angle(\boldsymbol{r}_1, \boldsymbol{r}_2)$ is the so-called *transfer angle*. Having thus found the state vectors $(\boldsymbol{r}_1, \boldsymbol{v}_{1+})$ at point P_1 and $(\boldsymbol{r}_2, \boldsymbol{v}_{2-})$ at point P_2 of the transfer orbit we derive from Eq. (7.3.3) the orientation of the conic transfer orbit as

$$\boldsymbol{e} = \left(\frac{1}{r_1} - \frac{1}{a}\right)\boldsymbol{r}_1 - \frac{1}{\mu}(\boldsymbol{r}_1\boldsymbol{v}_{1+})\boldsymbol{v}_{1+} = \left(\frac{1}{r_2} - \frac{1}{a}\right)\boldsymbol{r}_2 - \frac{1}{\mu}(\boldsymbol{r}_2\boldsymbol{v}_{2-})\boldsymbol{v}_{2-} \tag{8.2.3}$$

Having thus determined the relevant orbital elements $a, \boldsymbol{e}$ of the Lambert transfer orbit, we have found the solution to the orbital boundary value problem. Note that with such methods the orbital boundary value problem is also used to preliminarily determine an unknown orbit. Preliminary orbit determination will be discussed in Chap. 14.

With the state vectors $(\boldsymbol{r}_1, \boldsymbol{v}_{1+})$ and $(\boldsymbol{r}_2, \boldsymbol{v}_{2-})$ we also know the required orbital maneuvers and the total delta-v

$$\begin{aligned} \Delta\boldsymbol{v}_1 &= \boldsymbol{v}_{1+} - \boldsymbol{v}_{1-} \\ \Delta\boldsymbol{v}_2 &= \boldsymbol{v}_{2+} - \boldsymbol{v}_{2-} \\ \Delta v &= |\Delta\boldsymbol{v}_1| + |\Delta\boldsymbol{v}_2| \end{aligned} \tag{8.2.4}$$

Having thus fully determined the Lambert transfer we recognize that everything hinges on the problem of finding the semi-latus rectum p of the Lambert transfer orbit under the given boundary conditions Eq. (8.2.1) to which we turn now.

8.2.2 Lambert Transfer Orbits

We will first study the characteristics of the solutions of the orbital boundary value problem if only the position vectors $\boldsymbol{r}_1$, $\boldsymbol{r}_2$ are given. In this case there exists an infinite number of orbits with different a and e connecting P_1 and P_2. Let us first assume that with an additional specification we have picked a particular but otherwise arbitrary a.

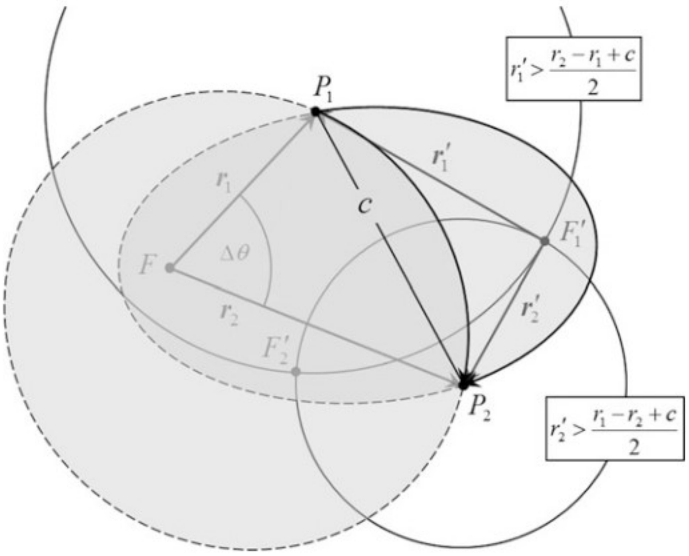
Conjugate Orbits: One *a*, But Two Transfer Orbits

It is a basic property of the orbital boundary value problem that for any particular semi-major axis a in general there exist two different transfer orbits, so-called *conjugate orbits*, with different eccentricity and hence semi-latus rectum, which we will label p and $\tilde{p}$.

From geometrical reasoning, it is enlightening to see why. Suppose there is a transfer orbit with a given a. We define the distances from its empty focus F' to the points P_1 and P_2 as r'_1 and r'_2, respectively. Then from the definition of an ellipse we have

$$\begin{aligned} r_1 + r'_1 &= 2a \\ r_2 + r'_2 &= 2a \end{aligned}$$

Since the location of the focal point F is given by the central mass, we can establish the transfer ellipses by determining their empty focal points $F'_{1,2}$. We do so by drawing a circle with radius $r'_1 = 2a - r_1$ around P_1 and a circle with radius



$r_1' > \frac{r_2 - r_1 + c}{2}$
P_1
r_1'
r_1
c
F
$\Delta\theta$
F_1'
r_2
r_2'
F_2'
P_2
$r_2' > \frac{r_1 - r_2 + c}{2}$

Fig. 8.6 Circles, with radii larger than some critical value, drawn around the points P_1 and P_2 intersect at two points defining the empty focal points F' of the two different transfer ellipses

$r_2' = 2a - r_2$ around P_2. If a is large enough ("large enough" will be shown in a moment to be $a \geq (r_1 + r_2)/2$), the two circles will intersect at two empty focal points on opposite sides of the chord connecting P_1 and P_2 as shown in Fig. 8.6, which define the two transfer ellipses.

A transfer orbit is called a *short path ellipse* if it has the shorter path between P_1 and P_2, and hence a smaller eccentricity, and a shorter transfer time; while the other is called a *long path ellipse*.

Note that their major-axes are indeed of identical length, only their eccentricities and their orientations are different.

When a is known, it can be shown (see Battin (1964, 1987), or Kemble (2006)) that the semi-latus rectum p of the two paths are given as

$$\begin{aligned} p &= a\,\frac{r_1 r_2}{c^2}\,(1 - \cos\Delta\theta)[1 - \cos(\alpha + \beta)] \\ &= 2a\,\frac{r_1 r_2}{c^2}(1 - \cos\Delta\theta)\sin^2\frac{\alpha+\beta}{2} \end{aligned} \quad \text{@ short path} \qquad (8.2.5\text{a})$$

$$\begin{aligned} \tilde{p} &= \frac{r_1 r_2}{a}\,\frac{1-\cos\Delta\theta}{1-\cos(\alpha + \beta)} \\ &= 2a\,\frac{r_1 r_2}{c^2}(1 - \cos\Delta\theta)\sin^2\frac{\alpha-\beta}{2} \end{aligned} \quad \text{@ long path} \qquad (8.2.5\text{b})$$

where the chord length c, which is the separation distance between P_1 and P_2, is given from trigonometry by

$$c = \sqrt{r_1^2 + r_2^2 - 2r_1 r_2 \cos \Delta\theta} \tag{8.2.6}$$

and

$$\sin\frac{\alpha}{2} := \sqrt{\frac{r_1 + r_2 + c}{4a}}, \quad \sin\frac{\beta}{2} := \sqrt{\frac{r_1 + r_2 - c}{4a}}$$

From Eqs. (8.2.5a) and (8.2.5b) we see immediately that

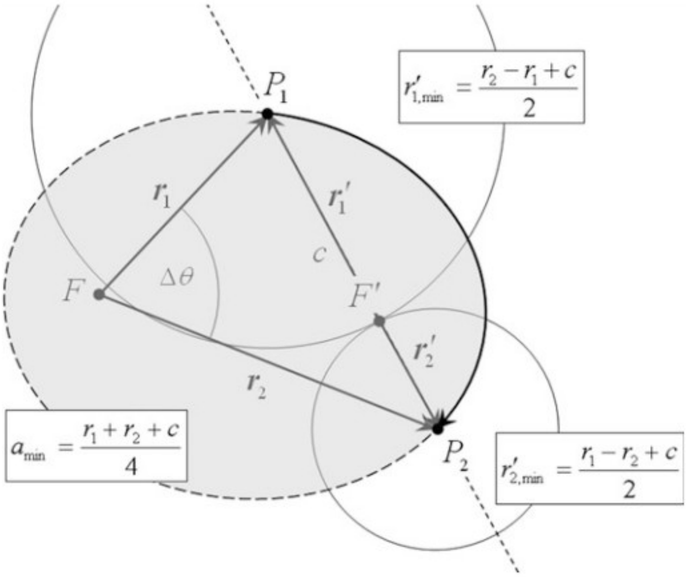
$$p \cdot \tilde{p} = \left[\frac{r_1 r_2}{c}(1 - \cos \Delta\theta)\right]^2 = p_{\min}^2$$

where $p_{\min}$ is the semi-latus rectum of the minimum energy transfer orbit discussed in the following (see Eq. (8.2.9)). We also see that owing to $0 \le \beta \le \alpha \le \pi$

$$c\tilde{p} < r_1 r_2 (1 - \cos \Delta\theta) < cp \quad \textbf{long/short path condition} \tag{8.2.7}$$

Minimum Energy Transfer Orbit, But Maximum Transfer Time

Because Eq. (7.3.18) directly relates the magnitude of the semi-major axis to the orbital energy by $\varepsilon = -\mu/2a$, this condition states that among all transfer orbits that



P_1
$r'_{1,\min} = \frac{r_2 - r_1 + c}{2}$
r_1
r_1'
c
F
$\Delta\theta$
F'
r_2'
r_2
$a_{\min} = \frac{r_1 + r_2 + c}{4}$
P_2
$r'_{2,\min} = \frac{r_1 - r_2 + c}{2}$

Fig. 8.7 The minimum energy transfer orbit occurs when the empty focal point lies on the chord c connecting point P_1 and P_2

go through P_1 and P_2 there is an orbit with minimum orbital energy. To figure out what its a is, we consider again $r_1 + r'_1 = 2a$ and, $r_2 + r'_2 = 2a$ from which follows

$$4a = r_1 + r_2 + r'_1 + r'_2$$

With $r_1 + r_2$ as a given quantity, a is minimum if $r'_1 + r'_2$ becomes minimal, which from Fig. 8.7 is the case if $F'_{1,2}$ lies on the chord c joining P_1 and P_2. Therefore the minimum energy transfer orbit has

$$a_{\min} = \frac{r_1 + r_2 + c}{4} \tag{8.2.8}$$

We recognize that in this limiting situation the two circles around P_1 and P_2 do not intersect, but just touch each other leading to just one empty focal point and therefore to one, and only one, transfer ellipse. If a is smaller than the minimum value the circles will not intersect and no transfer solution exists—the minimum energy orbit is its own conjugate. On the other hand, because $c \le r_1 + r_2$ always holds, a transfer orbit with $a \ge (r_1 + r_2)/2$ will always be large enough to ensure intersecting circles and hence link the points P_1 and P_2. It can be shown (see, e.g., Battin (1987) or Vallado (2001)) that $p_{\min}$ for the minimum energy orbit, is given by

$$p_{\min} = \frac{r_1 r_2}{c}(1 - \cos\Delta\theta) = \frac{c}{2}\left[1 - \left(\frac{r_1 - r_2}{c}\right)^2\right] \tag{8.2.9}$$

We summarize by stating that

> The **minimum energy ellipse** has a minimum semi-latus rectum given by Eq. (8.2.9) and its empty focal point lies on the chord connecting P_1 and P_2.

Notice that with the additional specification "minimum energy transfer" we have rounded out all boundary conditions and hence settled on a specific solution with an unique $a = a_{\min}$ and $e = \sqrt{1 - p_{\min}/a_{\min}}$.

Note that the occurrence of the minimum energy transfer orbit does not necessarily mean that the total delta-v for the Lambert transfer also becomes a minimum. As seen from Eqs. (8.2.2) and (8.2.4) the total delta-v rather depends in a complex way on the transition from the initial velocity to the transfer velocity at P_1 and back to the final orbital velocity at P_2. But, in general it can be said that any transfer close to a minimum energy transfer is a "good" transfer. Observe that for a minimum energy transfer Δt no longer is a variable that can be freely chosen. The free variable then is the proper configuration of the objects at P_1 and P_2 in their orbits around F that complies with a minimum energy transfer. The search for such an optimal configuration, the so-called orbit phasing, is the objective of Sect. 9.3 for interplanetary transfers.

It can be shown (Problem 8.8) that the minimum energy transfer orbit goes hand in hand with a maximum transfer time. The semi-latus rectum for a minimum energy transfer is given above as $4a_{\min} = r_1 + r_2 + c$. With the transformations introduced for Lambert's problem in Sect. 8.2.3, we have

$$\sin\frac{\alpha_{\min}}{2} = \sqrt{\frac{r_1 + r_2 + c}{4a_{\min}}} = 1,$$
$$\sin\frac{\beta_{\min}}{2} = \sqrt{\frac{r_1 + r_2 - c}{r_1 + r_2 + c}}$$

and hence $\alpha_{\min} = \pi$. With Lambert's equation (see Eq. (8.2.13)) the maximum transfer time of the minimum energy transfer orbit then reads

$$\begin{aligned}\Delta t_{\max} &= \sqrt{\frac{a_{\min}^3}{\mu}}[\pi - \beta_{\min} + \sin\beta_{\min}] \\ &= \sqrt{\frac{a_{\min}^3}{\mu}}\left[\pi - \arccos\left(\frac{c}{a_{\min}} - 1\right) + \sqrt{\frac{c}{a_{\min}}\left(2 - \frac{c}{a_{\min}}\right)}\right]\end{aligned} \tag{8.2.10}$$

The Fundamental Ellipse

There are many transfer orbits with metric orbital elements a, e that connect P_1 and P_2. However, as there is just one transfer orbit with a characteristic a—the minimum energy orbit—there exists just one transfer orbit with a specified characteristic eccentricity: the *fundamental ellipse* with a minimum eccentricity.

To find the orbit with minimum e we first investigate the eccentricity vector as given by the orbit equation Eq. (7.3.4) in vectorial form and apply it to the points P_1 and P_2, obtaining

$$\boldsymbol{e}\boldsymbol{r}_1 = p - r_1$$
$$\boldsymbol{e}\boldsymbol{r}_2 = p - r_2$$

Subtracting these from each other yields

$$\boldsymbol{e}(\boldsymbol{r}_1 - \boldsymbol{r}_2) = r_1 - r_2$$

Since $\boldsymbol{r}_1 - \boldsymbol{r}_2 = c\boldsymbol{u}_c$ is the cord with unit vector $\boldsymbol{u}_c$ and length c, we get

$$\boldsymbol{e}\boldsymbol{u}_c = \frac{r_1 - r_2}{c}$$

This equation states that the eccentricity vector of any transfer orbit between P_1 and P_2 has the same projection on the chord. The fundamental ellipse now is that one of those with the minimum eccentricity. Because the minimum eccentricity is achieved if $\boldsymbol{e}||\boldsymbol{u}_c$, we have for the fundamental ellipse

$$e_F = \frac{r_1 - r_2}{c} = \min \tag{8.2.11}$$

and because $\boldsymbol{e}||\boldsymbol{u}_c$ implicates $2a = r'_1 + r'_2 = r_1 + r_2$ we have

$$p_F = a\left(1 - e_F^2\right) = \frac{r_1 r_2}{c^2}(r_1 + r_2)(1 - \cos\,\Delta\theta) \tag{8.2.12}$$

Because the fundamental ellipse has a particular p_F it has a particular flight time, which is identical with that of its conjugate orbit having the same semi-latus rectum but different eccentricity.

Note that though the minimum energy transfer ellipse and the fundamental ellipse share the same semi-latus rectum $a_{\min} = a_F = (r_1 + r_2)/2$, they do not share the same position of the empty focal point F'. While F' for the minimum energy orbit lies on the chord, the one for the fundamental ellipse lies on a line through F that runs parallel to the chord (see the "low-e" ellipse in Fig. 8.6 that is close to the fundamental ellipse). Therefore,

The **fundamental ellipse** has the lowest eccentricity and shares the minimum semi-latus rectum given by Eq. (8.2.12) of all elliptic orbits that lie on P_1 and P_2. Its line of apsides runs parallel to the chord line.

8.2.3 Lambert's Problem

Apart from the minimum energy or minimum eccentricity specifications there might be other specifications that settle on a transfer orbit between P_1 and P_2 with a particular a. From a practical and historical point of view the most important, however, is the specification of a transfer time. The problem to find the according transfer orbit is called *Lambert's problem* (Lambert 1761). It can be stated as follows: "the determination of an orbit, having a specified transfer time and connecting two position vectors", or in other words "to solve for the trajectory connecting two position vectors with a given time of flight".

Because in Lambert's problem both transfer time and orbital anomalies are involved, for a solution we start out with Kepler's Eq. (7.4.15) for an elliptic transition and Eq. (7.4.30) for a hyperbolic orbit

$$n \cdot (t_1 - t_2) = n \cdot \Delta t = E_1 - E_2 - e(\sin E_1 - \sin E_2) \qquad \text{@ elliptic orbit}$$
$$n \cdot (t_1 - t_2) = n \cdot \Delta t = e(\sinh F_1 - \sin F_2) - (F_1 - F_2) \qquad \text{@ hyperbolic orbit}$$

It can be shown (for a proof see, e.g., Battin (1964, 1987), or Kemble (2006)) that with the substitutions

$$\sin\frac{\alpha - \beta}{2} := \frac{E_2 - E_1}{2}, \cos\frac{\alpha + \beta}{2} := e\,\cos\frac{E_2 + E_1}{2} \qquad \text{@ elliptic}$$

$$\sinh\frac{\gamma - \delta}{2} := \frac{F_2 - F_1}{2}, \cosh\frac{\gamma + \delta}{2} := e\,\cosh\frac{F_2 + F_1}{2} \qquad \text{@ hyperbolic}$$

and with the quantities

$$c = \sqrt{r_1^2 + r_2^2 - 2r_1 r_2 \cos\,\Delta\theta} \qquad @\, 0 \le \Delta\theta \le \pi$$

$$s_\pm := \frac{1}{2}\sqrt{\frac{r_1 + r_2}{c} \pm 1}$$

Kepler's equations can be rewritten to yield *for the short path and hence short transition times and for small transfer angles* $0 \le \Delta\theta \le \pi$ the Lambert's equations

Elliptic Orbit (short path, $0 \le \Delta\theta \le \pi$)

$$\boxed{\Delta t = \sqrt{\tfrac{a^3}{\mu}}[\alpha - \beta - (\sin\,\alpha - \sin\,\beta)]} \quad \textbf{Lambert's equation} \qquad (8.2.13)$$

with

$$\sin\frac{\alpha}{2} = \sqrt{\frac{r_1 + r_2 + c}{4a}} = \sqrt{\frac{c}{a}s_+} > 0$$

$$\sin\frac{\beta}{2} = \sqrt{\frac{r_1 + r_2 - c}{4a}} = \sqrt{\frac{c}{a}s_-} > 0 \qquad @ \quad 0 \le \beta \le \alpha \le \pi$$

$$p = a\tfrac{r_1 r_2}{c^2}(1 - \cos\Delta\theta)[1 - \cos(\alpha + \beta)]$$

Hyperbolic Orbit (short path, $0 \le \Delta\theta \le \pi$)

$$\boxed{\Delta t = \sqrt{\tfrac{-a^3}{\mu}}[\sinh\gamma - \sinh\delta - (\gamma - \delta)]} \quad \textbf{Lambert's equation} \qquad (8.2.14)$$

with

$$\sinh\frac{\gamma}{2} = \sqrt{-\frac{r_1 + r_2 + c}{4a}} = \sqrt{\frac{c}{-a}s_+} > 0$$

$$\sinh\frac{\delta}{2} = \sqrt{-\frac{r_1 + r_2 - c}{4a}} = \sqrt{\frac{c}{-a}s_-} > 0 \qquad @\, 0 \le \delta \le \gamma$$

$$p = a\tfrac{r_1 r_2}{c^2}(1 - \cos\Delta\theta)[1 - \cosh(\gamma + \delta)]$$

where c again is the chord length, i.e., the straight distance between the points P_1 and P_2, and $\Delta\theta = \angle(\boldsymbol{r}_1, \boldsymbol{r}_2)$ is again the so-called *transfer angle*. Obviously, $r_1 + r_2 + c \ge r_1 + r_2 - c$ implies that $0 \le \beta \le \alpha \le \pi$ must hold.

Parabolic and Near-Parabolic Trajectories

If $|a| \to \infty$, i.e., if we have a near-parabolic transfer path, it can be shown (see Problem 8.9) that a can be provided analytically as

$$\frac{c}{a} = \frac{5}{2} \frac{\Delta t \sqrt{\mu / c^3} - \frac{4}{3}\left(s_+^3 - s_-^3\right)}{s_+^5 - s_-^5} \quad \text{@ near-parabolic path} \tag{8.2.15}$$

Equation (8.2.15) provides also the condition at which $|a| \to \infty$, namely $\frac{3}{4} \Delta t \sqrt{\mu / c^3} \approx s_+^3 - s_-^3$. To determine the semi-latus rectum p for $c/a > 0$ Eq. (8.2.13), and for $c/a < 0$ Eq. (8.2.14) need to be applied.

If

$$\Delta t = \frac{4}{3} \sqrt{\frac{c^3}{\mu}} \left(s_+^3 - s_-^3\right) \quad \text{@ parabolic path}$$

then $a = \infty$ and we have a parabolic transfer path with a single p given by

$$\begin{aligned} p &= 2 \frac{r_1 r_2}{c} (1 - \cos \Delta\theta)(s_+ + s_-)^2 \\ &= 2 \frac{r_1 r_2}{c^2} \sin^2 \frac{\Delta\theta}{2} \left(r_1 + r_2 + 2\sqrt{r_1 r_2} \cos \frac{\Delta\theta}{2} \right) \end{aligned} \quad \text{@ parabolic path} \tag{8.2.16}$$

With this the orbit orientation $\boldsymbol{e}$ can be deduced via Eqs. (8.2.2) and (8.2.3).

Lambert's Theorem

From these results Lambert's theorem can be derived.

> **Lambert's theorem**
>
> *The transfer time of a body moving between two points on a conic trajectory is a function only of the sum of the distances of the two points from the origin of force, the length c of the chord joining these two positions, and the semi-major axis of the conic:* $\Delta t = f(r_1 + r_2, c, a)$

Alternatively, Lambert's theorem can be stated as

$$\Delta t = f(r_1, r_2, a, \Delta\theta)$$

This more explicitly shows that the transfer time does not depend on the individual locations of the starting or arrival point or their true anomalies, but just on their separation angle $\Delta\theta$. This is for instance useful in finding a solution to the orbital rendezvous problem (see Sect. 8.6). It is remarkable that transfer time does not depend on the eccentricity of the transfer orbit. Remarkably, this is the third orbital quantity, besides the specific orbital energy (Eq. (7.3.19)) and the orbital period of an ellipse (Eq. (7.4.2)), that does not depend on the eccentricity. It is just this independency of e that makes the fundamental ellipse dispensable for practical purposes.

Universal Formulation of Lambert's Equation

Given Lambert's equation we are set to provide a universal formulation of Lambert's equation. With P_1 and P_2 given, we know $\boldsymbol{r}_1, \boldsymbol{r}_2$, $\Delta\theta$, and hence chord length c. For a given Δt we then can derive from Lambert's equation (8.2.13) the semi-major axis a of the corresponding short transfer path numerically, for instance with Newton's method (see Sect. 7.4.2).

In the following we want to provide a numerically robust algorithm for any Keplerian orbit. For that we first define the dimensionless numbers

$$\begin{aligned}
&x := c/a \\
&\Delta\tau := \Delta t\sqrt{\frac{\mu}{c^3}} \\
&\boldsymbol{\rho}_1 = \boldsymbol{r}_1/c,\ \boldsymbol{\rho}_2 = \boldsymbol{r}_2/c \\
&s_\pm = \frac{1}{2}\sqrt{\rho_1 + \rho_2 \pm 1} \\
&c_\pm(x) := \sqrt{1 - x s_\pm^2}
\end{aligned}$$

With this and the condition $0 \le \beta \le \alpha \le \pi$ we find for an elliptic orbit

$$\begin{aligned}
\sin\,\alpha - \sin\,\beta &= 2\left(\sin\frac{\alpha}{2}\cos\frac{\alpha}{2} - \sin\frac{\beta}{2}\cos\frac{\beta}{2}\right) \\
&= 2(s_+ c_+ - s_- c_-)\sqrt{x} > 0 \\
\alpha - \beta &= 2\left(\arcsin s_+\sqrt{x} - \arcsin s_-\sqrt{x}\right) \\
&= 2\arcsin\left[(s_+ c_- - s_- c_+)\sqrt{x}\right] > 0
\end{aligned}$$

and for a hyperbolic orbit with $0 \le \beta \le \alpha$

$$\begin{aligned}
\sinh\,\gamma - \sinh\,\delta &= 2\left(\sinh\frac{\gamma}{2}\cosh\frac{\gamma}{2} - \sinh\frac{\delta}{2}\cosh\frac{\delta}{2}\right) \\
&= 2(s_+ c_+ - s_- c_-)\sqrt{-x} > 0 \\
\gamma - \delta &= 2\left(\mathrm{arsinh} s_+\sqrt{-x} - \arcsin s_-\sqrt{-x}\right) \\
&= 2\mathrm{arsinh}\left[(s_+ c_- - s_- c_+)\sqrt{-x}\right] > 0
\end{aligned}$$

so that we can rewrite and merge Lambert's equations for both elliptical and hyperbolic orbits into one equation

$$\frac{\Delta\tau}{2}x = \frac{g\left[(s_+ c_- - s_- c_+)\sqrt{|x|}\right]}{\sqrt{|x|}} - (s_+ c_+ - s_- c_-) \quad @\ \text{Keplerian orbits}$$

where

$$g\left(\sqrt{|u|}\right) := \begin{cases} \arcsin(\sqrt{u}) & @\ 0 < u \leq 1 \\ \operatorname{arsinh}(\sqrt{-u}) & @\ u < 0 \end{cases}$$

The similarity of the power series expansion in both cases gives rise to an universal **L-function**

$$\begin{aligned} L(u) &= 1 + \frac{1}{2 \cdot 3} u + \frac{1 \cdot 3}{2 \cdot 4 \cdot 5} u^2 + \frac{1 \cdot 3 \cdot 5}{2 \cdot 4 \cdot 6 \cdot 7} u^3 \dots \\ &\quad + \frac{(2n-1)!!}{2^n n! (2n+1)} u^n + \ \dots \qquad\qquad @ -\infty < u \leq 1 \\ &= \begin{cases} \dfrac{\operatorname{arsin}\sqrt{u}}{\sqrt{u}} & @\ 0 \leq u \leq 1 \\[2ex] \dfrac{\operatorname{arsinh}\sqrt{-u}}{\sqrt{-u}} = \dfrac{\ln\left(\sqrt{-u} + \sqrt{1-u}\right)}{\sqrt{-u}} & @\ u < 0 \end{cases} \end{aligned}$$

(For the mathematically inclined reader: Note the relationship between the L-function and Stumpff function $c_2(u)$, see Sect. 7.4.8). We therefore finally obtain

$$\boxed{\frac{\Delta\tau}{2} x = (s_+ c_- - s_- c_+) \cdot L(u) - (s_+ c_+ - s_- c_-)} \quad @\ \text{Keplerian orbits} \qquad (8.2.17)$$

with $u = (s_+ c_- - s_- c_+)^2 x$. Note that for $x = 0$ due to $L(0) = 1$ and $c_\pm(0) = 1$ the right hand side vanishes and so does the left hand side.

Owing to the above dimensionless formulation of Lambert's equation, Lambert's theorem can be reduced to $\Delta\tau = f\left(\frac{c}{r_1 + r_2}, \frac{c}{a}\right)$ or $\frac{c}{a} = g\left(\Delta\tau; \frac{c}{r_1 + r_2}\right)$, respectively, as displayed in Fig. 8.8. Because $0 \leq |r_2 - r_1| \leq c \leq r_2 + r_1$ the parameter $c/(r_1 + r_2)$ is restricted to

$$0 \leq \frac{c}{r_1 + r_2} \leq 1$$

and according to Eq. (8.2.8)

$$4a \geq r_1 + r_2 + c$$

Universal Semi-Latus Rectum

To determine the semi-latus rectum we further define the dimensionless numbers

$$\begin{aligned} \rho &:= (r_1 r_2 - \boldsymbol{r}_1 \boldsymbol{r}_2)/c^2 = \frac{1}{2}\left[1 - \left(\frac{r_1 - r_2}{c}\right)^2\right] \\ \lambda &:= 2(s_+ c_- + s_- c_+)^2 \end{aligned}$$

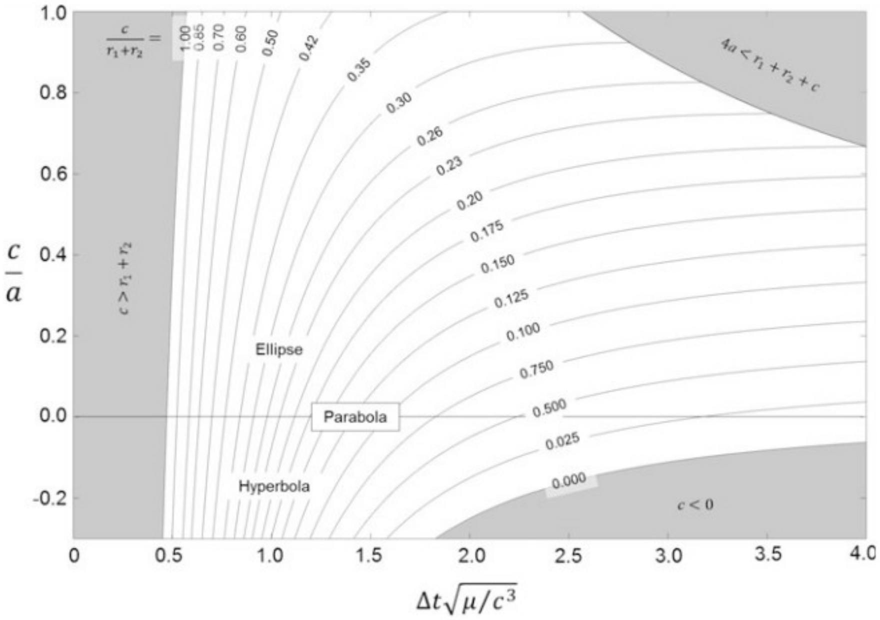


Fig. 8.8 Solution of Lambert's Problem in graphical form

which yields

$$r_1 r_2(1-\cos\Delta\theta) = r_1 r_2 - r_1 r_2 \cos\Delta\theta = r_1 r_2 - \boldsymbol{r}_1 \boldsymbol{r}_2 = c^2\rho$$

$$\begin{aligned} a[1-\cos(\alpha+\beta)] &= 2a\sin^2\frac{\alpha+\beta}{2} = 2a\left(\sin\frac{\alpha}{2}\cos\frac{\beta}{2} + \cos\frac{\alpha}{2}\sin\frac{\beta}{2}\right)^2 \\ &= 2c(s_+c_- + s_-c_+)^2 = c\lambda \qquad @ \quad x \geq 0 \end{aligned}$$

$$\begin{aligned} a[1-\cosh(\gamma+\delta)] &= -2a\sinh^2\frac{\lambda+\delta}{2} = -2a\left(\sinh\frac{\gamma}{2}\cosh\frac{\delta}{2} + \cosh\frac{\gamma}{2}\sinh\frac{\delta}{2}\right)^2 \\ &= 2c(s_+c_- + s_-c_+)^2 = c\lambda \qquad @ \quad x \leq 0 \end{aligned}$$

We therefore have from Eqs. (8.2.13), (8.2.14), and (8.2.16) for the short path of any Keplerian orbit

$$p = c\rho\lambda \qquad @\text{ Keplerian orbit} \quad \textbf{semi-latus rectum} \tag{8.2.18}$$

With this and some trigonometric expansions we find the following calculation scheme:

/4 A #! ! 8! !@@@

Calculation Scheme for an Universal Solution to Lambert's Problem

0. Given $\boldsymbol{r}_1, \boldsymbol{r}_2$, Δt, and μ

1. With $c := \sqrt{r_1^2 + r_2^2 - 2\boldsymbol{r}_1\boldsymbol{r}_2}$ calculate the dimensionless numbers

$$\Delta\tau = \Delta t\sqrt{\frac{\mu}{c^3}}$$

$$s_\pm = \frac{1}{2}\sqrt{\frac{r_1 + r_2}{c} \pm 1}$$

2. With $c_\pm := \sqrt{1 - xs_\pm^2}$ and $u = (s_+c_- - s_-c_+)^2 x$ solve the equation

$$\frac{\Delta\tau}{2} \cdot x + s_+c_+ - s_-c_- = (s_+c_- - s_-c_+)L(u)$$

for x with Newton's method or for difficult hyperbolic orbits $x < 0$ with the bisection method. (If $x = c/a < 0$ hyperbola, if $x = 0$ parabola, if $x > 0$ ellipse)

3. Calculate the dimensionless number and vectors

$$\lambda = 2(s_+c_- + s_-c_+)^2$$

$$\boldsymbol{\rho}_1 = \boldsymbol{r}_1/c,\ \boldsymbol{\rho}_2 = \boldsymbol{r}_2/c$$

$$\rho = \rho_1\rho_2 - \boldsymbol{\rho}_1\boldsymbol{\rho}_2 = \frac{1}{2}\left[1 - \left(\frac{r_1 - r_2}{c}\right)^2\right]$$

With this the eccentricity vector (see Eq. (8.2.3)) and the dimensionless terminal velocities (see Eq. (8.2.2)) and transfer path eccentricity (see Eq. (8.2.3)) are determined as

$$\boldsymbol{v}_{1+}\sqrt{\frac{c}{\mu}} = \frac{\sqrt{\rho\lambda}}{|\boldsymbol{\rho}_1 \times \boldsymbol{\rho}_2|}\left[\boldsymbol{\rho}_2 - \boldsymbol{\rho}_1 + \frac{1}{\lambda}\hat{\boldsymbol{\rho}}_1\right]$$
$$\boldsymbol{v}_{2-}\sqrt{\frac{c}{\mu}} = \frac{\sqrt{\rho\lambda}}{|\boldsymbol{\rho}_1 \times \boldsymbol{\rho}_2|}\left[\boldsymbol{\rho}_2 - \boldsymbol{\rho}_1 - \frac{1}{\lambda}\hat{\boldsymbol{\rho}}_2\right]$$
$$\boldsymbol{e} = (1 - x\rho_1)\hat{\boldsymbol{\rho}}_1 - \frac{c}{\mu}(\boldsymbol{\rho}_1\boldsymbol{v}_{1+})\boldsymbol{v}_{1+}$$

8.2.4 *Minimum Effort Lambert Transfer*

Having analyzed the Lambert transfer orbit we will now finally turn to the most important problem from a practical point of view: Given two transfer points P_1 and P_2 with state vectors $(\boldsymbol{r}_1, \boldsymbol{v}_{1-})$ and $(\boldsymbol{r}_2, \boldsymbol{v}_{2+})$ what is the Lambert transfer orbit with the least propulsion effort? So the additional scalar specification here is the least effort equaling a minimum total $\Delta\boldsymbol{v}$ as given in Eq. (8.2.4). In order to determine that transfer orbit, we recall the two orbital equations at P_1 and P_2

$$\begin{aligned} r_1 + \boldsymbol{e}\boldsymbol{r}_1 &= a\left(1 - e^2\right) \\ r_2 + \boldsymbol{e}\boldsymbol{r}_2 &= a\left(1 - e^2\right) \end{aligned}$$

These conditional equations leave one of the three orbital elements undetermined. It is this undetermined element that provides us with the freedom to optimize the transfer orbit. We choose as the free element the orientation of the conic orbit, position vector $\boldsymbol{r}_1$. We denote this angle as

$$\varphi = \angle(\boldsymbol{e}, \boldsymbol{r}_1)$$

We therefore have $\hat{\boldsymbol{e}}\hat{\boldsymbol{r}}_1 = \cos\varphi$ and for geometrical reasons $\hat{\boldsymbol{e}}\hat{\boldsymbol{r}}_2 = \cos(\Delta\theta - \varphi)$. From the first equation we then have

$$p = a\left(1 - e^2\right) = r_1(1 + e\cos\varphi) \tag{8.2.19}$$

Subtracting from this equation the second one from above yields

$$r_1 - r_2 + e r_1 \cos\varphi - e r_2 \cos(\Delta\theta - \varphi) = 0$$

from which we derive

$$e = \frac{r_2 - r_1}{r_1\cos\varphi - r_2\cos(\Delta\theta - \varphi)} \tag{8.2.20}$$

Hence, we have derived the orbital elements a, e and p as a function of the orientation of the transfer orbit $\varphi = \angle(\boldsymbol{e}, \boldsymbol{r}_1)$. We insert this result into Eq. (8.2.2) and find with Eq. (8.2.4) the total Δv as a function of φ. Employing an optimization algorithm that does "minimize $\Delta v(\varphi)$", one finds the optimal φ and from the above equations also the optimal orbital elements.

8.3 Hohmann Transfer

We have already seen that a minimum energy Lambert orbit does not necessarily imply a minimum energy Lambert transfer because for that we also have to take into account the delta-v of the two impulse maneuvers into and out of the transfer orbit. So we are now seeking for a minimum energy Lambert transfer. This is the Hohmann transfer.

The general problem statement is this: What is the transfer orbit between two Keplerian orbits with the least propulsion demand? Because this general problem is quite complex, we will restrict ourselves to the following conditions:

- The two orbits are elliptic and coplanar.
- The orbital bodies revolve around the same central body with the same orientation (co-revolving), so their angular momentum vectors are collinear, only their magnitudes are different.
- The orbital elements are such that the two orbits nowhere touch or cross each other.

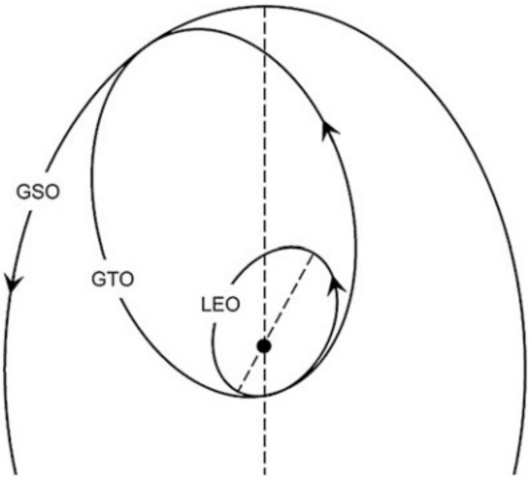
Due to the last constraint we can define an inner and an outer orbit, which we will denote by the symbols • and O.

Throughout this section we assume in addition that the transfers are achieved with impulsive thrust maneuvers, so-called *boosts* or *kick-burns* with $F_* \gg F_{ext}$ (see Sect. 2.3) so that the created Δv is determined solely by the thrust characteristics. This assumption is in general valid for today's chemical propulsion engines for orbit control.

8.3.1 The Minimum Principle

As an example for an orbit transfer, let us consider the situation where we are in an elliptic LEO, and we want to get from any point on this orbit into an elliptic geosynchronous orbit, GSO (a GSO is in sync with Earth's rotation only on the average of an orbit) (see Fig. 8.9). A kick-burn in LEO will first take us into an elliptic transfer orbit, the so-called GSO transfer orbit (GTO). This transfer orbit has to cross or touch the GSO at some point. Once we are at the crossing point, a second kick-burn would bring us into GSO.

Fig. 8.9 The GTO as a Hohmann transfer orbit from an elliptic LEO to an elliptic GSO (not to scale)



The general problem statement is this: What is the transfer orbit between two Keplerian orbits with the least propulsion demand? Because this general problem is quite complex, we will restrict ourselves to the following conditions:

- The two orbits are elliptic and coplanar.
- The orbital bodies revolve around the same central body with the same orientation (co-revolving), so their angular momentum vectors are collinear, only their magnitudes are different.
- The orbital elements are such that the two orbits nowhere touch or cross each other.

Due to the last constraint we can define an inner and an outer orbit, which we will denote by the symbols • and O.

Throughout this section we assume in addition that the transfers are achieved with impulsive thrust maneuvers, so-called *boosts* or *kick-burns* with $F_* \gg F_{ext}$ (see Sect. 2.3) so that the created Δv is determined solely by the thrust characteristics. This assumption is in general valid for today's chemical propulsion engines for orbit control.

8.3.1 The Minimum Principle

As an example for an orbit transfer, let us consider the situation where we are in an elliptic LEO, and we want to get from any point on this orbit into an elliptic geosynchronous orbit, GSO (a GSO is in sync with Earth's rotation only on the average of an orbit) (see Fig. 8.9). A kick-burn in LEO will first take us into an elliptic transfer orbit, the so-called GSO transfer orbit (GTO). This transfer orbit has to cross or touch the GSO at some point. Once we are at the crossing point, a second kick-burn would bring us into GSO.

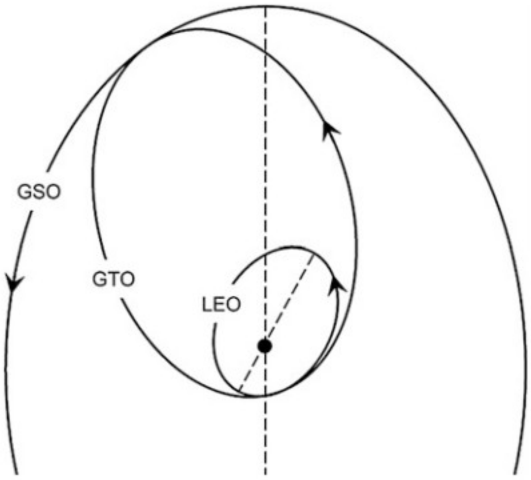


Fig. 8.9 The GTO as a Hohmann transfer orbit from an elliptic LEO to an elliptic GSO (not to scale)

Such a Hohmann transfer orbit is shown in Fig. 8.9. A Hohmann transfer of course also works the other way round, i.e., for a transfer from an outer to an inner elliptic orbit. So we have arrived at an answer to our optimization problem for a given starting point on the initial orbit. This leaves open the answer to the following question: At which point on the initial orbit should we perform the kick-burn to optimize the overall transfer between two elliptic orbits. One could presume that due to $\Delta\varepsilon \propto \boldsymbol{v} \cdot \Delta\boldsymbol{v}$ a first kick-burn at the highest orbital velocity, i.e., at the periapsis, would always be a good choice. But this neglects the second kick-burn at low speeds at the apoapsis of the transfer ellipse. A survey of the transfer at different orbital elements shows that the ratio of the eccentricities of the inner and the outer orbit is important. In general one can say that if the inner orbit has a higher eccentricity than the outer orbit, the optimal transfer varies, but

> If the inner orbit has a lower eccentricity than the outer orbit, the transfer to or from the apoapsis of the outer orbit requires the least delta-v budget.

The Earth–Mars transfer is a nice example for this rule, because here $e_{earth} = 0.0167$ and $e_{mars} = 0.0934$. Figure 8.10 shows the delta-v budget of the transfer as a function of the orbit angle of the transition point on the Mars orbit.

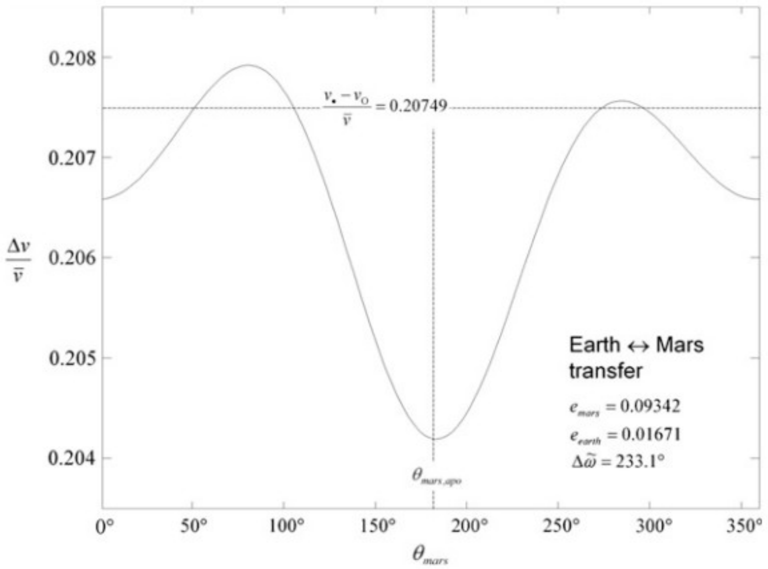

Fig. 8.10 Normalized delta-v budget for Earth ↔ Mars Hohmann transfers as a function of the orbit angle of the intersection with Mars orbit. The angle between their lines of apsis is 233.1°. The horizontal dashed line is the limiting value if both orbits were circular. Note the stretch of the *y*-scale

The transfer optimization problem gets even more intricate if arbitrary angles between the lines of apsides, or non-coplanar, or crossing orbits are considered. Because these cases become too complex to lay them out in a textbook, we skip them. In the following, we rather focus on the transfer between circular and near-circular orbits, which are of great practical value.

8.3.2 *Transfer Between Circular Orbits*

Hohmann transfers are specifically interesting between two circular orbits. Planetary orbits are mostly circular because at a given orbital energy they minimize atmospheric drag and provide steady orbit conditions, or because in the geostationary orbit the satellite has to rotate exactly in accord with the Earth. For circular orbits $r_\bullet = a_\bullet = const$ and $r_\bigcirc = a_\bigcirc = const$. It is easy to find out the metric orbital elements of a Hohmann transfer orbit between circular orbits. For the semi-major axis of this Hohmann transfer orbit, the following is obviously applicable:

$$a_H = \frac{1}{2}(a_\bullet + a_\bigcirc) \tag{8.3.2}$$

The transfer time is exactly half a period of the transfer ellipse, so according to Eq. (7.4.12)

$$t_H = \pi\sqrt{\frac{a_H^3}{\mu}} \tag{8.3.3}$$

The transfer ellipse with its two degrees of freedom a_H and e_H is completely and unambiguously determined by the boundary condition $r_{H,per} = a_H(1 - e_H)$ (see Eq. (7.4.6)) and by $r_{H,per} = a_\bullet$ and $r_{H,apo} = a_\bigcirc$. As for the semi-minor axis $b_H = a_H\sqrt{1 - e_H^2}$ applies, and the other metric orbital elements can be easily derived:

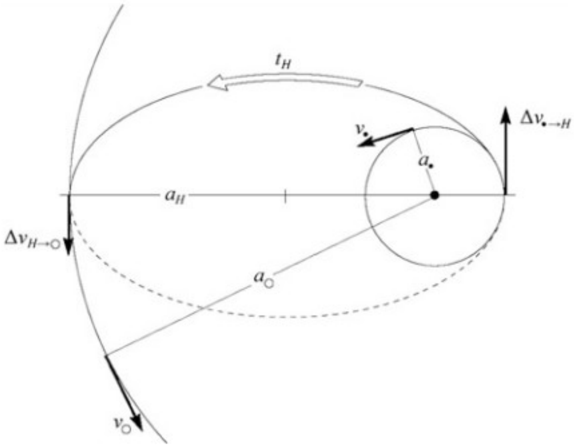
$$e_H = \frac{a_\bigcirc - a_\bullet}{a_\bigcirc + a_\bullet} \tag{8.3.4}$$

$$b_H = \sqrt{a_\bullet a_\bigcirc} \tag{8.3.5}$$

Let us determine the Δv demand for a Hohmann transfer between two circular orbits. According to Eq. (2.4.1), this is calculated for two Hohmann transfer kick-burns as the sum of the individual amounts (see Fig. 8.11):

$$\begin{aligned} \Delta v &= \left\{ \begin{matrix} |\Delta v_{\bullet\to H}| + |\Delta v_{H\to\bigcirc}| & @ \;\; \bullet \to \bigcirc \\ |\Delta v_{\bigcirc\to H}| + |\Delta v_{H\to\bullet}| & @ \;\; \bigcirc \to \bullet \end{matrix} \right\} \\ &= (v_{H\bullet} - v_\bullet) + (v_\bigcirc - v_{H\bigcirc}) \;@\;\; \bullet \leftrightarrow \bigcirc \end{aligned}$$

Fig. 8.11 Hohmann transfer between an inner and an outer circular orbit



The latter holds because $|\Delta v_{\bullet\to H}| = |\Delta v_{H\to\bullet}| = v_{H\bullet} - v_\bullet$ and $|\Delta v_{O\to H}| = |\Delta v_{H\to O}| = v_O - v_{HO}$. According to Eq. (8.3.4) $(1+e_H)/(1-e_H) = a_O/a_\bullet$ and therefore from Eq. (7.4.10) follows $v_{H\bullet} = v_{per} = v_\bullet\sqrt{a_O/a_H}$ and $v_{HO} = v_{apo} = v_O\sqrt{a_\bullet/a_H}$. Inserting this into the above equation yields the two contributions

$$\begin{aligned} |\Delta v_{\bullet\leftrightarrow H}| &= v_\bullet\left(\sqrt{\frac{a_O}{a_H}} - 1\right) \\ |\Delta v_{O\leftrightarrow H}| &= v_O\left(1 - \sqrt{\frac{a_\bullet}{a_H}}\right) \end{aligned} \tag{8.3.6}$$

which are shown in Fig. 8.12. So, in total we get

$$\Delta v = |\Delta v_{\bullet\leftrightarrow H}| + |\Delta v_{H\leftrightarrow O}| = v_\bullet\left(\sqrt{\frac{a_O}{a_H}} - 1\right) + v_O\left(1 - \sqrt{\frac{a_\bullet}{a_H}}\right) \tag{8.3.7}$$

If the terms in Eq. (8.3.7) are arranged skillfully and extended by $\sqrt{\mu} = v_\bullet\sqrt{a_\bullet} = v_O\sqrt{a_O}$, we get

$$\boxed{\Delta v = (v_\bullet - v_O)\left(\frac{\sqrt{a_\bullet} + \sqrt{a_O}}{\sqrt{a_H}} - 1\right) < v_\bullet - v_O} \quad @\,\bullet \leftrightarrow O \tag{8.3.8}$$

Equation (8.3.8) is valid for both transfer directions, i.e., • → O and O → •.

Why is There a Bump?

The two contributions exhibit quite different shapes. Why? And why does $\Delta v_{O\leftrightarrow H}$ have a bump? The first (transfer injection) boost increases continuously with increasing distance between the orbits. This is quite easy to understand, as the semi-major axis a_H of the transfer orbit is determined by this distance, and the

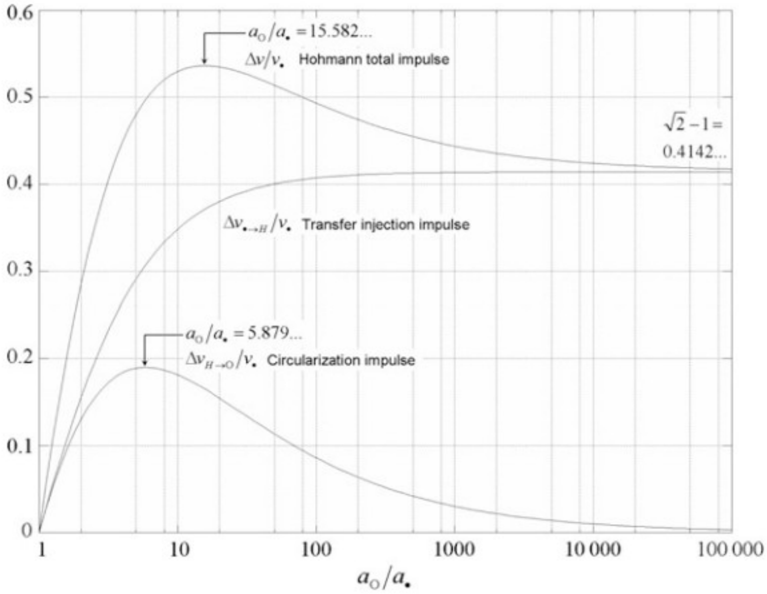


Fig. 8.12 Propulsion demand for Hohmann transfers from an inner to an outer orbit

transfer orbital energy also increases non-linearly with $\varepsilon = -\mu/2a$ according to Eq. (7.3.19). The second (circularization) boost, however, has a maximum at $a_O/a_\bullet = 5.879362...$ (exercise, Problem 8.4a). The reason is as follows. At the one extreme, if both orbits are in close vicinity to each other, i.e., $\Delta a = a_O - a_\bullet \to 0$, we havewith

$$a_H = \frac{1}{2}(a_\bullet + a_O) = a_\bullet\left(1 + \frac{1}{2}\frac{\Delta a}{a_\bullet}\right)$$

and according to Eq. (8.3.6)

$$|\Delta v_{H\leftrightarrow O}| \approx v_O\left(1 - 1\bigg/\sqrt{1 + \frac{1}{2}\frac{\Delta a}{a_\bullet}}\right) \approx \frac{1}{4}\frac{\Delta a}{a_\bullet}v_0$$

So, for $\Delta a = 0$ the second boost of course is zero and increases roughly linearly with increasing distance Δa. At the other extreme, when $a_O \to \infty$, then $a_H, \Delta a \to \infty$ as well, and we have for the second boost at infinite distance

$$|\Delta v_{H\leftrightarrow O}| = v_O\left(1 - \sqrt{\frac{a_\bullet}{a_H}}\right) \approx v_0\left(1 - \sqrt{\frac{2a_\bullet}{\Delta a}}\right) \approx v_0 \approx 0$$

So, because at infinity the Hohmann and the target orbital velocity is zero the transfer boost between the two vanishes as well. Because the second boost is positive between these limiting cases it must exhibit a maximum somewhere in between. Because of this maximum of the second boost, the total Hohmann transfer also has a maximum $\Delta v_{\max} \approx 0.536258 \cdot v_\bullet$ at $a_O / a_\bullet = 15.58172\ldots$ (exercise, Problem 8.4b).

Adjacent Circular Orbits

For a Hohmann transfer between adjacent circular orbits, $a_O \approx a_\bullet$, we can approximate (exercise, Problem 8.2)

$$\frac{\sqrt{a_\bullet} + \sqrt{a_O}}{\sqrt{a_H}} - 1 \;\approx 1 - \frac{1}{16}\left(\frac{a_O - a_\bullet}{a_\bullet}\right)^2 \to 1 \tag{8.3.9}$$

hence

$$\boxed{\Delta v \approx v_\bullet - v_O} \quad @\, a_O \approx a_\bullet \tag{8.3.10}$$

> *Example*
>
> For $a_O / a_\bullet \leq 2.5$, i.e., for orbits with altitudes up to 10,000 km above Earth's surface, the error due to Eq. (8.3.10) is smaller than 5.1%.

Distant Circular Orbits

For circular orbits that are distant from each other, we rewrite Eq. (8.3.8)

$$\frac{\Delta v}{v_\bullet} = \left(1 - \sqrt{\frac{a_\bullet}{a_O}}\right)\left(\sqrt{2}\frac{1 + \sqrt{a_\bullet / a_O}}{\sqrt{1 + a_\bullet / a_O}} - 1\right) = \sqrt{2}\frac{1 - a_\bullet / a_O}{\sqrt{1 + a_\bullet / a_O}} - 1 + \sqrt{\frac{a_\bullet}{a_O}}$$

For these distant orbits $a_\bullet / a_O \ll 1$ and we can approximate

$$\frac{\Delta v}{v_\bullet} = \sqrt{2} - 1 + \sqrt{\frac{a_\bullet}{a_O}} - \frac{3}{\sqrt{2}}\frac{a_\bullet}{a_O} + \cdots \tag{8.3.11}$$

Using $v = \sqrt{\mu / a}$ we therefore obtain in the limit of infinite distances

$$\Delta v = \left(\sqrt{2} - 1\right) v_\bullet + v_O \quad @\, a_O / a_\bullet \to \infty \tag{8.3.12}$$

Between these two limiting cases the expression $\left(\sqrt{a_\bullet} + \sqrt{a_O}\right) / \sqrt{a_H} - 1$ is strictly monotonously decreasing (see Fig. 8.13), and that is why in Eq. (8.3.8) the inequality strictly holds.

Hohmann Transfer as a Special Case of the Minimum Energy Lambert Transfer

Let us consider the case of a Lambert transfer orbit (see Sect. 8.2) between two circular orbits without specified transition points. We examine the minimum energy transfer orbit of Sect. 8.2.2, pick any P_1 on the initial circle, and, as shown in Fig. 8.14, move P_2, because it is arbitrary, until $\Delta\theta = \pi$. In this special case $c = r_1 + r_2$ and both the occupied and empty focal points lie on the chord. This is

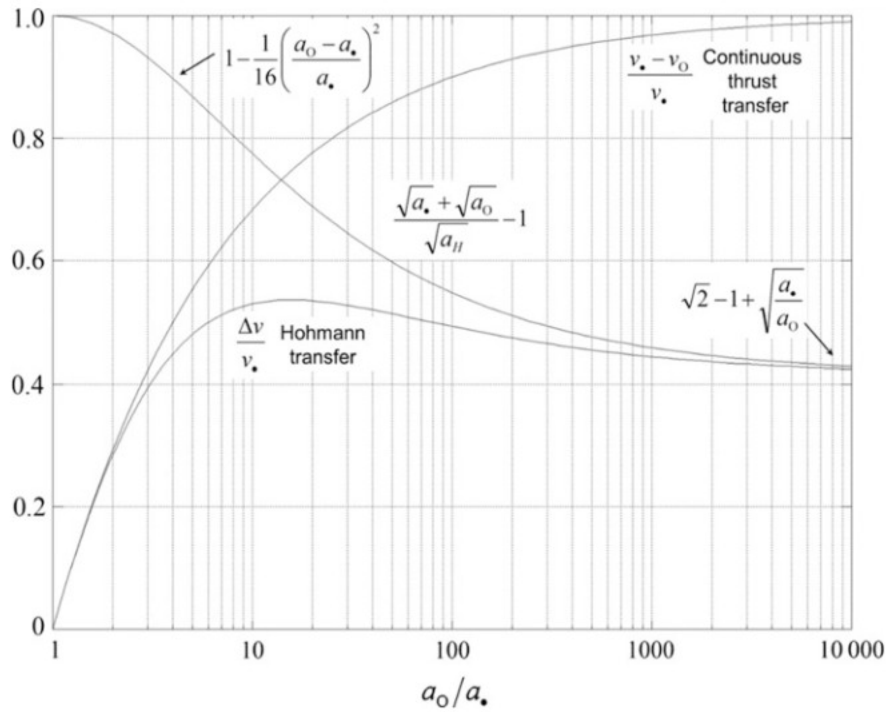

Fig. 8.13 The terms of the Eq. (8.3.8) and their limiting values. The factor $(v_\bullet - v_O)/v_\bullet$ is the propulsion demand of a continuous thrust transfer (see Sect. 8.4.5)

the condition of a minimum energy transfer orbit and it obviously is a Hohmann transfer orbit. By this procedure, we in a different way have verified that the Hohmann transfer is a minimum energy transfer with maximum transfer time.

Note that for this special Lambert transfer the eccentricity is no longer defined. In fact, whatever e might be, the transfer time is independent of e! For the Hohmann transfer, this additional degree of freedom is taken to adjust the tangents of the transfer ellipse to those of the circles at the touching points so that delta-v becomes minimal.

8.3.3 *Transfer Between Near-Circular Orbits*

We now consider Hohmann transfers between two coplanar, co-revolving, non-crossing ellipses, with small eccentricities $e_\bullet, e_O \ll 1$. The detailed analytical approximations are quite convoluted due to $e_\bullet e_O$ cross-terms, but the general upshot is that the dependency of delta-v as a function of $e_\bullet, e_O$ is very weak. This can be observed, for instance, in Fig. 8.15 where for Hohmann transfers between two apsides points on two orbits with $a_O/a_\bullet = 1.52365$ (Earth–Mars) the normalized delta-v is depicted as a function of $e_\bullet = e_O$ numerically.

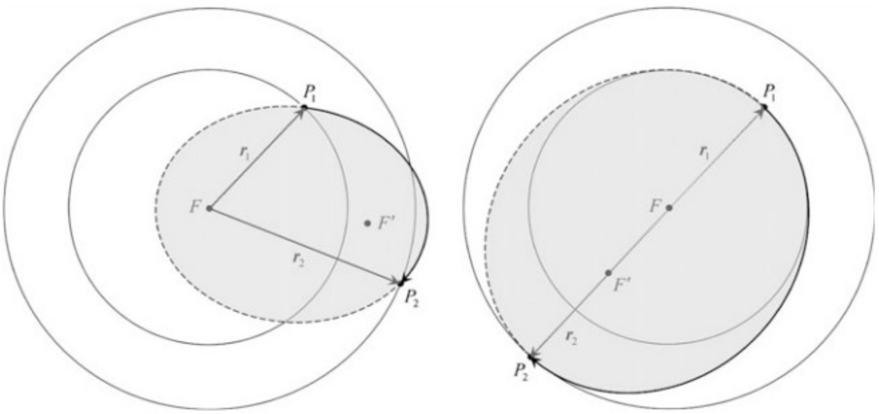

Fig. 8.14 A Lambert transfer between arbitrary points on two circular orbits (left) and the crossover to the Hohmann transfer for $\Delta\theta = \pi$ (right)

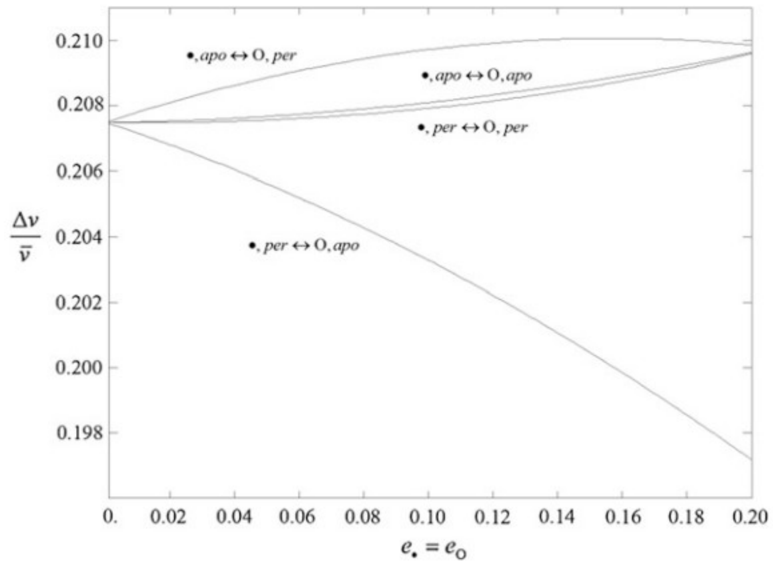

Fig. 8.15 The delta-v budget as a function of the common eccentricities. The dependencies are given for orbits with $a_O/a_\bullet = 1.52365$ (Earth–Mars). Note the stretched Δv-scale

For $e \leq 0.1$ the variations are smaller than 2% of their corresponding circular orbits value $(v_\bullet - v_O)/\bar{v} = 0.20749$. As we can see from Fig. 8.10 this is in accordance with the Earth ↔ Mars transfer, $e_{Mars} = 0.09342$ and $e_{earth} = 0.01671$, even if the transfers would be performed from any position of the orbit. So for all practical purposes, we get the same result as for a transition between two circular orbits.

$$\Delta v \approx (v_\bullet - v_\mathrm{O})\left(\frac{\sqrt{a_\mathrm{O}} + \sqrt{a_\bullet}}{\sqrt{(a_\mathrm{O} + a_\bullet)/2}} - 1\right) \qquad @\ e_\bullet, e_\mathrm{O} \leq 0.1 \tag{8.3.13}$$

Nevertheless, owing to the Oberth effect as discussed in Sect. 8.1.3, the general transfer rule is

> The most delta-v efficient Hohmann transfer between a near-circular or even elliptic inner orbit and any outer orbit is always from or to the periapsis of the inner orbit.

8.3.4 Sensitivity Analysis

From an energy point of view Hohmann transfers are the most favorable two-impulse transfer orbits. But they also have some disadvantages. They can be very sensitive to small inaccuracies of the transfer injection impulse. Let us have a closer look at this dependence for transfers between circular orbits.

Let r_{per} and r_{apo} be the periapsis and the apoapsis radius of the transfer orbit respectively (for convenience, we drop the index H to indicate the Hohmann transfer orbit). The periapsis is determined by the initial orbit radius. From the vis-viva Eq. (7.2.15) we get for the velocity on the Hohmann transfer orbit at the periapsis

$$v_{per}^2 = \frac{2\mu}{r_{per}} - \frac{\mu}{a} = \frac{\mu_\oplus}{a}\frac{1+e}{1-e}$$

If the transfer injection burn has a small error dv_{per} at the fixed periapsis $r_{per} = const$ we get

$$2v_{per}dv_{per} = \frac{\mu}{a^2}da$$

from which follows

$$\frac{da}{a} = 2\frac{av^2}{\mu}\frac{dv_{per}}{v_{per}} = 2\frac{1+e}{1-e}\frac{dv_{per}}{v_{per}} \tag{8.3.14}$$

So, a thrust error generates a certain variation of the semi-major axis. Now we want to know how this affects the position of the apoapsis. We start with Eq. (7.4.7)

$$r_{apo} = a(1+e)$$

Its change in position is determined by differentiation

$$\frac{dr_{apo}}{r_{apo}} = \frac{da}{a} + \frac{de}{1+e} \tag{8.3.15}$$

Both parameters a and e are not independent of each other, but linked by the constancy of the periapsis of the initial orbit:

$$const = r_{per} = a(1-e)$$

After differentiating this equation, we see how their changes depend on each other

$$de = (1-e)\frac{da}{a} \tag{8.3.16}$$

So together with Eq. (8.3.15), we get

$$\frac{dr_{apo}}{r_{apo}} = \frac{2}{1+e}\frac{da}{a}$$

and finally with Eq. (8.3.14), we get

$$\boxed{\frac{dr_{apo}}{r_{apo}} = \frac{4}{1-e}\frac{dv}{v} = \frac{4a}{r_{per}}\frac{dv_{per}}{v_{per}} = 2\left(1+\frac{r_{apo}}{r_{per}}\right)\frac{dv_{per}}{v_{per}}} \tag{8.3.17}$$

That is, for a given injection burn error dv_{per}, the relative target point accuracy decreases with increasing transfer distances.

> *Example 1*
>
> Let us examine the Hohmann transfer from an initial LEO orbit (h = 400 km) to GEO. Because of $r_{GEO}/r_{LEO} = 6.232$, we get
>
> $$\frac{dr_{apo}}{r_{apo}} = 14.46\frac{dv_{per}}{v_{per}}$$
>
> A relatively small burn error of just 0.5% would lead to an inaccuracy in the target distance of 7.2%. That is, 3000 km deviation from the GEO orbit!

> *Example 2*
>
> Let us have a look at the Hohmann transfer from an initial LEO orbit (h = 400 km) to the Moon. Because of $r_{moon}/r_{earth} = 56.654$, we get
>
> $$\frac{dr_{apo}}{r_{apo}} = 115.3\frac{dv_{per}}{v_{per}}$$
>
> This means that the same small burn error of just 0.5% would lead to an inaccuracy in the target distance of 58%. That would just bring us to nirvana!

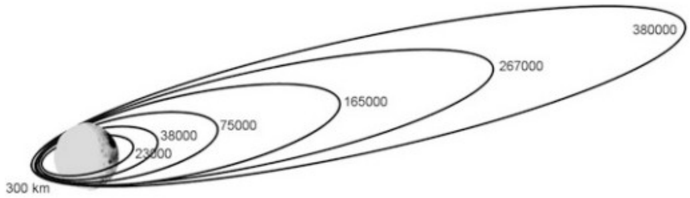

Fig. 8.16 The transfer trajectories of Chandrayaan-1 from Earth to Moon. The apogee (given in km) was increased step by step by successive kick-burns at 300 km perigee

Summary
Plain Hohmann transfers may be the most favorable transfer orbits from an energy point of view, but they implicate long transfer times and the large possible target errors.

However, already small deviations from an ideal Hohmann transfer and in-flight corrections strongly reduce these drawbacks as discussed in Sect. 9.3.2 for near-Hohmann transfers to Mars. In addition, if transfer time is not an issue, one can get a grip on the high sensitivity of highly elliptic transfer orbits by gradually raising the apogee of the transfer orbit to the final Hohmann transfer orbit. Thereby after each raising maneuver the next maneuver can be adjusted to the actual apogee. Figure 8.16 shows the transfer trajectory of the Indian Chandrayaan-1 Moon mission, which was launched on October 22, 2008 and arrived at the Moon 13 days, later where it was captured by Moon's gravitation into a highly elliptic Moon orbit.

8.4 Other Transfers

In this section we study some orbit transfers which are non-Hohmann, but nevertheless of practical value.

8.4.1 Parabolic Escape Transfer

In Sect. 7.4.4. we have studied parabolic orbits. They have the special property that the body reaches infinity at zero velocity. Therefore the simplest escape orbit is a parabolic orbit. We also saw that at a given orbital radius the escape velocity v_{esc} enables a spacecraft to go to infinity independent of the direction in which the final velocity vector points. Yet, the propulsion effect to achieve the escape velocity strongly depends on this direction (see Sect. 8.1.3). In Sect. 8.3.1 we saw that at a given orbital position with $\boldsymbol{r}_0, \boldsymbol{v}_0$ the least effort to achieve a predetermined $\boldsymbol{v}_{esc}$ is by the impulse maneuver $\Delta\boldsymbol{v}||\boldsymbol{v}_0$, i.e. a boost into the instantaneous flight direction in the initial orbit. From Eq. (7.3.16) this implies that the flight angle λ of an initial elliptic orbit with a, e and final parabolic orbit with p_p then is identical

$$\cos\gamma = \sqrt{\frac{a(1-e^2)}{r_0(2-r_0/a)}} = \sqrt{\frac{p_p}{2r_0}}$$

From this it follows that the semi-latus rectum of the parabolic escape orbit is

$$p_p = 2\frac{a(1-e^2)}{2-r_0/a} \quad @\ \Delta\boldsymbol{v}||\boldsymbol{v}_0 \tag{8.4.1}$$

The orientation of the escape orbit, i.e. its line of apsides is given from the parabolic orbit equation as

$$\angle(\boldsymbol{e}_p, \boldsymbol{r}_0) = \cos\,\theta_{p,0} = \frac{p_p}{r_0} - 1 \tag{8.4.2}$$

The initial elliptic orbit and the final parabolic orbit are coplanar.

Finally it would be interesting to know at which point on the ellipse an escape would be most efficient. We calculate Δv from the vis-viva equation to be

$$\Delta v = \sqrt{\mu}\left(\sqrt{\frac{2}{r_0}} - \sqrt{\frac{2}{r_0} - \frac{1}{a}}\right) \tag{8.4.3}$$

From this equation it is obvious that the required Δv lessens with smaller orbit radius. Therefore it is minimal at its periapsis and maximal at its apoapsis, although the differences are only slight for $e < 0.1$. Nevertheless, this result is a good example of the Oberth effect decribed in Sect. 8.1.3.

But, most importantly, the boost position solely determines the asymptotic direction of motion. So, the escape procedure is to first figure out the direction of asymptotic motion and measure it as an orbit angle relative to the line of apsides of the initial elliptic orbit. Call this angle θ_∞. Then $\theta_0 = \theta_\infty + \theta_{p,0}$ or

$$\cos(\theta_0 - \theta_\infty) = \cos\,\theta_{p,0} = \frac{p_p}{r_0} - 1 = \frac{2(1+e\,\cos\,\theta_0)^2}{1+2e\,\cos\,\theta_0 + e^2} - 1 \tag{8.4.4}$$

So, for a given θ_∞ the orbit angle θ_0 of the boost position is the root of this equation.

> *Example*
>
> We assume a circular orbit with $r = r_0 = a,\ e = 0$. At any point in orbit we want to transfer into an escape parabola with the least Δv effort. What then is the escape parabola?
>
> From Eq. (8.4.1) follows $p = 2r_0$ and from Eq. (7.3.16) $\sin\gamma = \sin 0° = 0 = \sin\theta \rightarrow \theta = 0°$. This means that the boost location constitutes the periapsis of the escape parabola.

8.4.2 Bi-elliptic Transfer

The maximum of the total delta-v for Hohmann transfers (see Fig. 8.12) at $a_O/a_\bullet = 15.582$ occurs because $\Delta v_{H\to O}$ achieves its maximum at $a_O/a_\bullet \approx 5.88$ for turning into the target orbit. This second delta-v contribution however vanishes for $r \to \infty$. This gives rise to the assumption that it might be possible to save propulsion demand with a total of three impulses by first escaping from the initial orbit to far out or even to infinity, and then turning back again to the coplanar target orbit (see Fig. 8.17).

We want to determine the propulsion demand for such a three-impulse transfer (a.k.a. *bi-elliptic transfer*). According to Eq. (8.3.12) the delta-v budget to a remote circular orbit with orbit radius $a_\times \gg a_O > a_\bullet$ and orbital velocity $v_\times = \sqrt{\mu/a_\times}$ is

$$|\Delta v_{\bullet\to\times}| \approx \left(\sqrt{2}-1\right)v_\bullet + v_\times$$

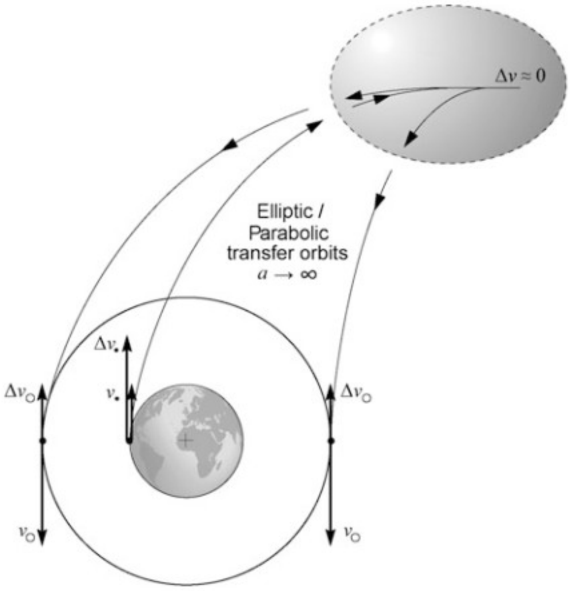
The delta-v budget for a kick-burn that brings us back into the target orbit in turn amounts to

$$|\Delta v_{\times\to O}| \approx \left(\sqrt{2}-1\right)v_O + v_\times$$

So, in total we have

$$\Delta v = |\Delta v_{\bullet\to\times}| + |\Delta v_{\times\to O}| \approx \left(\sqrt{2}-1\right)(v_\bullet + v_O) + 2v_\times \quad @\, a_\times \gg a_O \qquad (8.4.5)$$

Fig. 8.17 Schematic of a bi-elliptic transfer with an infinite intermediate orbit



For a bi-parabolic transfer, when the intermediate orbit is infinitely far away, then $v_\times = 0$ and the total delta-v budget becomes minimal

$$\Delta v = \left(\sqrt{2} - 1\right)(v_\bullet + v_\mathrm{O}) \quad @\, a_\times / a_\mathrm{O} \to \infty \tag{8.4.6}$$

Equation (8.4.6) is illustrated in Fig. 8.18. For $a_\mathrm{O}/a_\bullet > 11.938765\ldots$ the propulsion demand is indeed more favorable with bi-parabolic transfers than with Hohmann transfers (exercise, Problem 8.5). A practical and hence important benefit of a bi-parabolic transfer is that at the outermost position, where $v \approx 0$, a change of the orbital plane, flight direction, or even the direction of rotation of the orbital curve may be done virtually without any propulsion demand. The serious drawback is that it takes increasingly longer to get farther out.

Break-Even Point with Hohmann Transfer

To ease this problem, it would be interesting to know at which intermediate orbit distance the bi-elliptic transfer starts to be advantageous to the Hohmann transfer. From Eqs. (8.4.5) and (8.3.11) we get the conditional equation $\left(\text{note that } O(v_\times) = O(v_\mathrm{O}^2/v_\bullet)\right)$

$$\Delta v_{bi} \approx \left(\sqrt{2} - 1\right)(v_\bullet + v_\mathrm{O}) + 2v_\times < \left(\sqrt{2} - 1\right)v_\bullet + v_\mathrm{O} - \frac{3}{\sqrt{2}}\frac{v_\mathrm{O}^2}{v_\bullet} \approx \Delta v_H$$

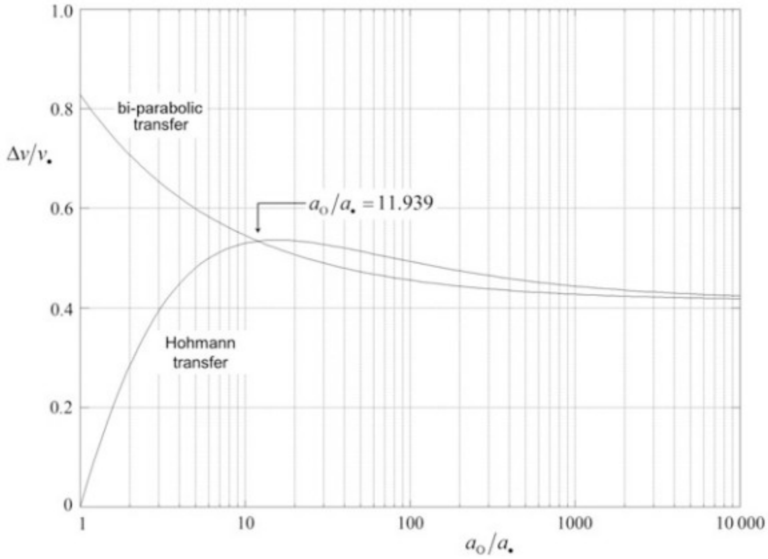


Fig. 8.18 Comparison between an infinite bi-parabolic transfer and a Hohmann transfer

This implies

$$\frac{v_\times}{v_\bigcirc} < 1 - \frac{1}{\sqrt{2}} - \frac{3}{2\sqrt{2}}\frac{v_\bigcirc}{v_\bullet}$$

and therefore

$$\frac{a_\times}{a_\bigcirc} > \frac{8}{\left[2\left(\sqrt{2}-1\right) - 3\sqrt{a_\bullet/a_\bigcirc}\right]^2} \tag{8.4.7}$$

For example let us assume three ratios $a_\bigcirc/a_\bullet = 20,\ 100,\ 500$. For this we find $a_\times > (322,\ 28.6,\ 16.60) \cdot a_\bigcirc = (6441,\ 2860,\ 8299) \cdot a_\bullet$.

Finally, one might question at which $a_\bigcirc/a_\bullet$ the bi-elliptic transfer is most advantageous to a Hohmann transfer, i.e.: When does $v_\times/v_\bigcirc$ become maximal, or when does the relation $a_\times/a_\bullet$ become minimal? The answer is easily calculated from Eq. (8.4.7) to be $a_\bigcirc/a_\bullet|_{opt} = \left[3/\left(\sqrt{2}-1\right)\right]^2 = 52.456$ and $a_\times/a_\bullet|_{\min} = 2445.8$. This optimum case corresponds roughly to a transition from an Earth parking orbit at altitude $h = 250\ km$ to the Moon, $a_{Moon}/a_{park} = 57.3$. Even at this near optimal situation one would need to travel to $a_\times = 2455 \cdot a_{park} = 42.8 \cdot a_{moon}$ to break even with a Hohmann transfer, not to talk about the travel time to get there and back to the Moon. This impractical situation, providing only humble delta-v advantage, is why bi-elliptic transfers are academic cases that are rarely employed.

8.4.3 Super-Synchronous Transfer Orbits

This section is about some special types of transfer orbits to GEO. A classical transfer orbit is the GEO transfer orbit (GTO), which is Hohmann transfer from a low Earth orbit to GEO. In practice, though, there is no LEO. The launch vehicle injects directly from its launch ascent trajectory into an elliptic orbit with apogee at GEO.

There are cases where other transfer orbits, so-called *super-synchronous (GEO) transfer orbit* (SSTO), a.k.a. Super-GTO, or GTO+, are superior to a regular GTO. A SSTO generally is an orbit that rather than a GEO synchronous orbit (GSO), which is any elliptic orbit (incl. GEO) with period of a sideral day (see Sect. 13.2), T_{GSO}, features $T_{SSTO} > T_{GSO}$. According to Eq. (7.4.12) this implies $a_{SSTO} > a_{GSO}$. There exist the following two types of SSTOs.

Bi-Elliptic Transfer

The delta-v benefit of a bi-elliptic transfer increases with the inclination to be changed at the apoapsis. This benefit is decisive for launches from launch sites at high latitude β, which equals the launch orbit inclination i (see Sect. 8.6.1), to GEO. For such a bi-elliptic transfer the upper stage of the rocket injects the satellite into an SSTO at the descending node of the launch trajectory, i.e. when crossing the equator. This injection burn includes the so-called minimum residual shutdown strategy (MRS) where any excess propellant is expended to reduce the inclination as far as possible, usually by 2–3°. The apogee of the SSTO usually is chosen to be twice to three times the GEO radius (see Fig. 8.19). At SSTO apogee an apogee boost places the spacecraft into a so-called interim transfer orbit (ITO) to GEO and at the same time zeroing the residual inclination. When arriving at GEO, a final burn brings the spacecraft into a so-called circular drift orbit, which is just little smaller than GEO to let the S/C drift from the burn position to its final longitude position. Having arrived there, tiny adjustment burns bring the S/C into its operational orbit state.

The key point with such SSTOs is that, even though the total Δv of all three burns may be larger, the satellite's propellant spending for the SSTO apogee boost and the final burns are lower than for a standard GTO. So, as long as the additional Δv of the rocket upper stage for SSTO is within its propellant budget, any reduction of the satellite's Δv is welcome to invest the saved propellant into later station-keeping and thus extend the satellite's orbital life time. This is why bi-elliptic SSTOs for transfering satellites into GEO are quite frequent for high latitude launch sites such as Cape Canaveral (Atlas) and Baikonur (Proton).

Common to all such SSTOs is the fact that the SSTO injection burn is performed at the descending node of the launch trajectory, which implies $\omega = 180°$ for the SSTO. Hence the tangent plane maneuver (see Sect. 8.1.4) at SSTO apogee into a ITO is a nodal transfer. The RAAN of the ITO is irrelevant because the inclination is usually nullified at SSTO apogee.

Hence both Δv_1 and Δv_2 are nodal transfers as determined by Eq. (8.1.20). The delta-v for the three burns are therefore as follows

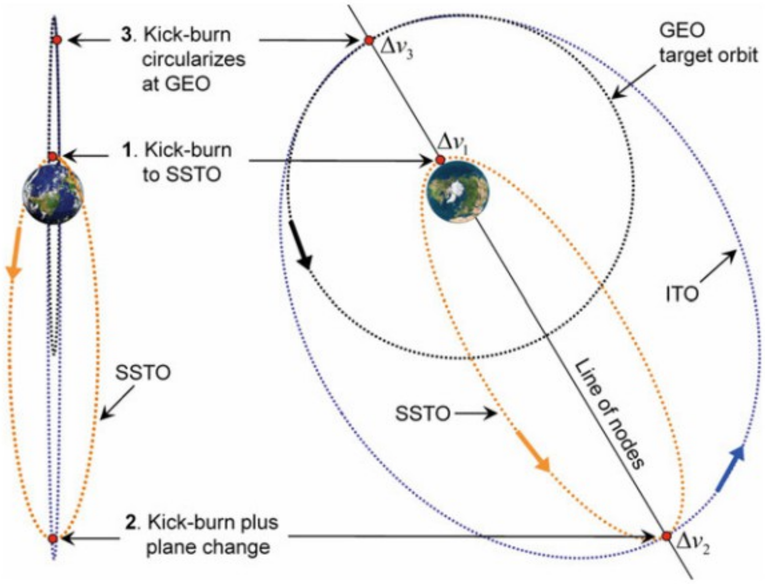

Fig. 8.19 A bi-elliptical super-synchronous transfer with its three kick-burns. Views are in Earth's equatorial plane (left) and normal to it (right)

$$\begin{aligned}\Delta v_1 &= \sqrt{v_{LEO-}^2 + v_{LEO+}^2 - 2v_{LEO-}v_{LEO+}\cos\Delta i_1}\\ \Delta v_2 &= \sqrt{v_{ITO-}^2 + v_{ITO+}^2 - 2v_{ITO-}v_{ITO+}\cos\Delta i_2}\\ \Delta v_3 &= v_{GEO-} - v_{GEO+}\end{aligned} \tag{8.4.8}$$

where the subscripts − and + indicate the values before and after the burn, respectively.

Case Study: The Super-Synchronous Transfer Orbit Mission of *Orion 1*

The Telstar 11 telecommunications satellite, operated by Loral Skynet, provided video for broadcast and business television, high-speed internet access and multimedia services, broadband and data networking to Europe, the United States to the Rocky Mountains and parts of Canada and Mexico.

It was launched as Orion 1 (a.k.a. Orion F1) on November 29, 1994, on an Atlas IIA rocket from Cape Canaveral (latitude 28.5°). The standard Atlas IIA GTO foresees a nodal transfer at the descending node, i.e. a GTO injection burn at 185 km altitude including an inclination change of about 2.8° (depending on the wind conditions during ascent and hence on the decisive propellant excess just before main engines cut off, MECO). A transfer burn at apogee, which is GTOs ascending node and a circularization burn including an inclination change of $\Delta i = 25°$ at the point where GTO touches the GEO, delivers the satellite into a so-called drift orbit. There the satellite drifts with a rate of 0.3°W per day into its final station-keeping box at 37.5°W. This earlier and standard Atlas IIA LEO→GTO→GEO sequence requires a GTO-injection boost of $\Delta v_{rocket} = 2.497\,\text{km/s}$ for the rocket's last stage and a $\Delta v_{sat} = 1.764\,\text{km/s}$ for the spacecraft. The latter would imply a lifetime in GEO to be less than 7 years, much less than required.

It was therefore decided that at the descending node the launcher should inject the spacecraft into a SSTO, in order to significantly reduce the later spacecraft's $\Delta v_{sat} = \Delta v_2 + \Delta v_3$ at the expense of a relatively small Δv_1 increase of the launcher. The SSTO chosen had the properties

$$\begin{aligned} r_{apo} &= 129{,}885\,\text{km}\\ r_{per} &= 6563.1\,\text{km}\\ i &= 25.7°\\ \Omega &= 173.6°\\ \omega &= 179.98°\end{aligned}$$

To bring the spacecraft from SSTO apogee into GEO, one apogee burn would change the inclination $\Delta i = 25^\circ$ and bring the S/C into the interim transfer orbit (ITO) to GEO, while a final burn at ITO perigee would circularize it into GEO. For safety reasons each burn was split into two, which in view of delta-v, however, are equal to the said two burns. According to Eq. (8.4.8) the delta-v for the three burns are as follows

$$\begin{aligned} v_{LEO-} &= 7.793\,\mathrm{km/s}, \\ v_{LEO+} &= 10.753\,\mathrm{km/s} \\ \Delta v_1 &= \sqrt{v_{LEO-}^2 + v_{LEO+}^2 - 2v_{LEO-}v_{LEO+}\cos(28.5^\circ - 25.7^\circ)} \\ &= 2.993\ \mathrm{km/s} \end{aligned}$$

$$v_{ITO-} = 0.5434\ \mathrm{km/s}, \quad v_{ITO+} = 1.227\ \mathrm{km/s}$$

$$\begin{aligned} \Delta v_2 &= \sqrt{v_{ITO-}^2 + v_{ITO+}^2 - 2v_{ITO-}v_{ITO+}\cos(25.7^\circ - 0.6^\circ)} \\ &= 0.770\ \mathrm{km/s} \end{aligned}$$

and

$$\begin{aligned} v_{GEO-} = 3.778\ \mathrm{km/s}, \quad v_{GEO+} = 3.075\ \mathrm{km/s} \\ \Delta v_3 = v_{GEO-} - v_{GEO+} = 0.703\ \mathrm{km/s} \end{aligned}$$

So, the Atlas rocket had to provide a $\Delta v_1 = 2.993$ km/s and hence an additional

$$\Delta v_{rocket+} = 2.993 - 2.497\ \mathrm{km/s} = 0.496\ \mathrm{km/s}$$

which was within the fuel budget. On the other hand, the total delta-v for the Orion satellite was $\Delta v_1 + \Delta v_2 = 0.770 + 0.703 = 1.473\,\mathrm{km/s}$ thus providing a benefit of

$$\Delta v_{sat+} = 1.473\,\mathrm{km/s} - 1.764\,\mathrm{km/s} = -291\,\mathrm{m/s}$$

This delta-v benefit extended Orion's lifetime for an additional 5 years, sufficient to meet the mission requirements.

Because any reduction of the satellite's total delta-v, $\Delta v_{sat} = \Delta v_2 + \Delta v_3$, is essential for the satellite's lifetime, Fig. 8.20 plots $\Delta v_2 + \Delta v_3$ for $\Delta i_1 = 0$ and different $\Delta i \equiv \Delta i_2$ as a function of SSTO apogee distance.

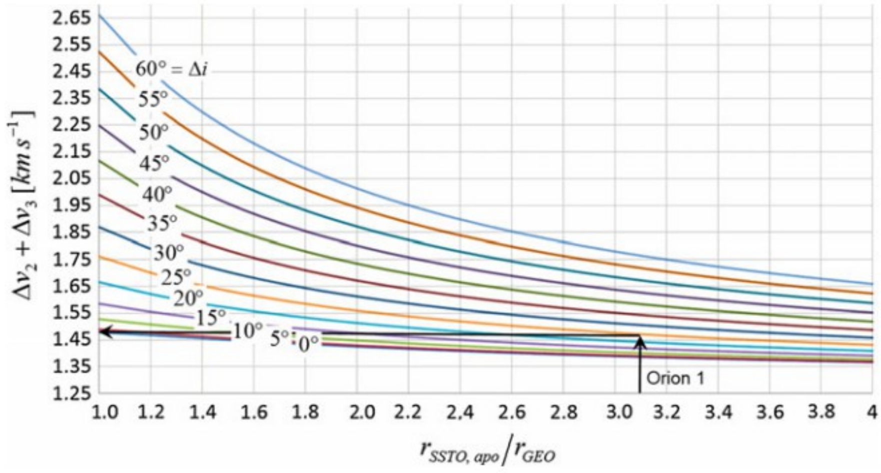

Fig. 8.20 The total delta-v of the satellite for a LEO → SSTO → ITO → GEO transfer as a function of relative SSTO apogee distance and for different inclination changes at the second kick-burn (SSTO apogee) and vanishing inclination change at the first and third kick-burn

Continuous Thrust Transfer

With today's trend to all-electric propulsion platforms (cf. Sect. 5.2.2, Subsection *Comparsion with other Thrusters*) there is the need for an efficient electric propulsion transfer from a SSTO, as provided by the launch vehicle, to GEO.

Early transfers were based on GTOs using a thrust arc strategy around apogee, similar to the chemical apogee-thrusts. Such a transfer requires about 150 days. In 1995, A. Spitzer proposed a thrust arc strategy based on SSTO (so-called Spitzer's scheme) with 16% less delta-v and a significantly reduced transfer time of about 110 days. Immediately thereafter it was found by C.R. Koppel that a continuous thrust strategy (CTS, see Sect. 8.4.5), i.e. continuously thrusting over all orbits, was even more practical. Although CTS requires a 17% larger delta-v than *Spitzer's scheme*, it reduces the transfer time to about 90 days, with an equivalent reduction of orbits passing the radiation of the Van Allen belts. This is why CTS for all-electric propulsion S/C today is the means of choice.

For a CTS the launch vehicle injects the S/C into a SSTO with typically 200 km × 60,000 km altitude and with a launch-specific non-zero RAAN and inclination. The electric thrust vector then is inertially oriented (star mode) with some out-of-plane component, such that in course of the transfer the in-plane component gradually removes the eccentricity (see Eq. (8.1.1b)) and the out-of plane component decreases the inclination to zero (see Eq. (8.1.1c), RAAN hence becomes irrelevant). The orbit thus gradually crosses over to the target GEO (see Fig. 8.21).

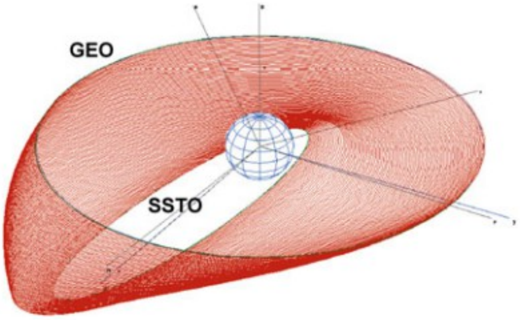

Fig. 8.21 Continuous thrust transfer from a SSTO (185 km × 6000 km, $i = 28^\circ$) to GEO (*Credit* C.R Koppel, 1999)

8.4.4 n-Impulse Transfers

Very generally it can be shown that for a transition between *any* two elliptic orbits the total delta-v budget for a three-impulse transfer (not necessarily bi-elliptic) might be smaller, but does not have to be, than that with the two-impulse Hohmann transfer. The above bi-elliptic transfer for $a_O/a_\bullet > 11.94$ is an example for this. In addition, it can also be shown that the total delta-v budget minimized by Hohmann or a three-impulse transfer cannot be further minimized by maneuvers with more than three impulses. So the Hohmann transfer or the minimum three-impulse transfer represents the absolute minimum for the propulsion demand in a two-body problem. But note that things are different in the three-body problem (see Note in Sect. 8.3.1).

8.4.5 Continuous Thrust Transfer

If we have electrical propulsion engines such as ion thrusters, thrust is low and continuous, so impulse transfers are impossible. An ion engine would rather have to fire permanently in the direction of motion (recall: $\Delta\varepsilon \propto \boldsymbol{v} \cdot \Delta\boldsymbol{v}$) to optimally but slowly spiral the satellite into higher and higher orbits. We now want to calculate the transfer orbit and the delta-v for a continuous tangential thrust maneuver for an initially circular orbit. How does an infinitesimal small tangential thrust $dv := \delta v_{||}$ alter a circular orbit? The answer is given by Eq. (8.1.14):

$$\frac{dr}{r} = 2\sqrt{\frac{r}{\mu}}\,dv$$

To find the total delta-v, we have to integrate the differentially small velocity increase between an initial $r_\bullet$ and final orbit radius r_O

$$\Delta v = \int dv = \frac{\sqrt{\mu}}{2}\int_{r_\bullet}^{r_O} \frac{dr}{r^{3/2}} = -\left.\sqrt{\frac{\mu}{r}}\right|_{r_\bullet}^{r_O} = v_\bullet - v_O \tag{8.4.9}$$

Of course it does not make a difference for the propulsion demand Δv whether we spiral up from $r_\bullet$ to r_O or down from r_O to $r_\bullet$. If we compare this result with Eq. (8.3.8), we see from Fig. 8.13 that the Hohmann transfer is always more favorable than a continuous thrust transfer. But with ion propulsions and their very tiny thrusts there is no alternative to that.

To calculate the transfer time between an initial circular orbit with orbit radius $r_\bullet$ and the instantaneous circular orbit with radius r, we need the explicit trajectory $r = r(t)$. As the circular condition $v = \sqrt{\mu/r}$ is valid for each point of the orbital curve, it is sufficient to find $v = v(t)$. We find it with the help of the thrust equation $F_* = m \cdot \dot{v} = \dot{m}v_*$. To be able to apply it, we have to consider the mass reduction $\dot{m}$ due to the propellant consumption. We assume that the vehicle with the mass m is accelerated by a constant thrust F with constant mass flow rate $\dot{m}_p = -\dot{m} = const$, so: $m = m_0 + \dot{m}t$. With this relation, we integrate the corresponding equation $dv = \dot{m}v_*/m \cdot dt$

$$\int_{v_\bullet}^{v} dv' = \int_0^t \frac{\dot{m}v_*}{m}\, dt'$$

to get

$$v - v_\bullet = v_* \int_0^t \frac{dt'}{m_0/\dot{m} + t'} = v_* \ln\left(\frac{m_0/\dot{m} + t}{m_0/\dot{m}}\right) = v_* \ln\left(1 - \frac{\dot{m}_p}{m_0} t\right) \tag{8.4.10}$$

Because of $v = \sqrt{\mu/r}$, this results in the following spiral trajectory (see Fig. 8.22)

$$r(t) = \mu\left[v_\bullet + v_* \ln\left(1 - \frac{\dot{m}_p}{m_0} t\right)\right]^{-2} \quad @\, \dot{m}_p = const \tag{8.4.11}$$

By solving for t we get the following from Eq. (8.4.10) for the transfer time

$$t_{CT} = \frac{m_0}{\dot{m}_p}\left[1 - \exp\left(\frac{v - v_\bullet}{v_*}\right)\right] = \frac{m_0 v_*}{F_*}\left\{1 - \exp\left[\frac{\sqrt{\mu}}{v_*}\left(\frac{1}{\sqrt{r}} - \frac{1}{\sqrt{r_\bullet}}\right)\right]\right\} \tag{8.4.12}$$

Example

A satellite is released from the Space Shuttle payload bay at an altitude of 300 km, and it is supposed to spiral with an ion thruster ($F_*/m_0 = 100\,\mu\mathrm{g} = 10^{-3}\mathrm{m\ s^{-2}}$ and $v_* = 10\,000\ \mathrm{m\,s^{-1}}$) to GEO. Because $v_\bullet = 7.72\,\mathrm{km\ s^{-1}}$ and $v_{GEO} = v_\mathrm{O} = 3.07\,\mathrm{km\ s^{-1}}$, the transfer time is calculated to be $t_{CT} = 43$ days.

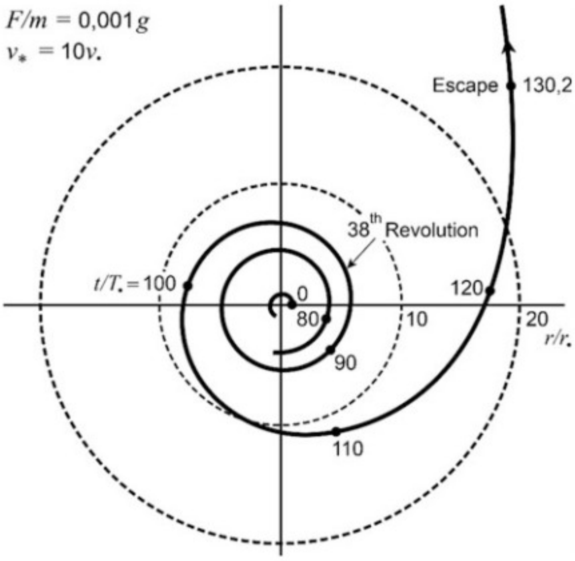

Fig. 8.22 Continuous thrust trajectory as a result of a continuous tangential thrust. Index • refers to the initial orbit. Because the spiral is very narrow at the beginning, only the last two revolutions are shown

8.5 Relative Orbits

Having explored the conditions for a general transfer between orbits, the more delicate problem is to meet a target point in the final orbit, a so-called orbital rendezvous. In this and the next section we will focus on orbital rendezvous in Earth orbits though the described methods apply to any planetary orbit. For interplanetary orbital rendezvous we refer the reader to Sect. 9.3.

In orbital rendezvous, there is generally a passive target object to rendezvous with an interceptor (a.k.a. *chaser*) as the active part that performs the rendezvous maneuvers. Rather than describe the required rendezvous maneuvers in an inertial reference frame such as a geocentric reference frame, it is very convenient to describe them relative to the target. It is convenient because if the interceptor moves in the vicinity of the target we can linearize the equations of motion, which will enable us to solve them analytically. On the other hand, the target in a conical motion about the center of gravity constitutes a non-inertial reference system, a fact that will complicate our equation of motion somewhat. Nevertheless, the description of relative motion about a target object, which is done in the following, is a prerequisite for analyzing rendezvous maneuvers, which is the objective of Sect. 8.6.

8.5.1 General Equation of Motion

Suppose there is a target object in a planetary orbit and a S/C (usually dubbed chaser) wants to navigate in its vicinity and with respect to it. Good examples are the approach maneuvers of a Soyuz vehicle to the ISS or the re-docking of the ascending Lunar Module to the Command/Service Module in low Lunar orbit during the Apollo moon missions. For this mission we need to know the relative motion to the target and how to maneuver to reach the target. This is the subject of the next two sections.

Let us assume the target (for instance, we assume to be the ISS) is in an arbitrary terrestrial conic orbit with position vector $\boldsymbol{R}$ in the geocentric reference frame. For this orbit Newton's gravitational EoM (7.1.19) must hold

$$\ddot{\boldsymbol{R}} = -\frac{\mu}{R^3}\boldsymbol{R} \tag{8.5.1}$$

Of course, Newton's gravitational EoM must equally hold for the chaser's orbit with position vector $\boldsymbol{\rho}$ in the geocentric reference frame, i.e.

$$\ddot{\boldsymbol{\rho}} = -\frac{\mu\boldsymbol{\rho}}{\rho^3}$$

We start deriving the chaser's equation of motion relative to the ISS by defining the relative vector $\boldsymbol{r} = \boldsymbol{\rho} - \boldsymbol{R}$ as shown in Fig. 8.23. The specific reference frame is the ISS-centric coordinate system RSW as described in Sect. 13.1.4, Fig. 13.4, with unit vectors $\boldsymbol{u}_x, \boldsymbol{u}_y, \boldsymbol{u}_z = \boldsymbol{S}, \boldsymbol{W}, \boldsymbol{R}$: The z-axis points along the radial vector while the x-axis points along the moving direction of the target. The y-axis completes the right-handed reference system. Our goal is to find the equation of motion of the relative vector

$$\boldsymbol{r} = \boldsymbol{\rho} - \boldsymbol{R} = x\boldsymbol{u}_x + y\boldsymbol{u}_y + z\boldsymbol{u}_z =: (x, y, z)$$

expressed in the co-moving coordinate system $(\boldsymbol{u}_x, \boldsymbol{u}_y, \boldsymbol{u}_z)$. Since we seek for a differential equation for $\boldsymbol{r}$, we first have to express $\boldsymbol{\rho}$ in terms of $\boldsymbol{R}$ and $\boldsymbol{r}$. Because $r \ll R$ we can expand the term $1/\rho^3$ as follows:

$$\begin{aligned}\frac{1}{\rho^3} &= \frac{1}{\left[x^2 + y^2 + (z+R)^2\right]^{3/2}} = \frac{1}{\left[r^2 + 2zR + R^2\right]^{3/2}} \approx \frac{1}{R^3}\frac{1}{(1+z/R)^3} \\ &\approx \frac{1}{R^3}\left(1 - 3\frac{z}{R}\right)\end{aligned}$$

and hence

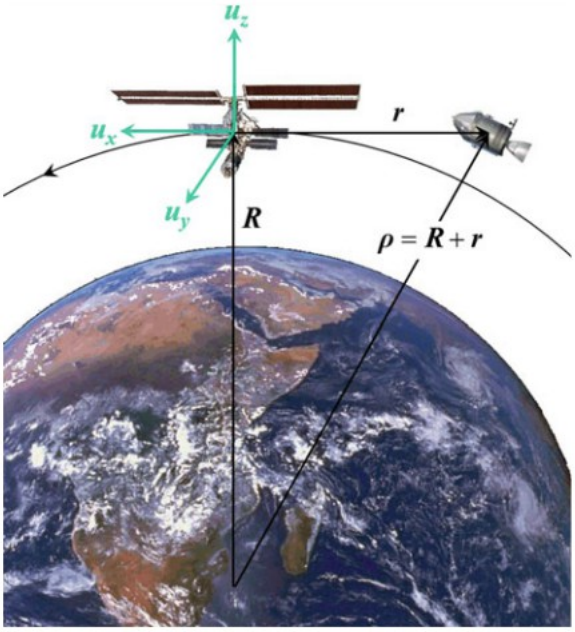

Fig. 8.23 Definition of relative vectors and RSW coordinate system in the target object (ISS), that moves on a circular orbit. The *z*-axis points along the radial vector while the *x*-axis points along the moving direction of the target object. The *y*-axis completes the right-handed reference system

$$\ddot{\boldsymbol{\rho}} = -\frac{\mu\boldsymbol{\rho}}{\rho^3} \approx -\frac{\mu}{R^3}(\boldsymbol{R}+\boldsymbol{r})\left(1-3\frac{z}{R}\right) \approx -\frac{\mu}{R^3}(\boldsymbol{R}+\boldsymbol{r}-3z\boldsymbol{u}_z)$$

Because from the definition of $\boldsymbol{\rho}$ and from Eq. (8.5.1) also $\ddot{\boldsymbol{\rho}} = \ddot{\boldsymbol{R}} + \ddot{\boldsymbol{r}} = -\mu\boldsymbol{R}/R^3 + \ddot{\boldsymbol{r}}$ holds, we get

$$-\frac{\mu}{R^3}\boldsymbol{R} + \ddot{\boldsymbol{r}} \approx -\frac{\mu}{R^3}(\boldsymbol{R}+\boldsymbol{r}-3z\boldsymbol{u}_z)$$

and finally

$$\boxed{\ddot{\boldsymbol{r}} = -\frac{\mu}{R^3}(\boldsymbol{r}-3z\boldsymbol{u}_z)} \quad @\, x,y,z \ll R \tag{8.5.2}$$

We want to solve this vector equation in the non-inertial co-moving target RSW coordinate system $(\boldsymbol{u}_x, \boldsymbol{u}_y, \boldsymbol{u}_z)$. Now, as $\boldsymbol{r} = x\boldsymbol{u}_x(t) + y\boldsymbol{u}_y + z\boldsymbol{u}_z(t)$ is already given in RSW, how is $\ddot{\boldsymbol{r}}$ expressed in it?

The answer is provided by Eq. (7.2.2) for $\boldsymbol{a} \equiv \boldsymbol{r} = x\boldsymbol{u}_x(t) + y\boldsymbol{u}_y + z\boldsymbol{u}_z(t) =: (x,y,z)_{xyz}$ and for the angular velocity of the target $\boldsymbol{\omega} = \omega(0,1,0)_{xyz}$ as

$$
\begin{aligned}
\ddot{\boldsymbol{r}} &= \ddot{\boldsymbol{r}}_{xyz} + 2\boldsymbol{\omega} \times \dot{\boldsymbol{r}}_{xyz} + \boldsymbol{\omega} \times (\boldsymbol{\omega} \times \boldsymbol{r}) + \dot{\boldsymbol{\omega}} \times \boldsymbol{r} \\
&= \left(\ddot{x} + 2\omega\dot{z} - \omega^2 x + \dot{\omega}z\right)\boldsymbol{u}_x + \ddot{y}\boldsymbol{u}_y + \left(\ddot{z} - 2\omega\dot{x} - \omega^2 z - \dot{\omega}x\right)\boldsymbol{u}_z \\
&= \begin{pmatrix} \ddot{x} + 2\omega\dot{z} - \omega^2 x + \dot{\omega}z \\ \ddot{y} \\ \ddot{z} - 2\omega\dot{x} - \omega^2 z - \dot{\omega}x \end{pmatrix}_{xyz}
\end{aligned}
$$

where

$$\dot{\boldsymbol{r}}_{xyz} := (\dot{x}, \dot{y}, \dot{z})_{xyz},\ \ddot{\boldsymbol{r}}_{xyz} := (\ddot{x}, \ddot{y}, \ddot{z})_{xyz}$$

If we insert this into Eq. (8.5.2), we finally obtain the equation of motion

$$\ddot{\boldsymbol{r}} = \begin{pmatrix} \ddot{x} + 2\omega\dot{z} - \omega^2 x + \dot{\omega}z \\ \ddot{y} \\ \ddot{z} - 2\omega\dot{x} - \omega^2 z - \dot{\omega}x \end{pmatrix}_{xyz} = -\frac{\mu}{R^3}\begin{pmatrix} x \\ y \\ z - 3z \end{pmatrix}_{xyz}$$

Because this vectorial equation must hold for each orthogonal component separately, we finally find the three differential equations

$$
\begin{aligned}
&\ddot{x} + 2\omega\dot{z} - \left(\omega^2 - \tfrac{\mu}{R^3}\right)x + \dot{\omega}z = 0 \\
&\ddot{y} \qquad\qquad + \tfrac{\mu}{R^3}y \qquad\quad = 0 \\
&\ddot{z} - 2\omega\dot{x} - \left(\omega^2 + 2\tfrac{\mu}{R^3}\right)z - \dot{\omega}x = 0
\end{aligned}
\quad @x, y, z \ll R \qquad \textbf{equations of motion} \qquad (8.5.3)
$$

This are the equations of motion of a chaser, not being subject to external forces, relative to a target with coordinates (x, y, z) in the target's topocentric RSW coordinate system, which quite generally is in a conic orbit about a center of gravity and, due to its conical trajectory, rotates with angular velocity $\omega(t)$. Note that from Eqs. (7.2.7), (7.3.7) and (7.4.13) follows

$$\frac{\mu}{R^3} = \sqrt{n_e}\omega^{3/2}$$

with

$$n_e := \frac{n}{\left(1 - e^2\right)^{3/2}} = \sqrt{\frac{\mu}{a^3\left(1 - e^2\right)^3}}$$

Observe that only the first and third equations are coupled. If initially $y(0) = 0$ and $\dot{y}(0) = 0$, i.e., if the chaser initially is in the orbital plane, then $\ddot{y} = 0$ and hence $y(t) = 0$, which means that it will always stay in that plane. Otherwise and if $R \approx const$ it will oscillate about this plane with frequency $\sqrt{\mu/R^3}$.

Elliptic Target Orbit

To get more practical and to find a solution to Eq. (8.5.3) we now assume an elliptic orbit with orbital elements a, e about a planet. For this, we get according to Eq. (7.2.7)

$$\omega = \frac{\sqrt{\mu a(1-e^2)}}{R^2}$$

and with Eqs. (7.3.15a) and (7.4.14c)

$$\dot{\omega} = -2\frac{\mu e \sin\theta}{R^3} = -\frac{2\mu a e}{R^4}\sqrt{1-e^2}\sin E$$

with

$$R(t) = a[1 - e\cos E(t)]$$

where the eccentric anomaly $E(t)$ is the solution of Kepler's Eq. (7.4.15)

$$n \cdot t = t\sqrt{\frac{\mu}{a^3}} = E(t) - e\sin E(t)$$

This transcendental equation can be solved by Newton's iteration method (Eq. (7.4.16))

$$E_{i+1} = E_i - \frac{E_i - e\sin E_i - n \cdot t}{1 - e\cos E_i}$$

Of course, similar equations can easily be derived for a hyperbolic trajectory (cf. Sect. 7.4.3).

Given these time dependent quantities, the differential Eq. (8.5.3) for a rendezvous on an elliptic target orbit can be solved numerically for instance by a Runge–Kutta method.

8.5.2 *Circular Orbits*

We now come to the most common situation where the target is in a circular orbit. Circular orbits are so common because for a given minimum altitude they have the lowest orbital energy, entailing the least delta-v to achieve. Therefore, nearly every target in a low Earth orbit will attain a circular or quasi-circular orbit. For instance, the ISS has an eccentricity of typically $e = 0.0001 - 0.001$, that can be shown to be induced by the anisotropies of Earth's gravitational potential (see Sect. 12.3.2).

For a circular orbit we have $\ddot{\boldsymbol{R}} = -\mu \boldsymbol{R}/R^3 = -n^2\boldsymbol{R}$ and $n = \sqrt{\mu/R^3} = 2\pi/T = const$. If be insert this into the general equation of motion Eq. (8.5.3) we obtain

$$\boxed{\begin{array}{l}\ddot{x}+2n\dot{z}=0\\ \ddot{y}+n^2y=0\\ \ddot{z}-2n\dot{x}-3n^2z=0\end{array}} \quad @\, x,y,z \ll R \quad \textbf{Hill's equations} \tag{8.5.4}$$

These are the famous *Hill's equations* (a.k.a. *Clohessy–Wiltshire equations*) governing the motion of a S/C, not being subject to external forces, with coordinates (x, y, z) in the topocentric RSW coordinate system of a target object circling a planet with constant orbital velocity $\omega = n$.

μg-Forces on Space Stations

A modest application of Hill's equation in a circular orbit is the residual forces acting on parts of a satellite or a space station. Such residual forces are important for experiments in space, which contribute some unwanted artificial gravity to the otherwise weightlessness in space. To determine their level, let us assume we have an experimental drawer in a science rack in one of the ISS laboratories located at the distance $\boldsymbol{r} = (x, y, z)$ from the center of mass (CM) of the ISS, which orbits at orbital frequency $n = \sqrt{\mu/R^3}$. Since the drawer is fixed relative to CM, we have $\dot{\boldsymbol{r}} = (\dot{x}, \dot{y}, \dot{z}) = 0$. If the sample in the drawer is further out in the z-direction (see Fig. 8.24) than CM, it experiences an enhanced centrifugal force, but smaller gravitational force. If it is further toward Earth it experiences the opposite effect: a smaller centrifugal force but a larger gravitational force. In total, it thus experiences some residual force, a so-called *tidal force*. We can determine this tidal force if we interpret the terms $\ddot{x}, \ddot{y}, \ddot{z}$ in Eq. (8.5.4) as the residual accelerations making up the tidal force. In doing so we end up with the tidal acceleration in terms of *Earth's mean gravitational acceleration at its surface* (see Sect. 7.1.2), $g_0 := \mu/R_\oplus^2 \approx \mu/R^2 = 9.80\,\mathrm{m\,s^{-2}}$, as

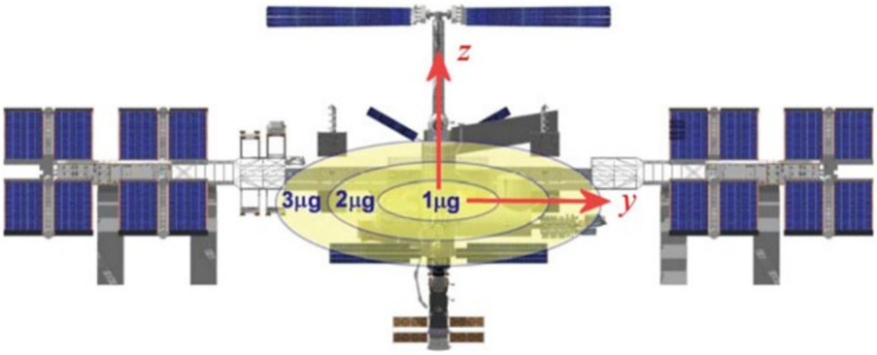

Fig. 8.24 The levels of residual μg-forces on the International Space Station at positions off the center of mass

$$\frac{\ddot{x}}{g_0} = 0, \quad \frac{\ddot{y}}{g_0} = -\frac{y}{R}, \quad \frac{\ddot{z}}{g_0} = 3\frac{z}{R}$$

So, depending on the distances y, z from CM we get different levels of tidal forces. By analyzing Eq. (8.5.3) we realize that in the z-direction there are two gravitational tide contributions and just one centrifugal tide contribution in the overall total of 3. In the y-direction there is just one contribution from the gravitational (lateral) tide. In general the tidal forces are of order $10^{-6}g = 1\mu g$. This is why experiments on space stations are commonly called μg-experiments. For instance, on the ISS, having a typical altitude of 350 km, a level of $1\mu g$ is obtained at a horizontal distance of $y = 10^{-6} \times 6.73 \times 10^6\,\text{m} = 6.73\,\text{m}$ and at a vertical distance of $z = \frac{1}{3} \times 10^{-6} \times 6.73 \times 10^6\,\text{m} = 2.24\,\text{m}$ from CM. Overall, we have μg-ellipses as depicted in Fig. 8.24.

Solution of Hill's Equations

To describe the explicit motion $\boldsymbol{r}(t) = (x(t), y(t), z(t))$ of a chaser, we have to solve Hill's equations. This can be done straightforwardly with only little effort. To do so efficiently, we first replace time by the dimensionless mean anomaly and define both it and its derivatives.

$$\begin{aligned} &M = nt \\ &(.)' := \frac{d}{dM} = \frac{1}{n}\frac{d}{dt}(.) \\ &(.)'' := \frac{d^2}{dM^2} = \frac{1}{n^2}\frac{d^2}{dt^2}(.) \end{aligned} \tag{8.5.5}$$

and initial conditions at $t = 0$ as

$$\begin{aligned} x(0) &= x_0, \quad x'(0) = x'_0 \\ y(0) &= y_0, \quad y'(0) = y'_0 \\ z(0) &= z_0, \quad z'(0) = z'_0 \end{aligned} \quad \textbf{initial conditions} \tag{8.5.6}$$

With this Hill's equations read

$$\begin{aligned} x'' + 2z' &= 0 \\ y'' + y &= 0 \\ z'' - 2x' - 3z &= 0 \end{aligned} \tag{8.5.7}$$

First observe that the second Hill equation is decoupled from all others. It has the form of a harmonic oscillator. We therefore find its solution as

$$y = y_0 \cos M + y'_0 \sin M$$

We now integrate the first Hill equation directly. By taking the initial conditions into account we get

$$x' = -2z + 2z_0 + x'_0$$

We insert this result into the third Hill equation getting

$$z'' = 2x' + 3z = -\left[z - \left(4z_0 + 2x'_0\right)\right]$$

This, too, is the equation of a harmonic oscillator for the expression $z - \left(4z_0 + 2x'_0\right)$ yielding

$$z - \left(4z_0 + 2x'_0\right) = z'_0 \sin M - \left(3z_0 + 2x'_0\right) \cos M$$

under consideration of the initial conditions $z(0) = z_0, z'(0) = z'_0$. We solve for z and find

$$z = 4z_0 + 2x'_0 + z'_0 \sin M - \left(3z_0 + 2x'_0\right) \cos M$$

Inserting this into the above equation $x' = -2z + 2nz_0 + x'_0$ we get

$$x' = -\left(6z_0 + 3x'_0\right) - 2z'_0 \sin M + \left(6z_0 + 4x'_0\right) \cos M$$

This can be integrated directly to deliver with initial condition $x(0) = x_0$

$$x = x_0 - 2z'_0 - \left(6z_0 + 3x'_0\right)M + 2z'_0 \cos M + \left(6z_0 + 4x'_0\right) \sin M$$

We summarize the results as

$$\begin{pmatrix} x \\ z \\ x' \\ z' \end{pmatrix} = \begin{bmatrix} 1 & 6\sin M - 6M & 4\sin M - 3M & 2\cos M - 2 \\ 0 & -3\cos M + 4 & -2\cos M + 2 & \sin M \\ 0 & 6\cos M - 6 & 4\cos M - 3 & -2\sin M \\ 0 & 3\sin M & 2\sin M & \cos M \end{bmatrix} \begin{pmatrix} x_0 \\ z_0 \\ x'_0 \\ z'_0 \end{pmatrix} \tag{8.5.8}$$

and in convenient terms

$$\boxed{\underbrace{\begin{pmatrix} x \\ z \\ \dot{x} \\ \dot{z} \end{pmatrix}}_{\substack{\textit{final} \\ \textit{state vector}}} = \underbrace{\begin{bmatrix} 1 & 6(\sin nt - nt) & (4\sin nt)/n - 3t & 2(\cos nt - 1)/n \\ 0 & 4 - 3\cos nt & 2(1 - \cos nt)/n & (\sin nt)/n \\ 0 & 6n(\cos nt - 1) & 4\cos nt - 3 & -2\sin nt \\ 0 & 3n \sin nt & 2\sin nt & \cos nt \end{bmatrix}}_{\textit{time-evolution matrix}} \underbrace{\begin{pmatrix} x_0 \\ z_0 \\ \dot{x}_0 \\ \dot{z}_0 \end{pmatrix}}_{\substack{\textit{initial} \\ \textit{state vector}}}} \tag{8.5.9}$$

and

$$\boxed{\begin{pmatrix} y \\ \dot{y} \end{pmatrix} = \begin{bmatrix} \cos nt & (\sin nt)/n \\ -n \sin nt & \cos nt \end{bmatrix} \begin{pmatrix} y_0 \\ \dot{y}_0 \end{pmatrix}} \tag{8.5.10}$$

These are the basic equations for orbital motion in the vicinity of the reference object and with respect to its co-moving topocentric coordinate system RSW.

Application to Orbital Rendezvous

A typical application of Eq. (8.5.9) is the design of an orbital rendezvous. If at time $t_0 = 0$ a S/C is at an initial point $\boldsymbol{r}_0 = (x_0, y_0, z_0)$ the problem to solve is: What should be the initial velocity $\boldsymbol{v}_0 = (\dot{x}_0, \dot{y}_0, \dot{z}_0)$ to meet after time t a given target point $\boldsymbol{r} = (x, y, z) = (0, 0, 0)$? The solution can be derived from the equations for x, y, and z of Eqs. (8.5.9) and (8.5.10) by setting $x = y = z = 0$ and solving for $\dot{x}_0, \dot{y}_0, \dot{z}_0$. If this is done, one straightforwardly obtains

$$\begin{aligned} \frac{\dot{x}_0}{n} &= \frac{2(\cos nt - 1)x_0 + (4 \sin nt - 3nt \cos nt)z_0}{3nt \sin nt + 8(\cos nt - 1)} \\ \frac{\dot{z}_0}{n} &= \frac{\sin nt \cdot x_0 - [6nt \sin nt + 14(\cos nt - 1)]z_0}{3nt \sin nt + 8(\cos nt - 1)} \\ \frac{\dot{y}_0}{n} &= -\frac{y_0}{\tan nt} \end{aligned} \tag{8.5.11}$$

or in matrix expression

$$\begin{pmatrix} \dot{x}_0 \\ \dot{z}_0 \end{pmatrix} = \frac{n}{3nt \sin nt + 8 \cos nt - 8} \begin{pmatrix} 2 \cos nt - 2 & 4 \sin nt - 3nt \cos nt \\ \sin nt & 14 - 14 \cos nt - 6nt \sin nt \end{pmatrix} \begin{pmatrix} x_0 \\ z_0 \end{pmatrix}$$

$$\dot{y}_0 = -\frac{n}{\tan nt} y_0$$

The required delta-v for these maneuvers then is given by

$$\Delta v = \sqrt{(\dot{x}_0 - \dot{x}_{0-})^2 + (\dot{y}_0 - \dot{y}_{0-})^2 + (\dot{z}_0 - \dot{z}_{0-})^2} \tag{8.5.12}$$

where $\boldsymbol{v}_{0-} = (\dot{x}_{0-}, \dot{y}_{0-}, \dot{z}_{0-})$ is the velocity of the S/C just before the impulse maneuver at (x_0, y_0, z_0).

It is an easy exercise to show that in the limit $t \to 0$ Eq. (8.5.11) pass over into

$$\begin{aligned} \dot{x}_0 &= -\frac{x_0}{t} - n z_0 - \frac{1}{6} n^2 x_0 t + O(n^3 z_0 t^2) \\ \dot{z}_0 &= -\frac{z_0}{t} + n x_0 - \frac{5}{6} n^2 z_0 t + O(n^3 x_0 t^2) \qquad @\, t \to 0 \\ \dot{y}_0 &= -\frac{y_0}{t} + \frac{1}{3} n^2 y_0 t + O(n^4 y_0 t^3) \end{aligned}$$

Therefore, for $(nt)^2 \ll 1$, which implies roughly $t < 0.02 \cdot T$, we can write

$$\boxed{\begin{aligned} \dot{x}_0 &= -\tfrac{x_0}{t} - n\,z_0 \\ \dot{z}_0 &= -\tfrac{z_0}{t} + n\,x_0 \\ \dot{y}_0 &= -\tfrac{y_0}{t} \end{aligned}} \quad @\ (nt)^2 \ll 1 \tag{8.5.13}$$

These expressions will later be useful to explore maneuvers in the vicinity of the target object.

8.5.3 Flyaround Trajectories

In order to fly in a controlled way in the vicinity of a target object we need to know: What does a flyaround trajectory of a S/C look like? We will now explore the two different types of trajectories because they are essential for understanding the general behavior of such a S/C.

The Prolate Cycloid

On November 18, 2008, the astronaut Heidemarie Stefanyshyn-Piper lost her toolbox in space when carrying out repair work outside the International Space Station. She accidentally and gently touched the toolbox (which should have been secured by a line either to her or the ISS, but was not) giving the box a push such that it slowly drifted away from the station (see Fig. 8.25).

This accident is a good example to study the trajectory of slowly moving objects near a reference system, which for our purposes is the ISS at an average altitude of 350 km. So, what was the trajectory of the toolbox? It is important to know in which direction the push was relative to the flight direction of the ISS. Because we do not know, we will assume two different situations. First, Heidemarie pushed the toolbox along the flight direction, with an initial velocity of, say, $\boldsymbol{v}_0 = (\dot{x}_0, \dot{y}_0, \dot{z}_0) = (v_0, 0, 0)$.

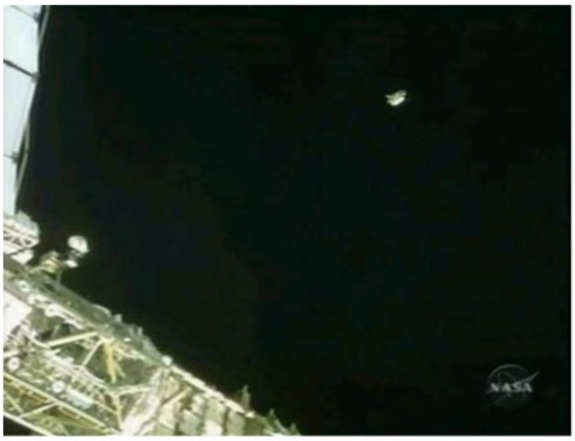

Fig. 8.25 The toolbox (top right) of astronaut Stefanyshyn-Piper slowly drifting away from the ISS truss structure (bottom left). *Credit* NASA

We study the trajectory in the RSW coordinate system of Heidemarie, so $\boldsymbol{r}_0 = (x_0, y_0, z_0) = (0, 0, 0)$. Under these initial assumptions, we read from Eq. (8.5.9)

$$\begin{aligned} x(t) &= \frac{v_0}{n}(4\sin nt - 3nt) \approx v_0 t \\ \dot{x}(t) &= v_0(4\cos nt - 3) \\ z(t) &= 2\frac{v_0}{n}(1 - \cos nt) \approx n v_0 t^2 \\ \dot{z}(t) &= 2v_0 \sin nt \end{aligned} \tag{8.5.14}$$

where the approximations are for early times on the trajectory, $nt \ll 1$. If we solve the approximation for x and insert it in the approximation for z, we obtain a parabolic trajectory

$$z = \frac{nx^2}{v_0}$$

To be more concrete, let us assume that Heidemarie pushed the toolbox backward, against flight direction, with an initial velocity of, say, $v_0 = -0.1\,\mathrm{m\,s^{-1}}$. Because v_0 is negative we get a down curved parabola (see Fig. 8.26): The toolbox dives below the orbit of the ISS, which first seems to be quite surprising. Interestingly the toolbox comes to a halt in –x-direction when $\cos nt = 3/4$ and thereafter moves back toward the ISS, yet at increasingly lower altitudes. After half an orbit, it reaches the lowest point (perigee), and then it climbs up to reach the initial altitude of 350 km after a full revolution of the ISS, however at a distance of 1.65 km in front of the ISS. The toolbox will repeat this loopy motion indefinitely thereby moving away from the ISS—the toolbox will be lost. Such a winding trajectory is mathematically called a *prolate cycloid*.

What is the reason for such a weird trajectory? When the toolbox is kicked off backward it has a lower velocity as it should have for a circular orbit at this altitude.

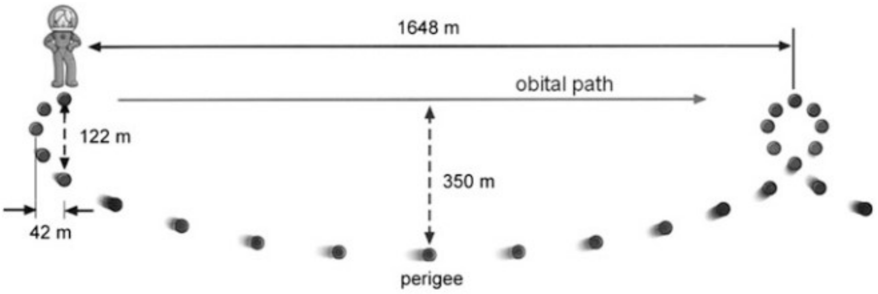

Fig. 8.26 The prolate cycloid trajectory of the toolbox that Heidemarie lost, if its initial motion, $v_0 = -0.1\,\mathrm{m\,s^{-1}}$, was reverse to the flight direction of the ISS. ISS altitude is $h = 350\,\mathrm{km}$

So the centrifugal force $F_c = mv^2/r$ is lower than the gravitational force, which rapidly pulls the box down. But upon dropping it gains speed, which brings it to a lateral halt at 42 m away from the ISS. With increasing speed the centrifugal force increases that after half a revolution at perigee brings the decline to a halt at 350 m below and 824 m ahead of the ISS. Since the speed now is too large for this altitude, the box dives up and decelerates until it "kisses" the orbit to iterate its dive.

The size of the cycloid depends linearly on the initial velocity while its orientation reverses when v_0 is with or against the flight direction of the ISS. Figure 8.27 gives an overview of this behavior for different initial x_0.

The reason for this weird motion can be understood when seen in a geocentric reference system (see Fig. 8.28). An object initially slower than the ISS at point 0 will have less orbital energy and hence move on an elliptic trajectory with smaller major-axis than the ISS. This implies that the object will drop below the ISS and will have a smaller orbital period, so showing up in front of the ISS after one revolution at the initial point 0. An object with a larger initial velocity will move on a larger ellipse with reversed behavior.

This view in an inertial reference frame makes clear that the prolate cycloid is the trajectory of a Hohmann transfer as observed in the target's reference frame. This should have been clear from the very beginning, because the initial kick-burn is tangential to the initial orbit. This is the attribute of a Hohmann transfer.

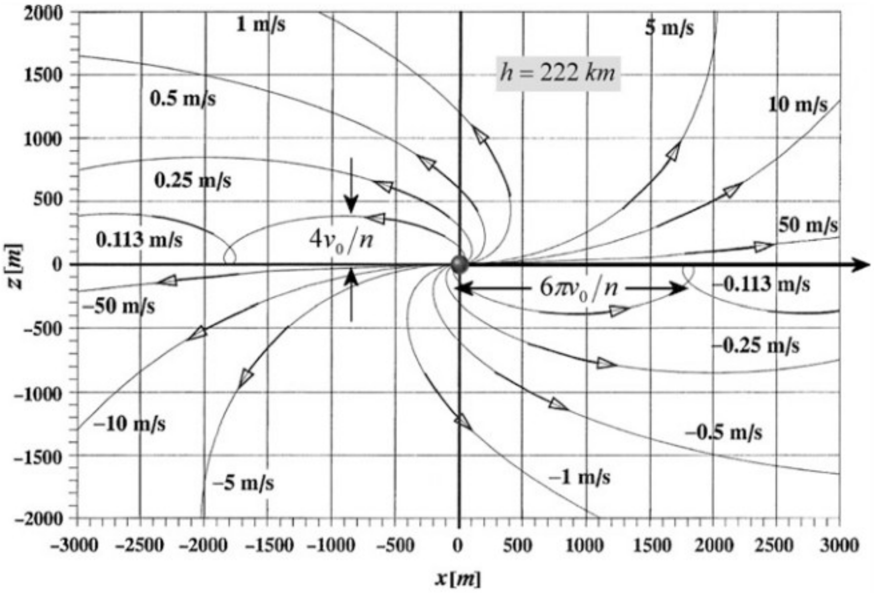

Fig. 8.27 Shown are for different v_0 in x-direction the trajectories (prolate cycloid) of the object moving relative to a reference point [center dot, which itself moves on an orbit at altitude $h =$ 222 km to the right (bold arrow)]. *Credit* Vallado (2007)

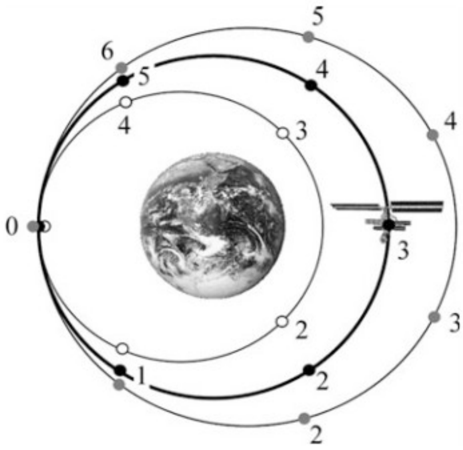

Fig. 8.28 A schematic sketch of the prolate cycloid motion as viewed from the inertial reference frame of Earth. The smaller ellipse is for an object with smaller velocity and the larger ellipse with a larger velocity at point 0. The numbered points give the positions on each orbit after constant time intervals

The Ellipse

We now assume that Heidemarie pushed the toolbox vertically to the flight direction, with initial velocity $\boldsymbol{v}_0 = (\dot{x}_0, \dot{y}_0, \dot{z}_0) = (0, 0, v_0)$. Interestingly, the trajectory of the toolbox would be totally different. From Eq. (8.5.9) we derive the trajectory to be

$$\begin{aligned} x &= 2\frac{v_0}{n}(\cos nt - 1) \approx -nv_0t^2 \\ z &= \frac{v_0}{n}\sin nt \approx v_0 t \end{aligned} \tag{8.5.15}$$

again with approximations for early times on the trajectory, $nt \ll 1$. By removing the time parameter for $nt \ll 1$, we again find a parabola, that, however, opens to the rear side of the ISS.

$$z = \sqrt{-\frac{v_0}{n}x}$$

To derive the full trajectory we recognize that we can solve both equations for $\cos\, nt$ and $\sin\, nt$ and via the trigonometric equation $\sin^2 x + \cos^2 x = 1$, we find

$$\frac{(x + 2v_0/n)^2}{(2v_0/n)^2} + \frac{z^2}{(v_0/n)^2} = 1$$

which is the equation of an ellipse with semi-major axis $a = 2v_0/n$ along the x-axis and semi-minor axis $b = v_0/n$ along the z-axis, and therefore eccentricity $e = \sqrt{1 - b^2/a^2} = \sqrt{3/4} = 0.8660\ldots$. Details of such ellipses with $v_0 = 0.1\,\mathrm{m\,s^{-1}}$ are shown in Fig. 8.29 and for varying initial velocities in Fig. 8.30.

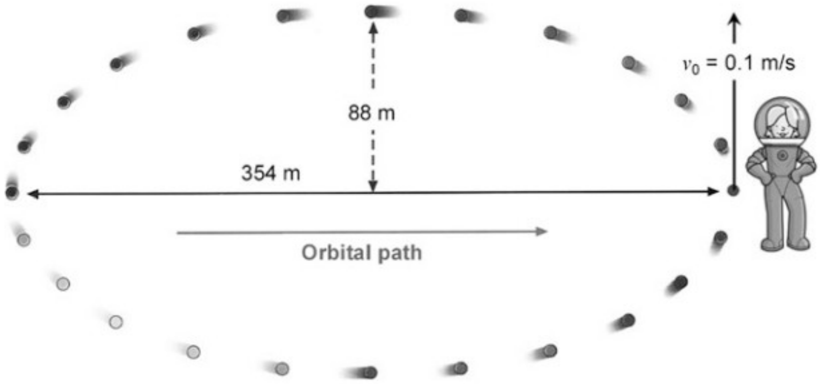

Fig. 8.29 The path of Heidemarie's toolbox if pushed with $v_0 = 0.1\ \mathrm{m\ s^{-1}}$ along the positive z-direction. The box follows a closed elliptic path and returns to Heidemarie after one orbital revolution of the ISS. ISS altitude is $h = 350$ km

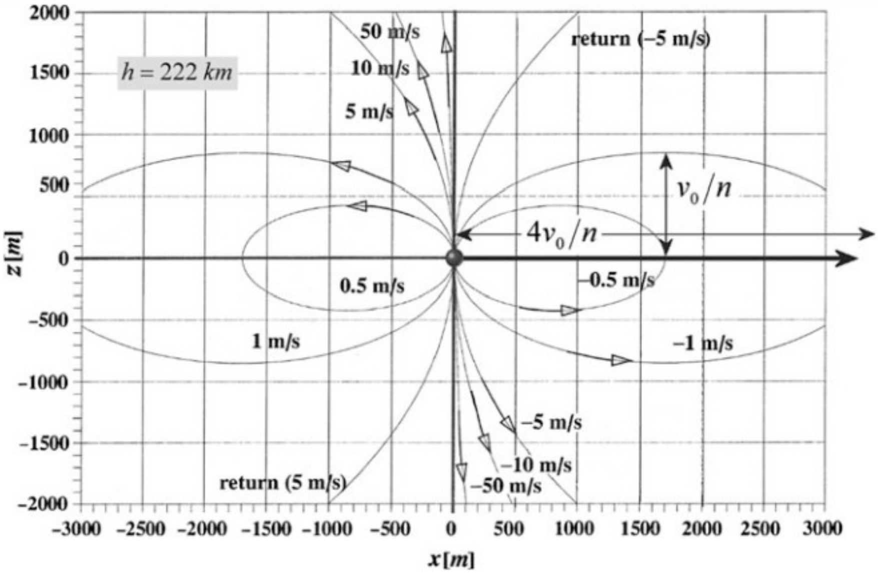

Fig. 8.30 Trajectories (ellipses) of an object moving relative to a reference point [center dot, which itself moves on an orbit at altitude $h = 222$ km to the right (bold arrow)] for different v_0 in z-direction. *Credit* Vallado (2007)

We can summarize the behavior of the toolbox as follows: When initially moving up, the orbital velocity remains constant. However, the angular velocity $\omega = v/r$ and the centrifugal force $F_c = mv^2/r$ decrease. Owing to this, the toolbox falls behind the ISS and also loses vertical speed, because the gravitation pull becomes bigger than the centrifugal force. After a quarter of an orbital revolution of the ISS, the toolbox drops down and crosses the orbit after half an orbital revolution, but now with downward velocity. The inverse behavior thereafter would bring the toolbox back to Heidemarie.

If a S/C relative to a target object starts its trajectory from the orbital path of the target object and initially moves along the x- or z-direction, the ellipse and the prolate cycloid are the two possible forms of this trajectory. The trajectories become more intricate if $\boldsymbol{v}_0$ is not pointing into the x- or z-direction, or the initial location is displaced from the orbital path, or both. In any of these cases the main features of such convoluted trajectories are the ellipse and the prolate cycloid. The reason is, whatever the initial conditions of the S/C might be, it will move on an ellipse around the Earth. If its semi-major axis a is the same as that of the target object it will just fly around the target object periodically. If its a is different, its orbital period will be different and therefore the periodic motion will be superimposed by a motion that let the S/C and the target object drift relative to each other. These two features are extensively used for applied orbital rendezvous maneuvers to which we will turn now.

8.5.4 Near-Circular Orbits

Differential Equations

We now want to convey these results to near-circular orbits, i.e. orbits with $e \ll 1$. For small eccentricities it is easy to show (exercise, Problem (8.9)) that Eq. (8.5.3) pass over into

$$\begin{aligned} \ddot{x} + 2n\dot{z} &= \quad en(nx \cos nt + 2nz \sin nt - 4\dot{z} \cos nt) \\ \ddot{y} + n^2 y &= -3en^2 y \cos nt \\ \ddot{z} - 2n\dot{x} - 3n^2 z &= 2en(-nx \sin nt + 5nz \cos nt + 2\dot{x} \cos nt) \end{aligned} \qquad @\, e \ll 1 \quad (8.5.16)$$

or in our dimensionless notation (see Sect. 8.5.2)

$$M = nt, \quad (.)' := \frac{d}{dM} = \frac{1}{n}\frac{d}{dt}, \quad (.)'' = \frac{d^2}{dM^2} = \frac{1}{n^2}\frac{d^2}{dt^2}$$

they read

$$\begin{aligned} x'' + 2z' &= \quad e(x \cos M + 2z \sin M - 4z' \cos M) \\ y'' + y &= 3e(-y \cos M) \\ z'' - 2x' - 3z &= 2e(-x \sin M + 5z \cos M + 2x' \cos M) \end{aligned} \qquad @\, e \ll 1 \quad (8.5.17)$$

Here M is measured relative to the periapsis of the elliptical target orbit.

Solution to Differential Equations

It is quite intricate to solve these differential equations. We therefore leave this as an exercise to the reader (see Problem 8.10) and provide here only the exact results:

$$x(M) = \left[\begin{pmatrix} 1 \\ 6\sin M - 6M \\ 4\sin M - 3M \\ 2\cos M - 2 \end{pmatrix}^T + e \begin{pmatrix} -\cos M + 1 \\ \sin M \cos M + 12 \sin M - 6M \cos M - 15M \\ 6\sin M \cos M - 3M \cos M - 3M \\ 3 \cos^2 M - 2 \cos M - 1 \end{pmatrix}^T \right] \begin{pmatrix} x_0 \\ z_0 \\ x'_0 \\ z'_0 \end{pmatrix}$$

$$y(M) = \left[\begin{pmatrix} \cos M \\ \sin M \end{pmatrix}^T + e \begin{pmatrix} \cos^2 M + \cos M - 2 \\ \sin M \cos M - \sin M \end{pmatrix}^T \right] \begin{pmatrix} y_0 \\ y'_0 \end{pmatrix} \tag{8.5.18}$$

$$z(M) = - \left[\begin{pmatrix} 0 \\ 3\cos M - 4 \\ 2\cos qM - 2 \\ -\sin M \end{pmatrix}^T + e \begin{pmatrix} 0 \\ 6\cos^2 M + 10\cos M + 6M \sin M - 16 \\ 4\cos^2 M + 2\cos M + 3M \sin M - 6 \\ -2\sin M \cos M + 2\sin M \end{pmatrix}^T \right] \begin{pmatrix} x_0 \\ z_0 \\ x'_0 \\ z'_0 \end{pmatrix}$$

We recall that M is measured relative to the periapsis of the elliptical target orbit. Observe that these solutions satisfy our standard initial conditions

$$\begin{aligned} x(0) &= x_0, \quad x'(0) = x'_0 \\ y(0) &= y_0, \quad y'(0) = y'_0 \\ z(0) &= z_0, \quad z'(0) = z'_0 \end{aligned}$$

Flyaround Trajectories

At the periapsis let us first place a S/C at $(x_0, 0, 0)$ behind the ISS with initial zero relative velocity, $\boldsymbol{v}_0 = (0, 0, 0)$, and see what happens. From Eq. (8.5.18) we obtain

$$\begin{aligned} x(t) &= [1 + e(1 - \cos nt)]x_0 \\ y(t) &= 0 \\ z(t) &= 0 \end{aligned}$$

If the reference orbit were circular we would get a steady distance, $x(t) = x_0 = \mathit{const}$ to the target because the orbit velocity is always constant. For an elliptical target the distance slightly changes over one orbit in the interval $x_0 \le x(t) \le (1 + 2e) \cdot x_0$. Where $x = (1 + 2e) \cdot x_0$ happens at the apoapsis (Fig. 8.31).

The Prolate Cycloid

We now start with an initial longitudinal velocity $\boldsymbol{v}_0 = (\dot{x}_0, \dot{y}_0, \dot{z}_0) = (v_0, 0, 0)$ and again study the trajectory in the RSW coordinate system of the ISS, so $\boldsymbol{r}_0 = (x_0, y_0, z_0) = (0, 0, 0)$. Under these initial assumptions, we read from Eq. (8.5.18) after some minor modification

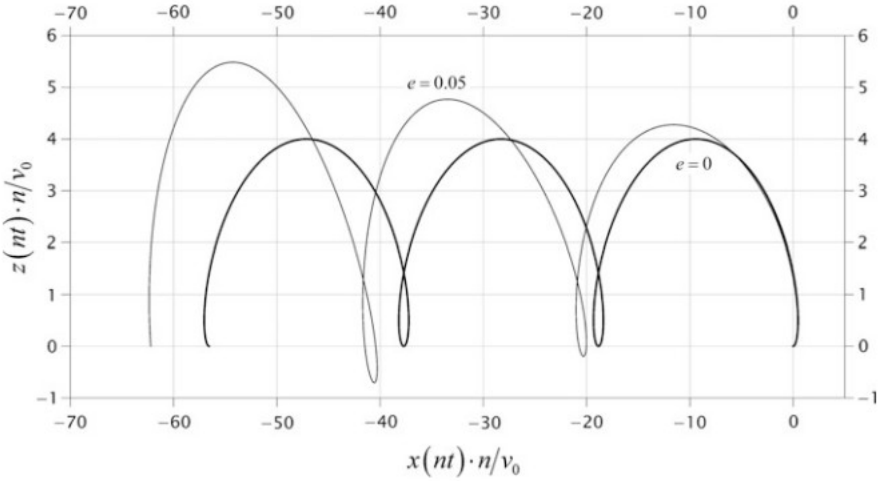

Fig. 8.31 The prolate cycloid as given by Eq. (8.5.19) with $e = 0.05$ and with $e = 0$ for reference

$$\begin{aligned} x(t) &= \frac{v_0}{n}[4\sin nt - 3nt + 3e(2\sin nt\cos nt - nt(1+\cos nt))] \\ \dot{x}(t) &= v_0[4\cos nt - 3 + 3e(2\cos 2nt - \cos nt + nt\sin nt - 1)] \end{aligned} \tag{8.5.19}$$

and

$$\begin{aligned} z(t) &= -\frac{v_0}{n}\left[2\cos nt - 2 + e\left(4\cos^2 nt + 2\cos nt + 3nt\sin nt - 6\right)\right]\dot{z}(t) \\ &= v_0[2\sin nt + e(4\sin 2nt - \sin nt - 3nt\cos nt)] \end{aligned}$$

The Ellipse

As in Sect. 8.5.2 we finally examine the flyaround trajectory with an initial transversal velocity $\boldsymbol{v}_0 = (\dot{x}_0, \dot{y}_0, \dot{z}_0) = (0, 0, v_0)$. In this case we find

$$\begin{aligned} x(t) &= \frac{v_0}{n}\left[2\cos nt - 2 + e\left(3\cos^2 nt - 2\cos nt - 1\right)\right] \\ z(t) &= \frac{v_0}{n}\sin nt[1 + 2e(\cos nt - 1)] \end{aligned} \tag{8.5.20}$$

We eliminate the time dependency by using $\sin^2 nt + \cos^2 nt = 1$ and find the trajectory

$$\left[\frac{x + 2v_0/n[1 - \frac{e}{2}(3\cos^2 nt - 2\cos nt - 1)]}{2v_0/n}\right]^2 + \left[\frac{z - 2ev_0\sin nt(\cos nt - 1)/n}{v_0/n}\right]^2 = 1$$

This is also an ellipse, with an center offset by $2e$ as shown in Fig. 8.32.

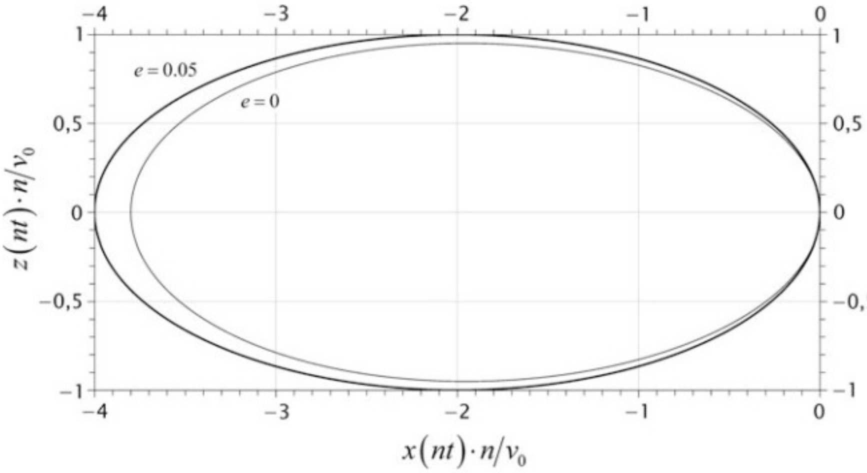

Fig. 8.32 The ellipse as given by Eq. (8.5.20) with $e = 0.05$ and $e = 0$ for reference

8.6 Orbital Rendezvous

Rendezvous and docking (R&D) form some of the most complex maneuvers to be carried out by a spacecraft in spaceflight. To accomplish successful rendezvous and mating of two spacecraft, absolute and relative navigation on orbit, sensing of the target object, precise attitude determination and control, maneuver planning, and the use of highly complex mechanisms must be mastered. The development of these skills was the purpose of the US Gemini program and the early Soviet Soyuz program, and they were further refined in the era of the Space Shuttle and the ISS. In recent years, the desire for autonomous robotic on-orbit servicing systems and plans for more ambitious human and robotic exploration of the solar system create new challenges for technology and mission designers.

The purpose of any R&D mission is to establish physical contact between two or more spacecraft to establish electrical, material, and crew exchange. Therefore R&D is a prerequisite for the construction and maintenance of space stations such as the ISS, as well as any servicing mission to satellites in Earth orbit. Such missions can be manned (e.g., the Hubble servicing missions) or unmanned (e.g., future On-Orbit Servicing). R&D is also a mission-enabling skill in human and robotic exploration of the solar system. Without successful R&D, the Apollo missions would not have been possible.

As the established term *rendezvous and docking* implies, the involved operations are divided into two distinct parts, each with a particular set of goals.

Rendezvous: During the rendezvous part of the mission, the involved spacecraft are guided to meet in the same volume of space, at the same time. In most applications, the target object (also often referred to as *resident space object*) is inert, and the interceptor (a.k.a. chaser) performs all maneuvers to meet the position and time requirements. However, as an exception to this rule, in the so-called *control box rendezvous*, it is the target spacecraft that executes a number of maneuvers to meet the interceptor after it was launched. This reduces interceptor vehicle propellant consumption, naturally at a cost to the target. It therefore can only be performed with targets having orbit maneuvering capabilities, which usually rules out space stations and a large number of satellites. Nonetheless, this type of rendezvous was performed on some Space Shuttle missions (e.g., STS-49 to service Intelsat VI) and was also planned for the contingency rescue mission STS-400 to Atlantis' Hubble Servicing Mission 4.

Docking: The goal of docking in a mission is to establish physical contact between the involved spacecraft. Although commonly the term *docking* is used, there actually exist two distinct cases: *docking*, and *capture and berthing*. In

(1) *Docking*. The interceptor approaches the target with non-zero relative velocity, brings its docking tool into alignment with the target's counterpart, and establishes a firm structural connection by using its own momentum. Docking therefore relies only on maneuvering capabilities of the two spacecraft and on properly functional docking tools. This approach was used during Gemini and Apollo and still is in use with Soyuz/Progress, the Space Shuttle, and ESA's Automated Transfer Vehicle (ATV) missions to ISS.
(2) *Capture and berthing*. The interceptor is maneuvered into close proximity of the target and an initial mechanical connection between both is established by a robotic manipulator. This manipulator can be either situated on the interceptor (as is the case with the Shuttle Robotic Manipulator System (RMS) used for capturing the Hubble Space Telescope), or on the target vehicle. This is the approach taken with the Space Station Remote Manipulator System (SSRMS) on ISS capturing the Japanese H-II Transfer Vehicle (HTV). After capture, the captured spacecraft is then moved by the manipulator to a berthing position, which is a device similar to a docking port.

The choice of the manipulator's location is, on the one hand, dependent on the sizes and masses of the spacecraft. The attitude of a heavier spacecraft is less influenced by the disturbance torques caused by the movement of the manipulator. On the other hand, a space manipulator is a very complex and hence an expensive mechanism. It will therefore be mounted on the spacecraft with the longer lifetime and/or reentry capability, and not on the disposable spacecraft like HTV.

The combination of both rendezvous and docking is not an end to itself, but serves to fulfill the purpose of a mission. It therefore must always be carefully planned and designed within the larger mission context. This influences not only design decisions such as launch windows, approach trajectories, and the selection of sensors, but also the general approach modes, be it operator-in-the-loop or autonomous robotic. To understand the challenges, choices, and trade-offs involved, the following section provides details about R&D mission design.

Mission Phases

Generally, R&D missions involve both an interceptor spacecraft, which begins the mission on the launch pad, and a target spacecraft, which is usually already in orbit by the time of the interceptor's launch. The following sections will discuss the mission phases of typical R&D missions in Low Earth Orbit (LEO), which are in the following order:

1. Launch
2. Phasing
3. Homing
4. Closing
5. Final Approach
6. Docking/Capture

This sequence of mission steps results in a typical R&D mission profile as shown in Fig. 8.33.

This R&D mission profile typically takes two days to accomplish. This is why it is sometimes called a *2-day rendezvous profile*. It is a standard profile used for R&D missions in particular for ISS R&D by Soyuz, Shuttle or ESA ATV.

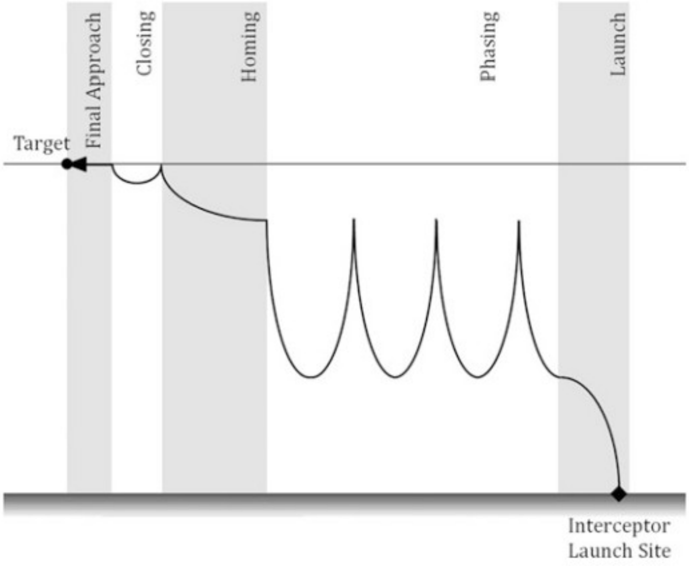

Fig. 8.33 Sketch of a typical R&D mission profile consisting of launch phase, phasing maneuvers, homing, and close-range rendezvous (closing and final approach) including docking

From $\cos i = \cos\beta \cdot \sin\varphi$ we can read that because $|\sin\varphi| \leq 1$, we have $\cos i \leq \cos\beta$ implying $i \geq \beta$. So there exists no launch azimuth to achieve an $i < \beta$, or in other words: Orbits with $i < \beta$ cannot be reached directly. This seemingly paradoxical situation is elucidated in Fig. 8.35. For example, launchers from Kennedy Space Center with $\beta = 28.47°$ cannot reach orbits with $i < 28.47°$. Only in the limiting case $\varphi = 90°,\ 270°$, i.e., if the launch azimuth is East or West (into a retrograde orbit), we obtain $i = \beta$. If orbits $i < \beta$ need to be reached, the launcher is first launched with $i = \beta$. When its orbit intersects the desired target orbit having $i < \beta$, a plane change maneuver (a.k.a. dogleg maneuver) is performed that, however, is associated with large propellant consumption and thus reduced payload for a given target orbit.

What is the right time to launch? The Universal Time of launch, T_{UT}, defines the moment in time when the launch site is in the plane of the International Space Station's orbit, the so-called *in-plane time*. At this launch time the interceptor reaches the targeted orbital plane with the least effort (delta-v). It is given by

$$\boxed{T_{UT} = \frac{\theta_{GMST} - \theta_{GMST0}}{\omega_{\oplus}}} \quad \textbf{in-plane time (launch time)} \qquad (8.6.2)$$

where $\omega_{\oplus} = 7.2921150 \times 10^{-5}\,\mathrm{s}^{-1}$ is Earth's sidereal rotation rate $\omega_{\oplus}$. The hour angle θ_{GMST}, representing the Greenwich Mean Sidereal Time (GMST) for the launch to occur at, is calculated as

$$\theta_{GMST} = \Omega + \lambda_u - \lambda$$

where the auxiliary angle λ_u (see Fig. 8.34), which is the difference between the launch site longitude λ and the target orbit is Right Ascension of Ascending Node (RAAN) Ω, is calculated from Napier's rules as

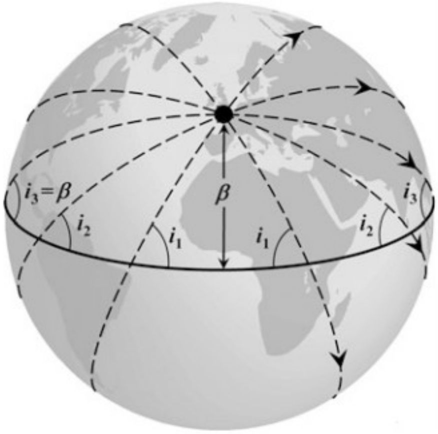

Fig. 8.35 Whatever the launch azimuth is, the accessible orbit inclination i is always larger than the latitude of the launch site β. If the launch azimuth is $\varphi = 90°$ then $i = \beta$ is achieved

$$\lambda_u = \arccos \frac{\cos \varphi_{1,2}}{\sin i} = \pm \arcsin \frac{\sqrt{1 - (\cos i / \cos \beta)^2}}{\sin i}$$

The required hour angle θ_{GMST0} of a particular launch day at hour 00:00 h can be obtained from the Astronomical Almanac of the given year or from

$$\begin{aligned}\theta_{GMST0} =& 100.4606184^\circ + 3600.77005361^\circ \, \mathrm{s}^{-1} \cdot T_{UT1} \\ &+ 0.00038793^\circ \, \mathrm{s}^{-2} \cdot T_{UT1}^2 - 2.6 \times 10^{-8\,\circ} \, \mathrm{s}^{-3} \cdot T_{UT1}^3\end{aligned}$$

The term T_{UT1} denotes the number of *Julian centuries* of the launch day at 00:00:00 h elapsed since the *standard epoch* J2000, which is given as

$$T_{UT1} = \frac{JD - 2\,451\,545.0}{36\,525}$$

where in turn the Julian date *JD* of the given launch day at 00:00:00 h, which should be provided in terms of years $\langle yyyy \rangle$, months $\langle mm \rangle$, and days $\langle dd \rangle$, is computed by

$$\begin{aligned}JD = 367 \cdot \langle yyyy \rangle - INT\left\{1.75 \cdot \left[\langle yyyy \rangle + INT\left(\frac{\langle mm \rangle + 9}{12}\right)\right]\right\} \\ + INT\left(\frac{275}{9} \langle mm \rangle\right) + \langle dd \rangle + 1\,721\,013.5\end{aligned}$$

where the function $INT(x)$ truncates the real number x to the next lower integer number.

Launch Windows

Any deviation from the in-plane launch time would implicate a dogleg maneuver and hence an additional propulsion demand for a plane-change maneuver (see Eq. (8.1.22) and Fig. 8.4 for details). On the other hand, since this precision is impractical to achieve both for organizational and technical reasons, one allows a small amount of time for the launch of the interceptor on both sides of the ideal launch time T_{UT}. This is the so-called **planar launch window**. The width of the planar launch window depends on the launch azimuth. If the launch azimuth is $\varphi \approx 90^\circ$, i.e., if the inclination matches the launch site latitude, the launch window is typically up to 1 h because no later plane adjustment would be necessary. With decreasing launch azimuth any deviation of the launch time from the in-plane time will cause increasing plane differences and hence an increasing propulsion demand to correct them. For Shuttle launches to the ISS $(i = 51.6^\circ)$ the planar launch window decreases to only 10 min. Targets above 57° inclinations have planar launch windows of less than 5 min. In missions to ISS, in practice the Shuttle launch time is appointed to the opening of the launch window, i.e., 5 min before the in-plane time. In case of a launch delay due to a possible countdown problem there remain 10 min to fix the problem. If no problem occurs, the Shuttle is put on hold for 5 min and is launched on in-plane time.

Apart from orbital mechanics there are other restrictions defining other kinds of launch windows on different time scales. An important consideration is the *sun angle*, which is the angle between the direction to the Sun and the targeted orbital plane. The sun angle is important for visibility conditions during final approach (cf. Fig. 8.45 where the Shuttle needs to see the ISS during daytime conditions, in particular during final approach) and for solar power generation of the docked spacecraft. For the Space Shuttle another concern is the ability to monitor its ascent and to visually check the external tank for damages during launch and ascent.

When launching toward ISS, traffic conditions also impact launch window planning, since multiple spacecraft such as Soyuz, Progress, ATV, HTV, or Shuttle want to approach the station, during beneficial lighting conditions. All these factors must be considered in mission planning, which leads to the small number of launch windows available to ISS or Hubble per year. This is the reason why the failure to launch a mission during the originally intended window can cause launch delays of months, instead of hours or days as dictated by orbital mechanics. Also the so-called *phase window* (see next section) restricts the launch opportunities.

For a given launch site the range of permitted launch azimuths is usually restricted due to safety concerns of flying a launch vehicle over densely populated areas. For instance, the launch azimuth restrictions at Kennedy Space Center are $35^\circ \leq \varphi \leq 120^\circ$, where the lower bound is due to the US West Coast and the upper bound to the Caribbean islands. This restricts the Shuttle to have only one launch opportunity per day to the ISS.

8.6.2 Phasing

After successful completion of the launch phase, the interceptor spacecraft achieves a stable orbit within the same plane as the target. The two orbits are thus coplanar and typically near circular. (Alternatively, the interceptor is in a plane from which the target plane can be reached within the capabilities of the orbital maneuvering system of the interceptor.)

However, the target might be anywhere on its orbit. Therefore, the first part of the target rendezvous, the so-called *far range rendezvous*, requires first a reduction in the distance to the target, until it can be acquired by the sensors of the interceptor, and then a transfer to a stable holding point on the trailing side of the target.

This first part of far range rendezvous phase is called *phasing* because it is to reduce the so-called *(orbital) phase angle* ϑ , which is the difference in true anomaly as measured in the flight direction from the target to the interceptor. Phasing is typically conducted in absolute navigation, i.e., with reference to an inertial reference frame, and guided by ground control. As an example, Space Shuttle phasing maneuvers are planned by mission control using orbit determination data obtained by ground radar and *Tracking and Data Relay Satellite System*

(TDRSS) Doppler measurements. By processing both the target and interceptor tracking data, the orbital phase angle is determined.

Usually, the interceptor needs to chase the target, so only negative initial phase angles are permitted. This is why the interceptor is often called *chaser*. In addition, only certain initial phase angles are permitted. Owing to performance limitations and constrained crew activities this so-called **phase window** (window accounting for phase angle makeup capability) varies for the Shuttle between $40^\circ \le -\vartheta_i \le 360^\circ$. The relationship of the phase window to the planar launch window changes each day and depends on the target's orbital period and inclination.

Owing to a given initial phase angle to be made up, the interceptor will have finalized its launch trajectory on a generally slightly elliptic or circular orbit with its semi-major axis a_I smaller than the a_T of the target orbit. Whether the initial apogee coincides with the target orbit depends on the particular rendezvous strategy, but usually the interceptor orbit nowhere crosses the target orbit. Because $a_I < a_T$ the orbital frequency (mean motion) is larger than that of the target, which implies that the orbital phase angle is reduced continuously—the goal of phasing.

How much is the phase angle reduced in course of one orbital revolution? Assuming small differences in the semi-major axes, which is a quite good approximation for LEO and since $n = \sqrt{\mu/a^3} = 2\pi/T$ of the target the phase reduction after one orbital revolution is

$$\Delta\vartheta = -\Delta n \cdot T = -\left(\frac{dn}{da} \cdot \Delta a\right) \cdot T = \frac{3}{2}\frac{n}{a} \cdot \Delta a \cdot T$$

Therefore

$$\Delta\vartheta = 3\pi \frac{\Delta a}{a} \text{ per orbit} \tag{8.6.3}$$

So, the phase angle from the interceptor (behind the target) to the target decreases if $a_I < a_T$, i.e., if $\Delta a = a_I - a_T < 0$. This phase angle reduction relates to a closing distance of

$$\Delta x = \Delta\vartheta \cdot a = -3\pi \cdot \Delta a \quad \text{per orbit}$$

To give an example, the ISS orbits Earth at an altitude of about $h = 350\,\text{km}$. Owing to drag becoming too excessive, the lowest chaser altitude is limited to about $h = 250\,\text{km}$. This implies $\Delta a \ge -100\,\text{km}$.

So, for instance the Soyuz is able to approach the ISS typically with $\Delta\vartheta_{\max} = 7^\circ$ per orbit equaling $\Delta x_{\max} = 820\,\text{km}$ per orbit. To limit the physical and fatigue stress to astronauts in the small S/C one typically sets a limit of two days to get to ISS docking. Accounting also for the first checkout orbit, the homing, closing, and final approach phases, the number of Soyuz phasing orbits are typically limited to 21 orbits equaling a maximum initial phase angle of $\Delta\vartheta_i \le 150^\circ$. This of course has a grave impact on the possible launch windows. To ease this problem and to even further reduce the stress to astronauts the trajectory department of RSC Energia in March 2013 implemented a new rendezvous profile for Soyuz TMA-08M and for later Soyuz missions, where the phasing orbits were reduced to 5 orbits or less (typically 4), which has become known as the *fast rendezvous profile* a.k.a. *four-orbit rendezvous profile*. This fast profile was tested first on the unmanned ISS supply mission Progress M-16M in August 2012, while it was first applied to the manned mission Soyuz TMA-08M in March 2013 and to all manned Soyuz mission since then. This new 4-orbit rendezvous profile implies and initial phase angle of $\Delta\vartheta_i 15^\circ - 20^\circ$, which is achieved by adjusting the ISS orbit raising maneuvers months before launch day such that the ISS falls within this initial phase angle range.

8.6.3 Homing Phase

The interceptor is now on a phasing orbit about 50 km away from the target drifting slowly toward the target. The objective of the upcoming homing transfer, the second part of the far range rendezvous, is to transfer the interceptor to a stable holding and aiming point in the vicinity of the target (see Figs. 8.33 and 8.36). A prerequisite of the transfer is that the target must be acquired by the relative navigation sensors of the interceptor. For the Space Shuttle, mission control hands over rendezvous guidance to the orbiter's crew at 74 km from the target. At this point a target like the ISS can be tracked using star trackers or radar.

Fig. 8.36 Homing, closing, and final approach profile and phases for ISS rendezvous. ISS safe-approach procedures require station-keeping points S on the V-bar, an approach corridor, and a keep-out sphere around ISS that approaching spacecraft must use. *Credit* Wartenberg and Amadieu/ESA

With the homing maneuver also the relative approach velocity must be reduced to a safe level. In addition, the dispersions in position, orientation, and angular rate must be reduced to meet the conditions required for the upcoming close range rendezvous. This includes the synchronization of the motion timeline of the two spacecraft.

LVLH Reference Frame

For the discussion of the now following rendezvous approaches, the *Local Vertical Local Horizontal* (LVLH) reference frame is defined (see Fig. 8.37). The origin of LVLH is located at the center of mass of the target. Its +*x*-axis, also called the +V-bar, points along the target's velocity vector. The −*z*-axis, referred to as +R-bar, points antiparallel to the target's radial vector. The −*y*-axis, also called +H-bar, completes the right-handed system and thus points along orbit normal. In the following a "+V-bar approach" means that the interceptor approaches the target on the target's +V-bar (into −V-bar direction). Accordingly, a "−R-bar approach" is on the target's −R-bar (into +R-bar direction), etc.

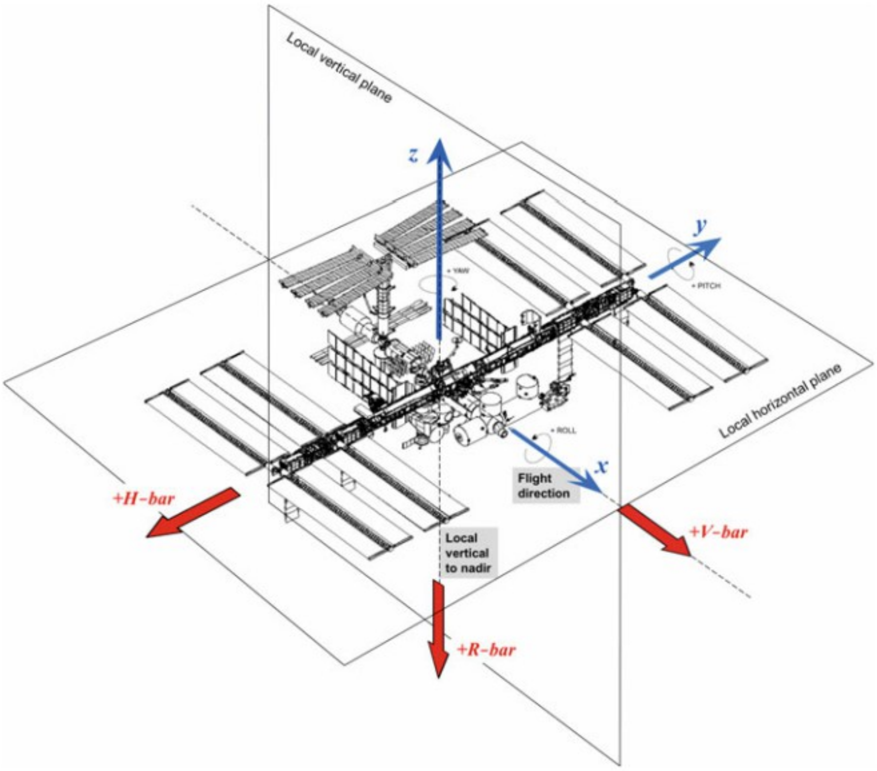

Fig. 8.37 Local vertical local horizontal (LVLH) reference frame: +V-bar (+*x*-axis) is in the direction of the spacecraft's velocity vector, +R-bar (+*z*-axis) is in the direction of the negative radius vector, and +H-bar (−*y*-axis) completes the right-handed system

Homing Transfer

The homing transfer, which commences at point S1 in Fig. 8.36, is a classical Hohmann transfer as described in Sect. 8.3. The principle situation is shown in Fig. 8.38, where the orbits, however, are not to scale because at the end of the phasing phase, the two orbits with $a \approx 6750\,\text{km}$ in LEO have a radial distance of typically only about 10 km. Owing to this, the phase angle at the beginning of the Hohmann maneuver is practically zero while its complement to 180°, the so-called *lead angle*, is $\alpha_L = 180^\circ - \vartheta \approx 180^\circ$.

Let ϑ_i be the initial phase angle and let ϑ_f be the final phase angle at S2 behind the target. The key question is: At a given a, Δa, and ϑ_f, what is the right ϑ_i and the right tangential kick-burn Δv to get to S2? To find an answer we apply from Sect. 8.3.2 the essential results of a Hohmann transfer to adjacent circular orbits as for rendezvous orbits

$$a_H = \frac{1}{2}(a_I + a) = a\left(1 + \frac{\Delta a}{2a}\right)$$

$$t_H = \pi\sqrt{\frac{a_H^3}{\mu}}$$

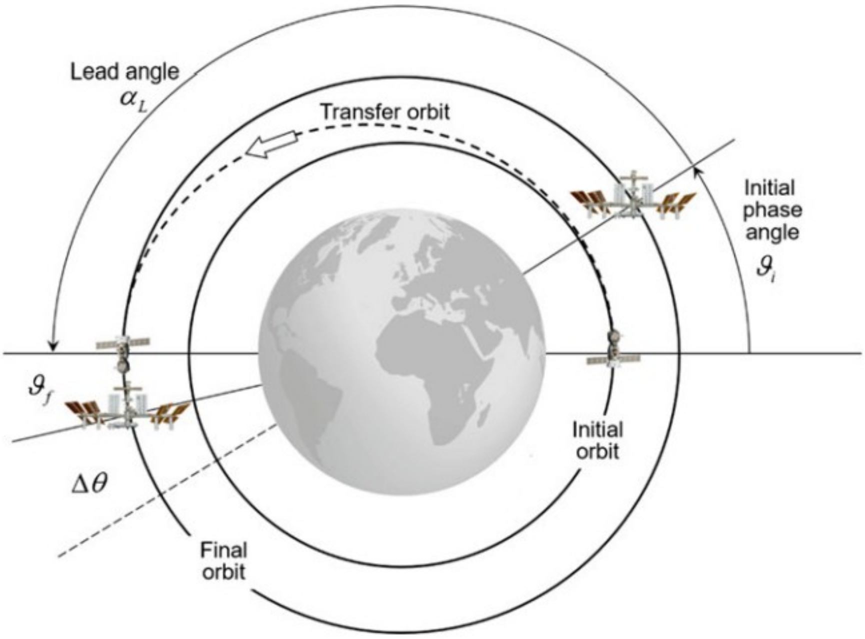

Fig. 8.38 General homing transfer of an interceptor (Soyuz) to meet a target point behind a target (ISS) in a circular coplanar orbit. Initially the required phase angle is ϑ and the interceptor begins the phasing maneuver by applying a thrust. After a half revolution on the transfer orbit, the interceptor reaches the target point, where a thrust maneuver brings the interceptor to a steady relative position behind the target and thus finalizes the Hohmann transfer

Now, while the interceptor transits over an orbit angle of 180° on the Hohmann transfer orbit, the target with $n = \sqrt{\mu/a^3}$ covers the orbit angle (see Fig. 8.38)

$$180^\circ - \Delta\theta = n \cdot t_H = 180^\circ \cdot \left(\frac{a_H}{a}\right)^{3/2} = 180^\circ \cdot \left(1 + \frac{\Delta a}{2a}\right)^{3/2} \approx 180^\circ \cdot \left(1 + \frac{3}{4}\frac{\Delta a}{a}\right)$$

Because in LEO $\Delta a/a \approx 10^{-3}$, we could safely neglect terms of higher order. Therefore, we have for the initial phase angle (see Fig. 8.38)

$$\vartheta_i = \vartheta_f + \Delta\theta = \vartheta_f - 180^\circ \cdot \frac{3}{4}\frac{\Delta a}{a}$$

or

$$\boxed{\vartheta_i = \vartheta_f - 135^\circ \frac{\Delta a}{a}} \tag{8.6.4}$$

For the required delta-v, we find with a circular orbital velocity $v = \sqrt{\mu/a}$

$$\Delta v = v_I - v_T = v_T\left(\sqrt{\frac{a}{a + \Delta a}} - 1\right) = v_T\left(\sqrt{1 - \frac{\Delta a}{a}} - 1\right)$$

and hence

$$\boxed{\Delta v = -\frac{1}{2}\frac{\Delta a}{a}\sqrt{\frac{\mu}{a}}} \tag{8.6.5}$$

> *Example*
>
> The Shuttle shall perform a homing maneuver from $\Delta a = -10\,\text{km}$ to a waiting point $S2 = 3\,\text{km}$ behind the ISS at $h = 350\,\text{km}$.
>
> We have $\vartheta_f = (180^\circ/\pi) \cdot (10/6728) = 0.085^\circ$ and $v_T = 7.697\ \text{km s}^{-1}$. With this we get $\vartheta_i = \vartheta_f + 0.201^\circ = 0.286^\circ$. This means the Shuttle has to perform a burn with $\Delta v = 5.72\ \text{m s}^{-1}$ into flight direction at a position 33.6 km behind the ISS. Because the Shuttle initially is 10 km below the ISS, the viewing distance to the ISS at burn is $\sqrt{10^2 + 33.6^2} = 35.0\,\text{km}$

NASA's Space Rendezvous History

At NASA there exist two general approaches for homing and closing maneuvers: The historical *coelliptic rendezvous* and today's *stable orbit rendezvous* (SOR).

Coelliptic Rendezvous

Coelliptic orbits are coplanar elliptic (including circular) orbits with a common occupied focus (see Fig. 8.39). The arguments of perigee ω are equal, meaning that the lines of apsides of the orbits are congruent. In addition to this, the differences in perigee and apogee radii are equal. In a spacecraft-fixed reference frame, coelliptic orbits appear as two parallel lines. These particular orbits allow for easy, intuitive,

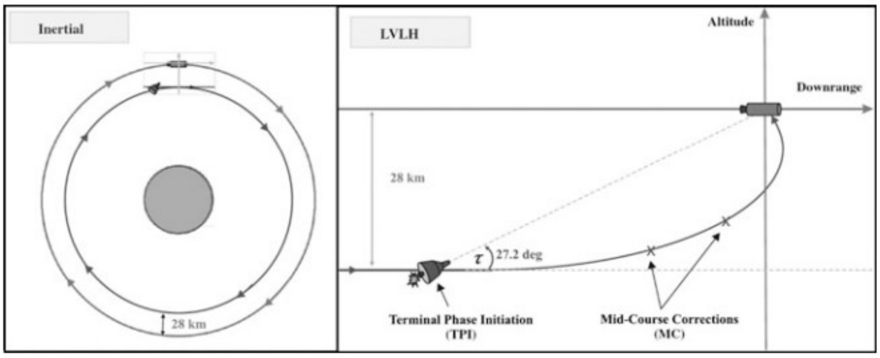

Fig. 8.39 Gemini coelliptic rendezvous in inertial and spacecraft reference frames; τ denotes the trigger angle between the direction to the target and the local horizontal plane at which the transfer maneuver is triggered. *Credit* Woffinden and Geller (2007)

and robust maneuver planning by means of so-called *trigger angle targeting*. This technique was developed during the Gemini program. It allows astronaut pilots to reliably achieve rendezvous by pointing the interceptor spacecraft at the target at a certain trigger angle τ (see Fig. 8.39) relative to the direction of flight and then engaging the orbital maneuvering thrusters, the so-called *Terminal Phase Initiation* (TPI). The trigger angle can be measured with simple cueing devices similar to a sextant. During the transfer, the target will move along its orbit within the so-called *transfer angle* α (the orbit angle covered during transfer). If rendezvous is achieved within a single revolution of the target, thus with $\alpha < 360°$, it is called a *direct rendezvous*. Any case with multiple target revolutions is referred to as *indirect rendezvous*. The point aimed at by the interceptor, in front of or behind the target, is referred to as the *downrange targeting location*.

It can be shown (see Woffinden (2007)), and this is a key property of coelliptic rendezvous, that for direct rendezvous, the elevation trigger angle τ is independent of the angular velocity ω and the relative altitude of the coelliptic trajectory. Hence, the same trigger angle applies for all orbits, regardless of the coelliptic height differential. For indirect rendezvous, the trigger angles show dependency on the ratio between the downrange targeting location and the relative altitude of the coelliptic trajectory. In recent numerical simulations it was determined that the optimal trigger angle for a minimum-Δv intercept maneuver is 27.0°, with a transfer angle of 163.1°. Interestingly, this is not equal to a Hohmann transfer with a trigger angle of 0° and a transfer angle of 180°. In reality, this optimal angle will not be perfectly achievable. A range between 26.8° and 27.3° was therefore identified as providing optimal combinations of required Δv, Line-of-Sight (LOS) approach rates, and positioning accuracy.

Interestingly, without running numerical computer simulations, NASA selected a trigger angle of 27° with a transfer angle of 130° for Gemini/Apollo rendezvous operations. For these manned rendezvous missions trigger angle targeting was particularly attractive. It allowed the use of the astronauts' eyes and simple elevation cueing for maneuver triggering in case of the failure of the rendezvous radar system. After applying the initial Δv along LOS, the pilot performed one or two mid-course correction maneuvers, before finally approaching the target for docking. During final approach, the pilot benefited from a low inertial LOS approach rate during final breaking and approach, as well as from good visibility of the target against the star background. This was important since LOS closing rates are difficult to judge visually without ambient references.

Coelliptic rendezvous remained NASA's rendezvous approach of choice throughout Gemini and Apollo. Its major strength was the backup capability to perform the TPI burn manually. It was then modified into a *dual coelliptic rendezvous* profile for the Skylab missions. In this profile, the interceptor flew a coelliptic transfer onto a holding orbit below the target. From there another coelliptic maneuver finalized rendezvous. The modifications were applied to improve the final approach lighting conditions for manual piloting, as well as the quality of long-range optical tracking using reflected sunlight. This dual coelliptic profile was then also the baseline for Shuttle R&D missions. Given the characteristics of typical Shuttle rendezvous targets, there existed concerns regarding the usability and quality of optical tracking of small target objects using reflected sunlight in the presence of Earth's illuminated surface and bright celestial objects. Another issue was the depletion of the Shuttle's *Reaction Control System* (RCS) propellant due to high relative approach velocities. This initially led to the adoption of a so-called *tuned coelliptic rendezvous* (TCR) profile.

Stable Orbit Rendezvous (SOR)

For current space station operations all these coelliptic rendezvous approaches were replaced by the so-called *stable orbit rendezvous*. Such a SOR was first flown on Gemini XI and was later suggested to address the concerns over target tracking and propellant consumption for Space Shuttle R&D. The reason is that it supports inertial approaches with lower relative velocity than the inertial approaches from the Apollo legacy coelliptic profile. In addition, a stable orbit profile desensitizes the mission timeline from trajectory considerations, as the interceptor could theoretically remain at the waiting point for indefinite periods of time. Stable orbit station-keeping at multiple kilometers of distance to the target (15 km for Space Shuttle ISS approaches) was also preferable to the close-range (at distances of tens of meters) station-keeping associated with coelliptic approaches. In such close proximity, continuous crew monitoring and frequent correction maneuver are needed, resulting in high propellant expenditure. Therefore, the advantages of SOR profiles over coelliptic approaches are lower propellant consumption and stable station-keeping points on V-bar, leading to less demand on crew position monitoring and correction. Hence, the SOR has become the standard for ISS operations for Space Shuttle, Soyuz and ATV, as well as for other rendezvous operations, such as with the Hubble Space Telescope.

For more details on coelliptic and Space Shuttle R&D missions refer, e.g., to Goodman (2006).

8.6.4 *Closing Phase*

Once on the target orbit at S2 (see Fig. 8.36) jets are fired to bring the interceptor to a hold at a safe distance about 3 km behind the target. The target now is within range of the interceptor sensors and thus relative navigation can commence. This station-keeping point S2 is essential to assess the situation and plan the upcoming closing maneuver.

The closing maneuver depends on the type of final approach: For a final ±R-bar approach the interceptor needs to get to the ±R-bar below/above the target. For a final +V-bar approach the interceptor needs to proceed further on the −V-bar closer to the target to the station-keeping point S3, and for a +V-bar approach the interceptor has to fly around the target to approach it from the leading end. Anyway, with the closing maneuver we ingress the *Approach Ellipsoid* of the ISS. All operations inside the Approach Ellipsoid are “combined operations” involving the mission control authorities in Houston and Moscow. From here on safety as not to collide with the ISS has the highest priority.

−V-Bar Approach

Let us assume that the docking port is on the trailing end of the target and therefore an approach further on the −V-bar is favorable. What are the options to carry it out? In Sect. 8.5.3 we have seen that we may approach the target on the V-bar either via a prolate cycloid (which is a Hohmann trajectory; see end of section “Ellipse” in Sect. 8.5.3) or via an ellipse. The decision is based on safety versus efficiency: If in course of the prolate cycloid we would lose control over the interceptor we would drift away infinitely and if it is a “flat” cycloid we might even hit the target. However, if safety is not paramount then one could traverse the distance from S2 to S3 by one or several cycles keeping the momentum along the V-bar and hence save fuel. At each reversal point one could even stop the approach, assess the situation, and fine-tune the further approach. This option is chosen by NASA for the Shuttle closing phase (see Fig. 8.45). If safety is top priority then the ellipse trajectory is the choice, because if control over the interceptor would be lost, it would automatically return to S2. However, this method requires to fire the jet at every intersection with the V-bar, thus coming to a halt and thereafter repeat the whole cycle procedure. “Safety-first” requirement of course comes at the expense of a higher propulsion demand.

So, for +V-bar approach of a “safety-first” rendezvous with the ISS as shown in Figs. 8.36 and 8.40 the ellipse maneuver is used. As shown in Sect. 8.5.3, in particular Figs. 8.29 and 8.30, a vertical (radial) burn v_0 will bring us on an ellipse to the next waiting point S3 that lies by $\Delta x = S2 - S3 = 4v_0/n < 0$, with $S2 < 0,\ S3 < 0$, closer to the target. When arriving at S3 a reverse burn must be fired to bring the interceptor to a halt. For the required delta-v for such a step of width Δx we find from Fig. 8.30

$$\boxed{\Delta v = \pm 2 \times \frac{\Delta x}{4}\sqrt{\frac{\mu}{a^3}}} \quad \text{@ elliptic trajectory} \qquad (8.6.6)$$

where the factor 2 indicates that we need two burns for the entire approach maneuver and the ± sign that the elliptic trajectory might be on either side of the V-bar. This maneuver can be performed at any step size and as often as wanted to get to S3. Observe that it does not make any difference for the total delta-v if a given distance is covered with more or less steps because $\Delta v \propto \Delta x$. How many increments are to be chosen is just a matter of safety and time (every step lasts one orbital period). So, if Δx is the total distance between S2 and S3, Eq. (8.6.6) provides the delta-v for the entire closing transfer independent of the number of steps. To approach the ISS, every incremental distance of 1 km requires $\Delta v = 2 \cdot 0.286\,\mathrm{m\,s^{-1}}$.

If the cycloidal approach would be chosen, we have from Fig. 8.27 $\Delta x = 6\pi v_0/n$ and hence

$$\boxed{\Delta v = \pm 2 \times \frac{\Delta x}{6\pi \cdot k}\sqrt{\frac{\mu}{a^3}}} \quad \text{@ cycloidal trajectory} \tag{8.6.7}$$

where Δx is the total distance between S2 and S3 and k is the number of cycloidal revolutions to traverse this distance. Here again the factor 2 indicates that we need a initiation burn at S2 plus a stop burn of equal absolute value at S3. We therefore see that the cycloidal approach is by a factor $6\pi \cdot k/4 = 4.7 \cdot k$ more efficient that the elliptic approach—at the expense of safety. We recall that every cycloidal or elliptic cycle takes a full orbital period.

Approach to +V-Bar

If one wants to approach on the –V-bar from S2 to the waiting point S3 on the +V-bar, i.e., to the other side of the target, one has to apply the same maneuvers (elliptic or cycloidal trajectories) as above, the only difference being that for $\Delta x = \mathrm{S2} - \mathrm{S3} < 0$ holds $\mathrm{S2} < 0,\ \mathrm{S3} > 0$.

Approach to ±R-Bar

If the final approach is on +R-bar or −R-bar the closing phase must bring the interceptor in a loop from −V-bar to ±R-bar (see Fig. 8.41) at below/above the target. Here again both the cycloidal and elliptic trajectory would do, but here both approaches are equally safe. This is because if control is lost for a cycloidal trajectory it would just pass by the target at the aimed distance and after that drift away from the target. In the elliptic trajectory case the interceptor would just orbit the target on an ellipse. Because we have seen that the cycloidal trajectory is much more efficient it is the preferred approach method.

The cycloidal loop is performed in two (or one) steps. First, a tangential burn Δv brings the interceptor on a prolate cycloid (Hohmann trajectory) to the transition point $\mathrm{S3}_-$ where a burn Δv is fired against the direction of movement. This brings the interceptor into a circular Earth orbit below/above the ISS. On this orbit it slowly drifts to the point S3 below the ISS from where the final approach commences. Note that neither $\mathrm{S3}_-$ nor S3 are stable points with respect to the ISS. If the first burn is accurate enough it can be set such that $\mathrm{S3}_-$ coincides with S3.

What needs to be determined is: Given the initial point S2 and a radial distance Δr (counted positively outward along the z-axis) the interceptor shall dive below $(\Delta r < 0)$ or above $(\Delta r > 0)$ the ISS, what is the delta-v to perform the entire maneuver? From Fig. 8.27 we derive that the diving distance is $\Delta r \equiv \Delta z = 4v_0/n$. We therefore find for the initial delta-v

$$\boxed{\Delta v_i = \frac{\Delta r}{4}\sqrt{\frac{\mu}{a^3}}} \quad \text{@ initial burn} \tag{8.6.8}$$

Upon diving down/up, the interceptor speeds up and according to Eq. (8.5.14) achieves at the lowest/highest point of the trajectory, which is S3$_-$, the relative velocity $\dot{x} = v_0(4\cos\pi - 3) = -7v_0$. This corresponds in an Earth centered system to

$$v_- = \sqrt{\frac{\mu}{a}} - 7v_0$$

At $r = a + \Delta r$, the anticipated circular orbit has an orbital velocity of

$$v_+ = \sqrt{\frac{\mu}{a + \Delta r}} = \sqrt{\frac{\mu}{a}}\left(1 - \frac{1}{2}\frac{\Delta r}{a}\right) = \sqrt{\frac{\mu}{a}} - 2v_0$$

where the latter follows by applying Eq. (8.6.8). For the delta-v of the braking burn at S3$_-$, we therefore obtain

$$\boxed{\Delta v_f = v_- - v_+ = -5v_0} \tag{8.6.9}$$

So the total delta-v is

$$\Delta v = |\Delta v_i| + |\Delta v_f| = 6 \times \frac{\Delta r}{4}\sqrt{\frac{\mu}{a^3}}$$

Thus, while for the −V-bar approach our effort to get to S3 is maximally $\Delta v = 2|v_0|$ (elliptic trajectory), it is much bigger, namely $\Delta v = 6|v_0|$, in the case of an approach to ±R-bar.

8.6.5 Final Approach

The interceptor is now on the waiting point S3 just outside of the Keep-Out Sphere, about 200 m away from the ISS (see Fig. 8.42). This is where the *final approach* (a.k.a. *proximity operations or terminal phase*) begins. Other than during the stable orbit rendezvous where the interceptor approached the target via stable orbits (i.e., cycloidal trajectories that can be stopped at the reversal points or elliptic trajectories that even back off from the target if rendezvous control is lost and therefore are "safe" orbits), the trajectories now are more or less straight to directly intercept the

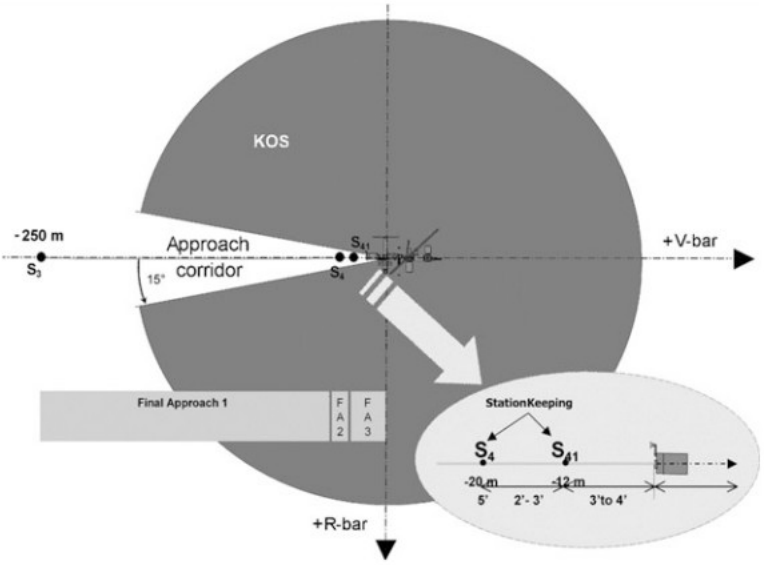

Fig. 8.42 ISS approach corridor for V-bar approach. *Credit* Wartenberg and Amadieu/ESA

target and therefore are on "collision course" with it. The final approach ends at a distance of a few meters upfront the ISS, either when docking is imminent or when the target is within capture distance of the manipulator. During this phase the spacecraft usually maneuvers autonomously, i.e., without intervention by ground control. The spacecraft control loop must therefore be closed locally, either by the crew or by the automatic controllers. Final approach can thus be considered the most critical part of the R&D mission. During this phase, minor errors can cause accidents.

±V-Bar approach

First, we consider the approach on +V-bar or on −V-bar (see definition of "±V-bar approach" in the section *LVLH Reference Frame* above) from waiting point S3 through the conical approach corridor with half angle 15° to the next waiting point S4 (the initial waiting point for docking approach). To penetrate the cone one could continue to apply the ellipse maneuvers. However, every incremental step takes one orbital period of 91.5 min in case of the ISS, which is far too much.

One therefore switches to another approach mode called *forced translation.* Figure 8.43 shows its principle. Let us assume a burn is performed aiming directly at the target. According to Fig. 8.27, the higher speed would force the interceptor to drift upward (centrifugal force is bigger than the gravitational force at this circular altitude), violate the approach cone, and never encounter S4 (see Fig. 8.43). However, we can counteract the updrift by providing in addition to the forward translation an initial small downward force. If this is done properly, it forces the

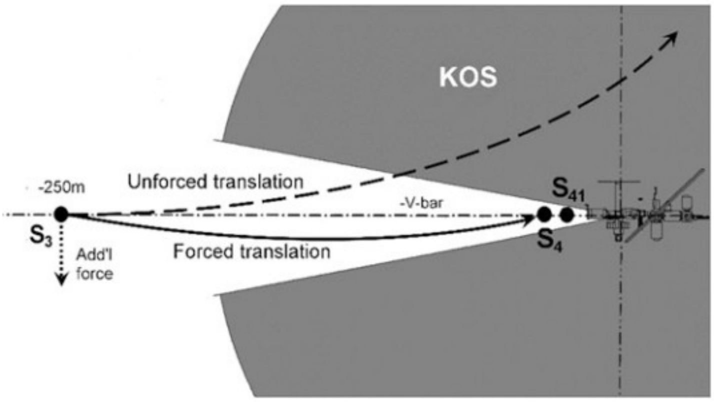

Fig. 8.43 A straight trajectory would turn up and leave the approach corridor. A downward forced translation enforces the trajectory to stay in the corridor and hit the waiting point

initial trajectory slope down just that the trajectory at its end hits S4. The forward translation with this extra little downward force is called *forced translation*.

It needs to be determined how big the additional delta-v, equivalent to the downward force, is. We therefore revisit Sect. 8.5.2 where we have shown that for translation times $(nt)^2 \ll 1$ Eq. (8.5.13) holds. These equations give the answer to the question what the initial velocity $\boldsymbol{v}_0 = (\dot{x}_0, \dot{y}_0, \dot{z}_0)$ at the initial point (x_0, y_0, z_0) should be in order to meet after time *t* a given target point at the origin $(0, 0, 0)$. In our case the vector from the target point to the initial distance of the interceptor is $(x_0, y_0, z_0) = (\pm\Delta x, 0, 0)$ for a ± V-bar approach. Therefore, Eq. (8.5.13) reduces to

$$\boldsymbol{v}_0 = \left(v_{0x},\ v_{0y},\ v_{0z}\right) = \left(\mp\frac{\Delta x}{t},\ 0,\ \pm n \cdot \Delta x\right) \quad @ \pm \text{V-bar approach} \qquad (8.6.10)$$

$$\Delta\boldsymbol{v} = \boldsymbol{v}_0 - \boldsymbol{v}_i$$

where $n = \sqrt{\mu/a^3}$, $\Delta\boldsymbol{v}$ is the initiation burn vector, and $\boldsymbol{v}_i$ is the interceptor's velocity incident of the starting point S3 (if the starting point was a waiting point, $\boldsymbol{v}_i = 0$). Of course, for braking the forced translation at S4 the same amount of Δv is required, however, for v_{0x} into the opposite direction. The initial speed in *x*-direction, v_{0x}, is easy to grasp: The required speed is distance divided by flight time. The delta-v in negative *z*-direction (radial thrust downward) is just the forced part. Assuming that the delta-v in each direction is generated by separate thrusters (as usually the case), the absolute value of the total approach delta-v is

$$\Delta v = 2\left(\frac{\Delta x}{t} + n \cdot \Delta x\right) = 2 \cdot \Delta x \cdot \left(\frac{1}{t} + n\right)$$

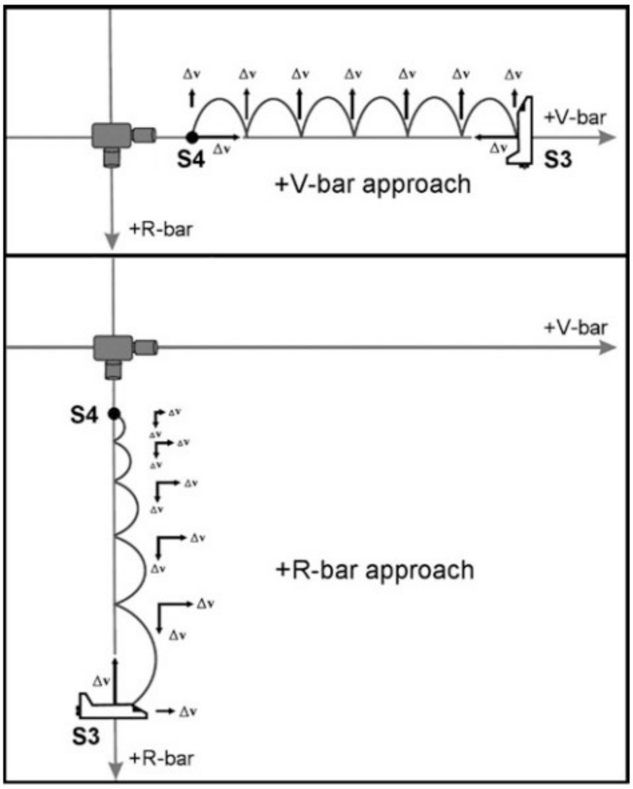

Fig. 8.44 Final approach hopping profiles of a Shuttle final approach along the +V-bar (above) and the +R-bar (below, including deceleration burns). *Credit* Woffinden and Geller (2007)

It would not be wise to cover the final approach distance in one move. Initial point and/or firing errors would jeopardize encountering exactly the target point. One rather splits the distance into two or more parts and whenever the trajectory meets the V-bar a new forced delta-v of $\pm 2 \times n \cdot \Delta x$ is applied starting the forced translation anew. This leads to a hopping approach as depicted in Fig. 8.44 (top) for a Shuttle +V-bar approach. This is why it is called *hopping trajectory*. Because the total delta-v has the linear dependency $\Delta v \propto \Delta x$, it does not make any difference in terms of delta-v effort to split the final approach distance into k shorter hops of length ε, $\Delta x = k \cdot \varepsilon$, but still cover the total distance in the same time t, or not. However, owing to boost errors, it is preferable to make more shorter hops.

±R-Bar Approach

Forced translation can also be applied on the +R-bar or −R-bar, which for instance is performed by a Soyuz or Progress docking to the radial port (Pirs docking compartment) of the ISS. This approach was originally designed for docking the Shuttle with *MIR*. It was also used on Hubble servicing mission STS-82. To determine the initiating delta-v for the forced translation from S3 to S4 we have from Eq. (8.5.13) with the initial distance vector $(0, 0, \mp\Delta z)$ for ±R-bar approach

$$\boldsymbol{v}_0 = \left(v_{0x},\ v_{0y},\ v_{0z}\right) = \left(\pm n \cdot \Delta z,\ 0,\ \pm\frac{\Delta z}{t}\right) \quad @ \pm \text{R-bar approach} \qquad (8.6.11)$$

$$\Delta\boldsymbol{v} = \boldsymbol{v}_0 - \boldsymbol{v}_i$$

where $n = \sqrt{\mu/a^3}$, $\Delta\boldsymbol{v}$ the initiation burn vector, and $\boldsymbol{v}_i$ is the interceptor's velocity incident to the starting point S3. The total approach delta-v is by the same token as above

$$\Delta v = 2 \cdot \Delta z\left(\frac{1}{t} + n\right)$$

And also in this case owing to the linear dependency $\Delta v \propto \Delta z$ it does not make any difference in terms of delta-v effort to split the distance into more shorter hops. Thus, we might have also hopping trajectories as shown in Fig. 8.44 (bottom).

Proximity Operations

From an orbital mechanics point of view the last few meters starting out from S4, the docking approach in the proximity of the target, is the most easy part of the rendezvous. This is because for very short distances $x,\ z,\ \tau \to 0$ and hence

$$\begin{aligned} v_{0x} &= -\frac{x_0}{t} - nz_0 & v_{0x} &= -\frac{x_0}{t} \\ v_{0z} &= -\frac{z_0}{t} + nx_0 \ \rightarrow & v_{0z} &= -\frac{z_0}{t} \\ v_{0y} &= -\frac{y_0}{t} & v_{0y} &= -\frac{y_0}{t} \end{aligned} \qquad (8.6.12)$$

$$\Delta\boldsymbol{v} = \left(v_{0x},\ v_{0y},\ v_{0z}\right) - \boldsymbol{v}_i$$

where $\boldsymbol{v}_i$ is the interceptor's velocity incident to the starting point S4. Therefore, if on this docking approach the commander or pilot navigates the interceptor, steering becomes intuitively easy because the required momentary speed is just distance per time. However, in order not to crash into the docking port the approach speed has to be continuously reduced (see Fig. 8.44, bottom).

Docking/Capture Phase

At the end of the final approach phase, the interceptor is in position in front of the target's docking port or capture interface and all thrusting has ceased. The interceptor's relative velocity is either zero for capture & berthing, or slightly above zero for docking. On one hand, this approach rate must be great enough to prevent the vehicles from bouncing off each other without capture being achieved. On the other hand, it must be low enough to prevent structural damage or loss of control and/or the ability to attenuate the momentum. The exact position, velocity, orientation, and angular rate tolerances depend on the specific docking or capture tools being used.

The docking/capture phase is the conclusion of a R&D mission. It encompasses the following activities:

- docking/capture of the target by the interceptor (or vice versa)
- establishment of a rigid structural connection
- connection of fluid, gas, electrical, propellant and communication lines
- establishment of a pressurized passageway, if crew transfer is part of the mission goals.

Docking means that the active spacecraft positions itself and establishes the physical connection using its own momentum. In capture and berthing, either the target or interceptor is captured, positioned and connected by a robotic manipulator to a berthing mechanism. Berthing thus allows contact to be made at a near-zero cloture rate, which means a higher level of control for the operator and avoids the process of one vehicle basically flying into the other. It is therefore the generally preferable approach but comes at the cost of requiring a complex, heavy and expensive *Remote Manipulator System* (RMS).

8.6.6 Shuttle-ISS Rendezvous

The Shuttle's close range rendezvous with the ISS is somewhat different, though, because the docking port is on the leading side (+V-bar) of the ISS. Therefore, beginning at S2 the Shuttle flies in two cycloidal steps and within two orbits a homing approach from S2 to S3 such that it goes up just below the ISS (see Fig. 8.45). Note that the launch window was chosen such that daytime (i.e., sunlight) condition is at those parts of the trajectory, including the final approach and docking (see Figs. 8.46 and 8.47), where the ISS needs to be seen from the Shuttle and vice versa. Just before arriving at S3 the commander of the Shuttle takes over manual control for the remainder of the approach and docking. He will stop the Shuttle at S3 some 180 m below the ISS and will maneuver the Shuttle through a 9 min, 360° backflip (a.k.a. *Rendezvous Pitch Maneuver*, RPM) that allows the station crew to take pictures of the Shuttle's heat shield to see whether it was damaged during launch. The Commander then will move the Shuttle at a so-called TORVA maneuver from the +R-bar to the +V-bar in a position about 120 m directly in front of the station in preparation for the final approach to the pressurized mating adapter PMA-2 located at the leading end of the US utility hub *Harmony*.

Acronyms for NASA Rendezvous Maneuvers

NC	(Phasing correction burn) Performed to hit a range relative to the target at future times
NH	(Height adjust burn) Performed to hit a delta-height relative to the target at future times
NPC	(Plane change burn) Performed to remove planar errors relative to the target at future times
NCC	(Corrective combination burn) First on-board targeted burn in the rendezvous sequence to reduce phasing and height errors relative to the target at Ti
Ti	(Terminal intercept burn) Second on-board targeted burn in the rendezvous sequence to place the orbiter on a trajectory to intercept the target in one orbit
MC-1,2,3,4	(Midcourse correction burns) On-board targeted burns to correct the post Ti trajectory in preparation of the final approach phase
RPM	(Rendezvous Pitch Maneuver) A 360° backflip that allows the station crew to take pictures from the Zvezda Service Module of the Shuttle's heat shield
TORVA	(Twice Orbital Rate R-bar to V-bar Approach) This manually performed maneuver brings the orbiter from the +R-bar to the +V-bar

8.6.7 Plume Impingement

The term *plume impingement* covers all effects exerted on the target object if it is impacted by the exhaust gases of the interceptor's reaction control system (RCS, the maneuvering control system of an interceptor) thrusters. One of these effects is the plume pressure force acting on the target and causing position and attitude disturbances. Another is the heat load placed on the target's structure by the hot gases. This can lead to overheating of parts of the surface and the underlying structure. The third effect is the contamination of the target's surfaces by combustion products and unburned propellant components. This can cause contamination of not only sensitive elements on the target's surfaces, particularly optical elements such as camera lenses, solar arrays or docking sensors, but also of sealing elements of the docking mechanism. This risk of contamination must be considered in particular during orbit servicing missions such as Hubble servicing, where these considerations impacted the design of final approach trajectories.

Therefore, plume impingement is one of mission planners' major concerns during proximity operations, apart from collision avoidance and maneuver precision. It can only be avoided if thruster activity near the target is minimized. This in turn means that the interceptor's relative velocity must diminish below a threshold value as it approaches the target. During Gemini and Apollo, plume impingement never became a significant issue due to the thrust magnitude, the position and canting of the RCS nozzles, as well as the roughly equal sizes of interceptor and target and the absence of large appendages such as solar arrays. This changed during the Skylab missions. During Skylab 2, the Apollo *Command and Service Module* (CSM) was maneuvered within close proximity so that a crewman standing in the hatch could reach the stuck solar array with a deployment tool. The CSM thrusting to null the closing velocity triggered Skylab AOCS to fire its jets in order to maintain its attitude. This resulted in an opening rate between the two vehicles. On the later Apollo-Soyuz Test Mission, four of the CSM's thrusters were inhibited 2 s prior to docking contact in order to prevent plume loading of the Soyuz solar arrays.

Space Shuttle

These lessons were carried into the Space Shuttle design process. The massive orbiter is designed to assemble and maintain large space stations and service comparatively small and light satellites. These are equipped with large solar arrays and antennas or sensitive optics. Plume impingement therefore is a prime concern. The size of the Shuttle was predetermined by the payload it was designed to carry and the location of RCS thrusters by its shape, which in turn was determined by the requirements of re-entry and atmospheric flight. Plume impingement concerns could therefore be addressed only by careful design of R&D approaches.

The underlying assumptions were as follows: The target spacecraft could not be designed with features preventing contamination (e.g., movable sensor covers as

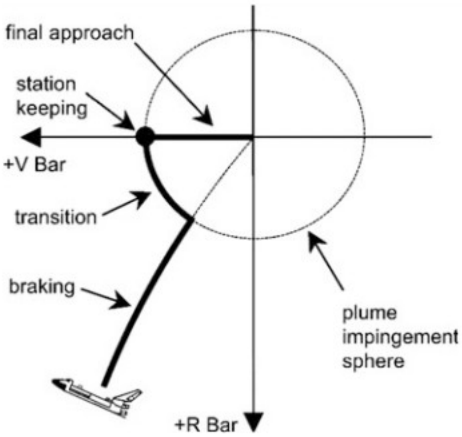

Fig. 8.48 Approach profile to avoid plume impingement on target. When the approaching interceptor reaches the border of a plume impingement sphere, it performs a transition maneuver to a station-keeping point on the V-bar following the borders of the plume impingement sphere. After the station-keeping point is reached, the interceptor flies a forced translation final approach. *Credit* Goodmann (2006)

found on Hubble), and the control of the target attitude could not prevent contamination. Therefore, on each mission a target-dependent minimum range existed, at which the thrusters could still be fired in the direction of the target without contamination concern. At the minimum range, the orbiter was to transition from a direct approach trajectory to a station-keeping point on the V-bar (see Fig. 8.48). From this point on the final approach would be flown in forced translation. A number of such approaches were planned for the Shuttle's *Long Duration Exposure Facility* (LDEF) mission. Simulations showed that an Apollo-type inertial approach and braking technique would cause LDEF to tumble. In addition, plume impingement induced dynamics at grapple ranges that could make both LDEF deployment and retrieval difficult.

Another countermeasure for plume impingement issues specific to the Space Shuttle was the development of the *Low-Z* approach. In this approach, all forward firing RCS jets are inhibited, with all thrust thus acting primarily along the spacecraft's longitudinal x-axis (see Fig. 8.49). All braking thrust in the z-direction therefore results from the canting of the longitudinal thrusters. This provides minimal RCS braking capability while minimizing RCS plume impingement. It is also expensive in terms of propellant use. Notwithstanding its limitations, *Low-Z* mode has been employed on satellite servicing missions, including Hubble servicing, and the missions to MIR and ISS.

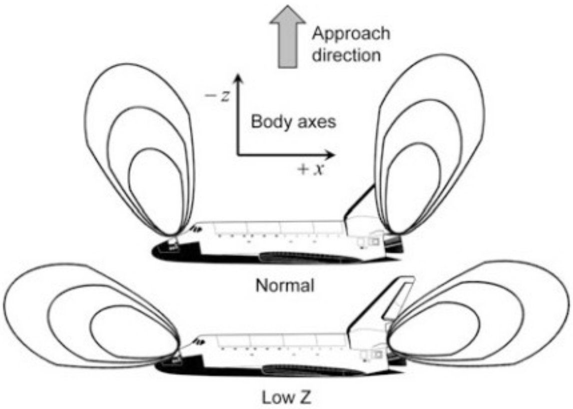

Fig. 8.49 Space shuttle low-Z RCS mode. The orbiter's thrusters are fired only in the Shuttle's longitudinal axis (x-axis). This significantly reduces plume impingement. On the other hand, owing to the canting of the thrusters, this provides minimal braking capability in the forward z-direction

8.7 Problems

Problem 8.1 *Efficiency of Combined Orbital Maneuvers*
Prove the statement in Sect. 8.1.3 that in terms of delta-v an orbit transition with $\boldsymbol{v}_1 || \boldsymbol{v}_2$ combined with a change in orbit orientation $v_1 = v_2,\ \phi \neq 0$ is always more efficient than performing the two changes sequentially at the same point in space.

Problem 8.2 *Adjacent Circular Orbit Approximation*
Prove Eq. (8.3.9)

$$\frac{\sqrt{a_\bullet} + \sqrt{a_\mathrm{O}}}{\sqrt{a_H}} - 1 \ \approx 1 - \frac{1}{16}\left(\frac{a_\mathrm{O} - a_\bullet}{a_\bullet}\right)^2 \quad @\, a_\mathrm{O} \to a_\bullet$$

Problem 8.3 *Transfer between Aligned Ellipses*
Consider a Hohmann transfer between two coplanar and coaxial ellipses. Show that the propulsion demand for the transition between the periapsis of the inner ellipse and the apoapsis of the outer ellipse is

$$\begin{aligned}\Delta v &= \sqrt{\mu}\left(\frac{1}{\sqrt{r_{\bullet,per}}} - \frac{1}{\sqrt{r_{\mathrm{O},apo}}}\right)\left(\frac{\sqrt{r_{\mathrm{O},apo}} + \sqrt{r_{\bullet,per}}}{\sqrt{a_T}} - \frac{\sqrt{r_{\mathrm{O},apo}}\sqrt{1+e_\bullet} - \sqrt{r_{\bullet,per}}\sqrt{1-e_\mathrm{O}}}{\sqrt{r_{\mathrm{O},apo}} - \sqrt{r_{\bullet,per}}}\right)\\ &\leq \sqrt{\mu}\left(\frac{1}{\sqrt{r_{\bullet,per}}} - \frac{1}{\sqrt{r_{\mathrm{O},apo}}}\right)\end{aligned}$$

Remark *For circular orbits this expression passes over to Eq. (8.3.8).*

Problem 8.4 *Hohmann Transfer Maxima*

(a) Prove that the maximum of the circularization impulse $\Delta v_{HO \to O}$ (see Fig. 8.12) is the root of the equation $x^3 - 5x^2 - 5x - 1 = 0$. Find the root $x = r_O / r_\bullet = 5.879362\ldots$ by Newton's method.

(b) By the same token, prove that the propulsion demand of a Hohmann transfer achieves a maximum at $x = a_O / a_\bullet = 15.58172\ldots$, which is the root of $x^3 - 15x^2 - 9x - 1 = 0$.

Problem 8.5 *Hohmann Versus Bi-Elliptic Transfer*

Prove that for $x = r_O / r_\bullet > 11.9387654724\ldots$ the bi-elliptic transfer has a lower propulsion demand than the Hohmann transfer. Show that $x = r_O / r_\bullet$ is the root of the equation $x - 1 = \sqrt{1+x}(\sqrt{x} - \sqrt{2} + 1)$.

Problem 8.6 *Variations of Orbital Elements by Kick-Burns*

(a) Prove Eq. (8.1.1) as described in the text.

(b) Prove Table 8.1 by applying Eq. (8.1.1) at the given positions.

Problem 8.7 *Orbit Phasing*

Suppose two satellites are flying in a close formation on the same orbit at relative distance s and orbital period T. Show that, if s needs to be corrected, a kick-burn $\delta v_{||}$ at the periapsis will cause a position shift of

$$\delta s_{per} = 3T \frac{1+e}{1-e} \delta v_{||}$$

at the periapsis after one orbit, while a kick-burn $\delta v_{||}$ at the apoapsis will cause a position shift of

$$\delta s_{apo} = 3T \frac{1-e}{1+e} \delta v_{||}$$

at the apoapsis after one orbit.

Problem 8.8 *Maximum Transfer Time for Minimum Energy Transfer*

Given the minimum energy transfer orbit between two points P_1 and P_2 having $4a_{\min} = r_1 + r_2 + c$. Show that for any slightly larger transfer orbit with $a = a_{\min} + \Delta a$ the transfer time is

$$\Delta t \approx \Delta t_{\max} - 4a_{\min} \sqrt{\frac{\Delta a}{\mu}} \quad @\, \beta < \pi$$

$$\Delta t \approx \Delta t_{\max} - a_{\min} \sqrt{\frac{\Delta a}{\mu}} \quad @\, \beta \approx \pi$$

and therefore the minimum energy transfer orbit indeed has a maximum transfer time. We will explore the characteristic square root behavior $\delta(\Delta t) \propto -\sqrt{\Delta a}$ near the maximum transfer time for a Hohmann transfer a bit further in Sect. 9.3.2 before Eq. (9.3.15).

Problem 8.9 *Lambert's Problem for $a \to \infty$*

Prove that from Lambert's Eq. (8.2.13) for $a \to \infty$ follows

$$a = \frac{3}{40} \cdot \frac{\Delta_+^{5/2} - \Delta_-^{5/2}}{6\Delta t\sqrt{\mu} - \left(\Delta_+^{3/2} - \Delta_-^{3/2}\right)}$$

with $\Delta_\pm = r_1 + r_2 \pm \sqrt{r_1^2 + r_2^2 - 2r_1 r_2 \cos \Delta\theta}$. Since $\sqrt{\Delta_\pm} = 2s\sqrt{c}$ this delivers Eq. (8.2.15).

Problem 8.10 *Solution of the Differential Equations for Elliptic Orbits*
It is the objective of this exercise to solve the differential Eq. (8.5.17). According to the theory of differential equations the general solution is the sum of the solution of the homogeneous differential equations given by Eq. (8.5.8) and a special solution to the inhomogeneous differential equations. We therefore just have to seek for this special solution.

(a) Before doing so we make use of the fact that the right hand side of the differential solution is small, namely of order e. We therefore can insert the homogeneous solutions on the right hand side. Show that the differential equations then read

$$x'' + 2z' = e \begin{pmatrix} \cos M \\ -6M\cos M + 8\sin M - 6\sin 2M \\ -3M\cos M + 4\sin M - 4\sin 2M \\ -2\cos M - 2\cos 2M \end{pmatrix}^T \begin{pmatrix} x_0 \\ z_0 \\ x_0' \\ z_0' \end{pmatrix}$$

$$y'' + y = -3e \begin{pmatrix} \cos^2 M \\ \sin M \cos M \end{pmatrix}^T \begin{pmatrix} y_0 \\ y_0' \end{pmatrix}$$

$$z'' - 3z - 2x' = 2e \begin{pmatrix} -\sin M \\ 6M\sin M + 8\cos M + \frac{3}{2}\cos 2M - \frac{9}{2} \\ 3M\sin M + 4\cos M + \cos 2M - 3 \\ +2\sin M - \frac{1}{2}\sin 2M \end{pmatrix}^T \begin{pmatrix} x_0 \\ z_0 \\ x_0' \\ z_0' \end{pmatrix}$$

(b) Define the second equation as

$$y'' + y = f(M)$$

The homogeneous differential equation is known to have the fundamental system of solutions $y_{1,2}(M) = (\sin M, \cos M)$. Now, according to the theory of differential equations a special solution is given as

$$y^*(M) = -\sin M \int_{M_0}^{M} \frac{f(\mu)\cos\mu}{W(\mu)} \cdot d\mu + \cos M \int_{M_0}^{M} \frac{f(\mu)\sin\mu}{W(\mu)} \cdot d\mu$$

where $W(M)$ is the Wronskian of the fundamental system of solutions. Show that this delivers

$$y^*(M) = -e \begin{pmatrix} \cos^2 M + \cos M - 2 \\ \sin M \cos M - \sin M \end{pmatrix}^T \begin{pmatrix} y_0 \\ y'_0 \end{pmatrix}$$

(c) By the same token as in Sect. 8.5.2 derive the differential equation $z'' + z = g(M)$. Show that

$$u'' + u = e \begin{pmatrix} 0 \\ -12\cos M + 9\cos 2M \\ -6\cos M + 6\cos 2M \\ -3\sin 2M \end{pmatrix}^T \begin{pmatrix} x_0 \\ z_0 \\ x'_0 \\ z'_0 \end{pmatrix} =: g(M)$$

with $u = z - (4 + 13e)z_0 - (2 + 4e)x'_0$. Then apply the above integral expression for the special solution $z^*(M)$. Finally integrate the differential equation $x' + 2z = h(M)$ directly to derive $x(M)$.

Invariant Angular Elements

The classical way of doing this is using the geocentric equatorial coordinate system *IJK* (see Sect. 13.1.4), in which the Cartesian coordinate system $(\boldsymbol{u}_I,\ \boldsymbol{u}_J,\ \boldsymbol{u}_K)$ has the following orientation (see Fig. 13.2): The unit vector $\boldsymbol{u}_I$ points to the vernal point, $\boldsymbol{u}_K$ to Earth's north pole, and $\boldsymbol{u}_J = \boldsymbol{u}_K \times \boldsymbol{u}_I$. With this we establish the unit vector

$$\boldsymbol{u}_n = \frac{\boldsymbol{u}_K \times \hat{\boldsymbol{h}}}{\left|\boldsymbol{u}_K \times \hat{\boldsymbol{h}}\right|} \quad \text{unit vector to the ascending node}$$

These unit vectors determine the following angular orbital elements (see Fig. 7.10)

$$i = \arccos\left(\boldsymbol{u}_K \hat{\boldsymbol{h}}\right) \qquad 0 \le i < 180^\circ \tag{7.3.21}$$

$$\Omega = \begin{cases} \arccos(\boldsymbol{u}_I \boldsymbol{u}_n) & @ \ \boldsymbol{u}_J \boldsymbol{u}_n \ge 0 \\ 2\pi - \arccos(\boldsymbol{u}_I \boldsymbol{u}_n) & @ \ \boldsymbol{u}_J \boldsymbol{u}_n < 0 \end{cases} \qquad 0 \le \Omega < 360^\circ \tag{7.3.22}$$

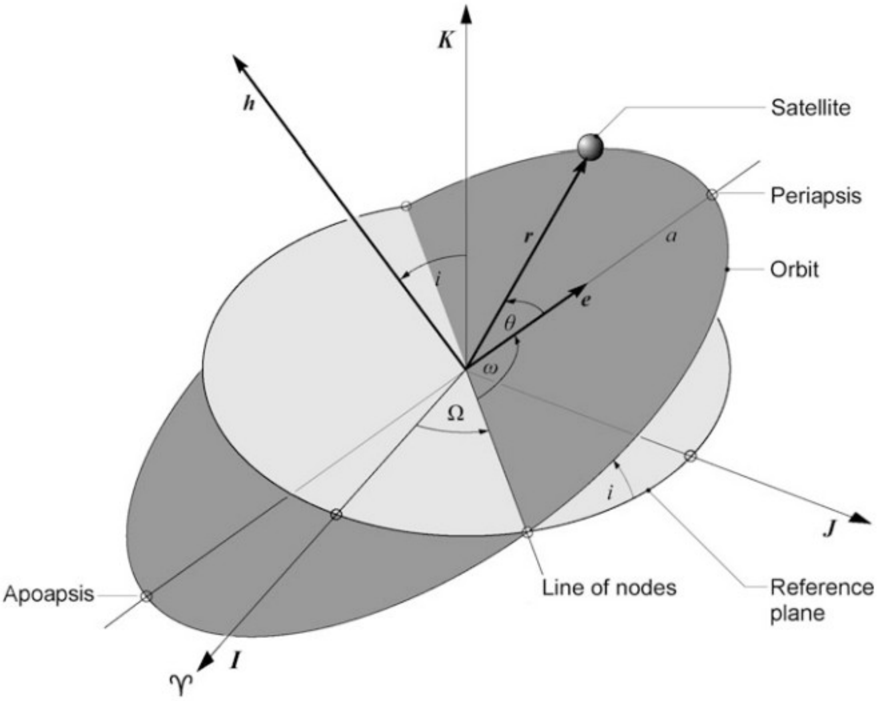

Fig. 7.10 The graphical representation of orbital elements of an elliptic satellite orbit in a geocentric equatorial coordinate system *IJK* (see Sect. 13.1.3), where the plane spanned by *I* and *J* with the *I*-axis oriented toward the vernal point ♈ is the reference plane. The orbital plane and reference plane intersect in the so-called line of nodes. The line of nodes in turn intersects the orbit in the so-called ascending node (where the satellite moves toward the upper side with respect to ***h*** of the reference plane) and in the descending node (vice versa)

$$\omega = \begin{cases} \arccos(\boldsymbol{u}_n \hat{\boldsymbol{e}}) & @ \ \boldsymbol{u}_K \hat{\boldsymbol{e}} \geq 0 \\ 2\pi - \arccos(\boldsymbol{u}_n \hat{\boldsymbol{e}}) & @ \ \boldsymbol{u}_K \hat{\boldsymbol{e}} < 0 \end{cases} \quad 0 \leq \omega < 360° \tag{7.3.23}$$

The following classification of orbits according to their inclination is common:

$i = 0°$	*Equatorial Orbit*. Prominent examples are the geostationary orbits.
$0° < i < 90°$	*Prograde Orbit*. This orbit is used by most satellites in Low Earth Orbits.
$i \approx 90°$	*Polar Orbit*. Orbits used for sun-synchronous Earth observation satellites.
$i > 90°$	*Retrograde Orbit*. Very few satellites have been put into this type of orbit.

Invariant Orbit Vectors

In terms of these angular elements, the eccentricity vector can be represented in the *IJK* system as follows (see also Sect. 13.1.5)

$$\boldsymbol{e} = e \begin{pmatrix} \cos\Omega\,\cos\omega - \sin\Omega\,\sin\omega\,\cos i \\ \sin\Omega\,\cos\omega + \cos\Omega\,\sin\omega\,\cos i \\ \sin\omega\,\sin i \end{pmatrix}_{IJK} \quad \textbf{eccentricity vector} \tag{7.3.24}$$

Equivalently, the angular momentum unity vector $\hat{\boldsymbol{h}}$, also known as the *three-dimensional inclination vector* (a.k.a. *orbit pole vector*), given as (see Eq. (13.1.5)) as

$$\boldsymbol{I} \equiv \hat{\boldsymbol{h}} = \begin{pmatrix} \sin\Omega\,\sin i \\ -\cos\Omega\,\sin i \\ \cos i \end{pmatrix}_{IJK} \quad \textbf{three-dimensional inclination vector} \tag{7.3.25}$$

For instance, in Fig. 12.28 this 3D-inclination vector depicts the evolution of i, Ω under lunisolar perturbations. Its projection onto the *IJ* reference plane is known as

$$\boldsymbol{i} = \sin i \begin{pmatrix} \sin\Omega \\ -\cos\Omega \end{pmatrix}_{IJ} \quad \text{(two-dimensional) } \textbf{inclination vector} \tag{7.3.26}$$

Note that for $i \to 0$ conveniently

$$\boldsymbol{i} = i \begin{pmatrix} \sin\Omega \\ -\cos\Omega \end{pmatrix}_{IJ} \quad @ \ i \to 0$$

We now rotate the inclination vector in the *IJ* reference plane by 90° counter-clockwise into the direction of the ascending node and thus get the *ascending node vector*

$$\boldsymbol{n} = \sin i \begin{pmatrix} \cos\Omega \\ \sin\Omega \end{pmatrix}_{IJ} = \sin i \begin{pmatrix} \cos\Omega \\ \sin\Omega \end{pmatrix}_{EQ} \quad \textbf{ascending node vector} \qquad (7.3.27)$$

All the above invariant quantities are orbital elements. This gives rise to the question of whether there is a minimum number of orbital elements that uniquely specify an orbit and how many of them are constant.

State Vector

We investigate the above question by going back to the basics of orbital motion. Depending on the initial conditions, orbital motion takes place in 6-dimensional phase space $\boldsymbol{r}$, $\boldsymbol{v}$, a space in which all possible states of a system are represented, with each possible state corresponding to one unique point in the phase space. Once an initial state $(\boldsymbol{r}_0, \boldsymbol{v}_0)$ is given, the two first-order differential vector equations

$$\dot{\boldsymbol{r}} = \boldsymbol{v}, \quad \dot{\boldsymbol{v}} = -\frac{\mu}{r^3}\boldsymbol{r}$$

derived from Newton's gravitation equation of motion (7.1.19) determine the future motion in phase space. Obviously, phase space has 6 dimensions and therefore the 6 elements of an initial state vector are the minimum number of orbital elements plus the independent parameter *t*. This is the significance of the state vector $(\boldsymbol{r}, \boldsymbol{v})$ as introduced in Sect. 7.2.2. It also has the advantage that it is the direct outcome of ranging and range rate measurements as part of orbit determination procedures (see Sect. 14.2.1). On the other hand it has the major drawback that $\boldsymbol{r}$ and $\boldsymbol{v}$ continuously change with time.

Number of Constant Orbital Elements

So, what is the maximum number of constant orbital elements? We have seen in Sect. 7.1.3 that linear momentum, angular momentum, and total energy always need to be conserved. Because the motion of a 2-body system in a central force field, such as the gravitational field and as shown in Sect. 7.2.2, always takes place in just 2 dimensions, we expect that any orbital motion exhibits $2 + 2 + 1 = 5$ constant (integrals) of motion and hence 5 constant orbital elements. This leaves one degree of freedom to the orbital motion, which is the 1-dimensional line of orbit. We therefore expect one additional orbital element to determine the moving position of the body on its orbit. Hence, in total there must be 5 constant orbital elements and 1 time-dependent orbital element. Obviously $\boldsymbol{h}$, $\boldsymbol{e}$ and $\theta(t)$ lend themselves as such orbital elements. Although they seem to make up $3 + 3 + 1 = 7$ elements, one has to consider the constraint $\boldsymbol{h} \cdot \boldsymbol{e} = 0$, and therefore the set $(\boldsymbol{h}, \boldsymbol{e}, \theta(t))$ actually represents the set of 6 independent elements and hence a minimum complete set of orbital elements.

We have seen that we may choose many different sets of 5 constant orbital elements, and any set is equivalent to any other. Next we to explore some common sets of orbital elements.

Common Sets of Orbital Elements

The most vivid orbital elements are the angular orbital elements i, Ω, ω (see Fig. 7.10) as given in Eq. (7.3.21), (7.3.22), and (7.3.23). In addition and from Eq. (7.3.7) we have from $\boldsymbol{h}$, $\boldsymbol{e}$

$$e = |\boldsymbol{e}|$$

$$a = \frac{\boldsymbol{h}^2}{\mu(1-e^2)}$$

We thus obtain the highly important and so-called six *classical orbital elements* (see Fig. 7.10)

Classical Orbital Elements $\left(a, e, i, \Omega, \omega \,/\, t - t_p \leftrightarrow M\right)$

Two elements, so-called *metric elements*, describe the dimension of the orbit:

a **Semi-major axis** axis, $-\infty < a < \infty$.
It specifies the size of the orbit. Hyperbolic orbits have negative values.

e **Eccentricity**, $0 \le e < \infty$.
It specifies the shape and jointly with a the type of the orbit.

The next three elements are called *angular elements*. Two elements describe the orientation of the orbital plane:

i **Inclination**, $0 \le i < 180°$
Angle between the angular momentum vector h and the z-direction of the reference frame = angle between the corresponding planes perpendicular to these vectors.

Ω **Right ascension of ascending node** (abbreviated: RAAN), $0 \le \Omega < 360°$
Longitude of the ascending node = angle between the line from the origin O of the reference frame to the vernal point and from O to the ascending node.

One element *determines* the orientation of the orbit in the orbital plane:

$\boldsymbol{\omega}$ **Argument of periapsis**, $0 \le \omega < 360°$
Angle in the orbital plane between line of nodes and the periapsis measured in the direction of the motion.

The sixth parameter is the orbital state sequencer, it determines the location on the orbit. The following two sequencers can be used alternatively:

$\boldsymbol{t - t_p}$ **Time after periapsis passage**
$\boldsymbol{t_p}$ is the time, when the satellite was at periapsis (a.k.a. *epoch*).

or

M Mean anomaly, $M > 0$
$M := n \cdot (t - t_p)$, dimensionless (see Sect. 7.3.2).

Although M formally is an angle (however not having an geometrical interpretation) with dimension [rad], it commonly is treated as dimensionless and hence in modern orbital mechanics is a more convenient variant of time. Both sequencers have the disadvantage that their relationship to r and θ (see Sect. 7.4.2) is transcendental.

There is an alternative and more traditional set of orbital elements, called *Keplerian elements*

Keplerian Elements $(a, e, i, \Omega, \omega \,/\, \theta \leftrightarrow E,\ F, G)$
The Keplerian elements share the metric and angular classical orbital elements. The following two sequencers can be used alternatively:

θ True anomaly (a.k.a. *orbit angle*), $0 \le \theta < 360°$
Angle between the direction to the periapsis and the current position vector $\boldsymbol{r}$.

or

E Eccentric anomaly for elliptic orbits (see Sect. 7.4.2), $0 \le E < 2\pi$
F Hyperbolic anomaly for hyperbolic orbits (see Sect. 7.4.3), $0 \le F < \infty$
G Universal anomaly for all orbits (see Sect. 7.4.6), $0 \le G < \infty$

The advantage of this set is that the determination of $r(\theta)$, or equivalently $r(E, F, G)$, is algebraic and hence straightforward. The disadvantage is that θ is not a convenient orbital state sequencer, but time t. The inclusion of θ, which Leonhard Euler called "angle of elements", into the set of elements dates back to Johann Bernoulli.

Sometimes the compound angle

$$u = \omega + \theta \qquad \textbf{argument of latitude}$$

i.e., the position of the orbit measured relative to the line of nodes, is a more valuable parameter for orbit analysis. Note that, though $\boldsymbol{h},\ \boldsymbol{e},\ \theta(t)$ usually are defined in the geocentric equatorial coordinate system, of course any inertial reference system will do and only the angular elements will change by a different choice of reference system.

Degenerate Orbits

There exist two particular cases where some of the angular elements become undefined:

1. ω and θ (or M) will become undefined for $e = 0$.
2. Ω and ω will become undefined for $i = 0$.

Both happens, for example, for satellites in geostationary orbit. These degenerate cases, however, pose no problem.

In the first case, $e = 0$, where ω becomes irrelevant the argument of latitude $u = \theta$ is used as a substitute to determine the orbital position, i.e. the true anomaly is measured relative the line of nodes.

In the second case, the compound angles

$\varpi = \Omega + \omega$	**longitude of periapsis**	$@\ i = 0$
$L = \Omega + \omega + \theta = \varpi + \theta = \Omega + u$	**orbital longitude**	$@\ i, e = 0$
$l = \Omega + \omega + M = \varpi + M$	**mean longitude**	$@\ i, e = 0$

measured relative to the vernal point Υ are used as substitutes for ω and θ or M (Ω is irrelevant for $i = 0$). The line of nodes and the vernal point then become the respective common reference directions in the orbital plane. Note that Ω is measured in the reference plane, while ω and θ are measured in the orbital plane. So, for $i > 0$, the compound angles ϖ, L, and l would be "doglegged" and no longer be true angles, but nevertheless they can be defined as mathematical quantities and treated like that. These doglegged compound angles are frequently used in the literature, but will not be used in this book.

Equinoctial Elements and Coordinate System

One problem of orbit degeneracy with angular elements arises because Ω and ω are measured relative to the ascending line of nodes, which vanishes for $i = 0$. This problem can be removed by rotating the *IJ* reference plane along the line of nodes by the inclination angle into the orbital plane and renaming the axes $K \rightarrow W,\ I \rightarrow E,\ J \rightarrow Q$. This reference frame is called *equinoctial coordinate system EQW* (see Fig. 7.11). By construction, for $i \rightarrow 0$ it crosses over into the *IJK*

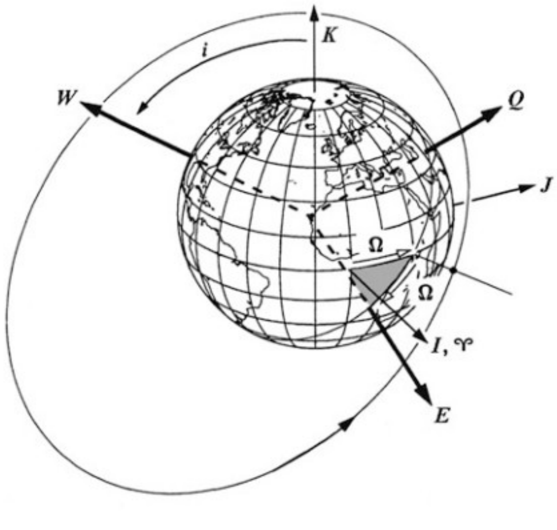

Fig. 7.11 The equinoctial coordinate system EQW. This system is formed from the IJK system by rotating IJK by the inclination angle about the line of nodes. *Credit* Vallado (2007)

coordinate system. The other orbit degeneracy problem, namely that ω and θ (or M) will become undefined for $e = 0$, can be removed by making the eccentricity vector part of the orbital elements. Both strategies are adopted to form a nonsingular set of orbital elements, the so-called **standard equinoctial orbital elements**, which read as follows:

(Standard) Equinoctial Elements $(a,\ h,\ k,\ p,\ q,\ l)$

a Semi-major axis, $-\infty < a < \infty$

Two components of the eccentricity vector:

h $= e\ \sin(\omega + \Omega)$
k $= e\ \cos(\omega + \Omega)$

Two components of the rescaled ascending node vector:

p $= \tan\frac{i}{2} \sin\Omega$
q $= \tan\frac{i}{2} \cos\Omega$

The sixth parameter again determines the location of the periapsis in time:

l $= \Omega + \omega + M(t)$, mean longitude, $0 \leq l < 360°$

Note that the RAAN angle Ω now lies in the orbital plane and therefore the mean longitude $l = \Omega + \omega + M$ is no longer doglegged, but a true angle in the orbital plane. Since the equinoctial elements exhibit no singularities they are frequently employed in perturbational equations for equatorial orbits. For more details of equinoctial elements see Battin (1987), and for coordinate transformations to and from the equinoctial coordinate system see Vallado (2007).

In terms of the invariant orbit vectors we can identify

$$\boldsymbol{e} = \begin{pmatrix} h \\ k \end{pmatrix}_{EQ} = e \begin{pmatrix} \sin(\omega + \Omega) \\ \cos(\omega + \Omega) \end{pmatrix}_{EQ} \tag{7.3.28}$$

and the vector (q, p) actually is a rescaled ascending node vector

$$(q, p) = \frac{1}{1 + \cos i} \boldsymbol{n} = \tan\frac{i}{2} \cdot \begin{pmatrix} \cos\Omega \\ \sin\Omega \end{pmatrix}_{EQ}$$

The reason for scaling by $1/(1 + \cos i)$ lies in the better adaptation to Lagrange's planetary equations where the equinoctial elements are frequently used for GEO orbits.

The introduction of the singular free parameters (h, k) and (q, p) is most probably due to Joseph-Louis Lagrange. Today, there are some variants of the standard equinoctial orbital elements, most importantly the so-called **modified equinoctial orbital elements** (Walker et al. 1985) with the only modification $a \rightarrow p = a(1 - e^2)$. But also the replacements $\tan\frac{i}{2} \rightarrow \tan i$, $\sin i$, or $\sin\frac{i}{2}$ are quite common.

Conversion: State Vector → Orbital Elements

A frequent problem encountered in astrodynamics, in particular with orbit determination, is the conversion of the state vector $(\boldsymbol{r},\ \boldsymbol{v})$ into (osculating) Keplerian elements and vice versa. In the following, we will have a look at this problem.

First, we want to convert a state vector $(\boldsymbol{r},\ \boldsymbol{v})$ to Keplerian elements. To start with, we compute

$$\boldsymbol{h} = \boldsymbol{r} \times \boldsymbol{v}$$

$$\hat{\boldsymbol{h}} = \boldsymbol{h}/h, \quad \hat{\boldsymbol{r}} = \boldsymbol{r}/r, \quad \hat{\boldsymbol{v}} = \boldsymbol{v}/v$$

The semi-major axis then is determined from the vis-viva Eq. (7.2.14) as

$$a = \frac{\mu r}{2\mu - r v^2} \tag{7.3.29}$$

Observe that the semi-major axis and thus the orbital period $T = 2\pi\sqrt{a^3/\mu}$ can be determined merely from the absolute values of the position vector and orbital velocity. For the eccentricity we have from Eq. (7.3.3) and with Eq. (7.3.6)

$$e = |\boldsymbol{e}| = \sqrt{1 - \frac{h^2}{\mu a}}$$

$$\hat{\boldsymbol{e}} = \boldsymbol{e}/e$$

$$\theta = \begin{cases} \arccos(\hat{\boldsymbol{r}}\hat{\boldsymbol{e}})@ \ \ \hat{\boldsymbol{r}}\hat{\boldsymbol{v}} \geq 0 \\ 2\pi - \arccos(\hat{\boldsymbol{r}}\hat{\boldsymbol{e}})@ \ \ \hat{\boldsymbol{r}}\hat{\boldsymbol{v}} < 0 \end{cases} \tag{7.3.30}$$

The angular orbital elements i, Ω, ω are given in the geocentric equatorial reference system *IJK* by Eqs. (7.3.21), (7.3.22), and (7.3.23). To determine the mean anomaly M, we derive from Eq. (7.4.13a)

$$\begin{array}{ll} E = \arccos[(1 - r/a)/e] & @ \ \ |\hat{\boldsymbol{r}} \times \hat{\boldsymbol{e}}| > 0 \\ E = 2\pi - \arccos[(1 - r/a)/e] & @ \ \ |\hat{\boldsymbol{r}} \times \hat{\boldsymbol{e}}| < 0 \end{array} \tag{7.3.31}$$

Hence from the Kepler's Eq. (7.4.15) we derive

$$M = E - e\ \sin E$$

and from Eq. (7.4.14d) we have alternatively

$$\theta = 2\arctan\left(\sqrt{\frac{1+e}{1-e}}\tan\frac{E}{2}\right)$$

Conversion: Orbital Elements → State Vector
Let the orbital elements $a, e, i, \omega, \Omega, \theta$ or $a, e, i, \omega, \Omega, M$ be given. The orbit radius then is determined as

$$r = \frac{a(1-e^2)}{1+e\,\cos\theta} = a(1-e\,\cos E)$$

where E is the solution of $M = E - e\,\sin E$ (see Newton's method in Sect. 7.4.2). As shown in Sect. 13.1.5, the radial vector and the orbital velocity vector in the *IJK* system (see Sect. 13.1.3) are then determined as

$$\boldsymbol{r} = r\begin{pmatrix} \cos\Omega\,\cos u - \sin\Omega\,\sin u\,\cos i \\ \sin\Omega\,\cos u + \cos\Omega\,\sin u\,\cos i \\ \sin u\,\sin i \end{pmatrix}_{IJK} \tag{7.3.32}$$

$$\boldsymbol{v} = \sqrt{\frac{\mu}{a(1-e^2)}}\begin{pmatrix} -\cos\Omega(\sin u + e\,\sin\omega) - \sin\Omega(\cos u + e\,\cos\omega)\cos i \\ -\sin\Omega(\sin u + e\,\sin\omega) + \cos\Omega(\cos u + e\,\cos\omega)\cos i \\ (\cos u + e\,\cos\omega)\,\sin i \end{pmatrix}_{IJK} \tag{7.3.33}$$

with $u = \omega + \theta$ the argument of latitude. For equatorial orbits Ω is undefined and can be set to zero. The same holds for ω in circular orbits, and hence $u = \theta$.

7.4 Keplerian Orbits

In this chapter we study the detailed properties of the different Keplerian orbits (a.k.a. *conic orbits*) and derive and present their basic results. This includes, in particular, the analytic solutions to $t = t(\theta)$ and the numeric algorithms to calculate $\theta = \theta(t)$ for elliptic and hyperbolic orbits.

7.4.1 Circular Orbit

The most common orbits of spacecraft around celestial bodies are circular or near-circular in shape, since they take on the highest minimum orbital altitude (implies least atmospheric drag) at a given orbital energy (cf. Fig. 7.7) and provide steady orbit conditions. According to Eq. (7.3.18) they also feature maximum angular momentum at a given orbital energy. For $e = 0$, Eq. (7.3.9) can be solved immediately and according to Eq. (7.3.5) we get

$$\begin{aligned} r &= a = p = const \\ \theta &= \sqrt{\frac{\mu}{a^3}}\cdot\left(t - t_p\right) = n\left(t - t_p\right) \end{aligned} \tag{7.4.1}$$

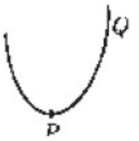
Chapter 8

Curvature

1 Meaning of Curvature



In the adjoining figure we see that the curve bends more sharply at the point P than at the point Q. We express this feeling by saying that the curve has a greater curvature at P than at Q. However, in order to get a quantitative estimate of curvature, we should give a mathematical definition of curvature which should be in agreement with our intuitive notion of curvature.

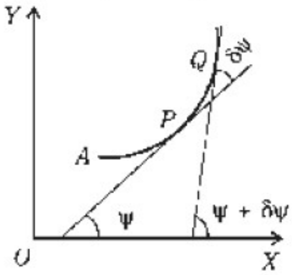
2 Definition of Curvature **(Purvanchal 2010)**

Let P and Q be two neighbouring points on a curve, ψ and $\psi + \delta\psi$ the angles which the tangents at P and Q make with the x-axis.

Let A be any fixed point on the curve.

Let arc $AP = s$, arc $AQ = s + \delta s$, so that arc $PQ = \delta s$.

The symbol, $\delta\psi$ denotes the angle through which the tangent turns as a point moves along the curve from P to Q through a distance δs. The angle $\delta\psi$ is called the *contingence* of the arc PQ. Obviously, $\delta\psi$ will be large or small, as compared with δs, depending on the degree of sharpness of



the bend of the arc PQ. This suggests us to make the following definitions :

(*i*) $\delta\psi$ *is defined to be* **total curvature** *of the arc PQ ;*

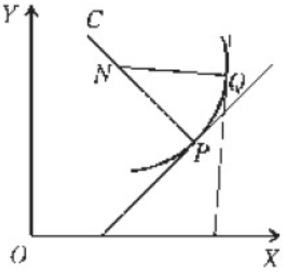
(*ii*) *the ratio* $\dfrac{\delta\psi}{\delta s}$ *is defined to be the* **average curvature** *of the arc PQ ;*

(*iii*) *the* **curvature** *of the curve at P is defined to be* $\lim\limits_{Q\to P}\dfrac{\delta\psi}{\delta s}$ *i.e.,* $\dfrac{d\psi}{ds}$.

Thus $\dfrac{d\psi}{ds}$ *is a mathematical measure for the curvature of curve at any point P.*

3 Radius of Curvature **(Meerut 2010)**

Let P be a given point on a given curve, and Q any other point on it in the neighbourhood of P. Let N be the point of intersection of the normals at P and Q. Suppose N tends to definite position C as Q tends to P, whether from the right or from the left.



Then C is called the **centre of curvature** of the curve at P.

The distance CP is called the **radius of curvature** of the curve at P and is usually denoted by the Greek letter ρ.

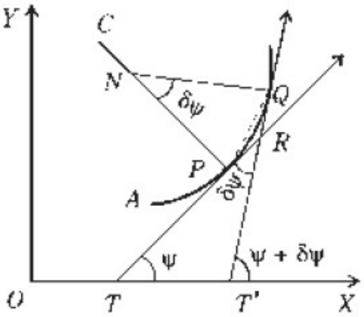
The circle with its centre at C and radius CP is called the **circle of curvature** at P. Any chord drawn through P, of the circle of curvature at P, is called a **chord of curvature at** P.

4 Intrinsic Formula for the Radius of Curvature **(Kashi 2011)**

The relation between s and ψ for any curve is called its **intrinsic equation**. Let P be a given point on the curve $s = f(\psi)$, and Q a point on it in the neighbourhood of P. Let ψ and $\psi + \delta\psi$ be the angles which tangents at P and Q make with the x-axis. Let A be any fixed point on the curve. Let

arc $AP = s$, arc $AQ = s + \delta s$, so that arc $PQ = \delta s$.

Let R be the point of intersection of the tangents at P and Q and N be the point of intersection of the normals at these two points. Suppose $N \to C$ as $Q \to P$.



Then the radius of curvature at $P = \rho = \lim\limits_{Q\to P} PN$.

We have $\angle PNQ = \angle TRT' = \delta\psi$.

Now from the triangle PNQ, we have

$$\frac{PN}{\sin NQP} = \frac{\text{chord } PQ}{\sin PNQ} = \frac{\text{chord } PQ}{\sin \delta\psi}.$$

$$\therefore \qquad PN = \frac{\text{chord } PQ}{\sin \delta\psi}\sin NQP = \frac{\text{chord } PQ}{\delta s}\cdot\frac{\delta s}{\delta\psi}\cdot\frac{\delta\psi}{\sin\delta\psi}\cdot \sin NQP.$$

Now as $Q \to P$, we have $\delta\psi \to 0$, $\delta s \to 0$, chord $PQ \to$ tangent at P,

$QN \to$ normal at P and consequently $\angle NQP \to \dfrac{\pi}{2}$.

Therefore $\rho = \lim\limits_{Q \to P} PN$

$$= \left(\lim_{Q \to P} \frac{\text{chord}\, PQ}{\text{arc}\, PQ} \right) \cdot \left(\lim_{\delta\psi \to 0} \frac{\delta s}{\delta \psi} \right) \cdot \left(\lim_{\delta\psi \to 0} \frac{\delta \psi}{\sin \delta\psi} \right) \cdot \left(\lim_{Q \to P} \sin NQP \right)$$

$$= 1 \cdot \left(\frac{ds}{d\psi} \right) \cdot 1.\sin \frac{\pi}{2} = \frac{ds}{d\psi}.$$

Hence, $\boldsymbol{\rho = \frac{ds}{d\psi}}$.

Corollary : The curvature of the curve at any point P is by definition, equal to $\frac{d\psi}{ds}$. Hence *the curvature of the curve at any point is equal to the reciprocal of the radius of curvature at that point i.e., curvature =* $\frac{1}{\rho}$.

Example : *Find the radius of curvature for the curve whose intrinsic equation is*

$$s = a \log \tan \left(\frac{\pi}{4} + \frac{\psi}{2} \right).$$

Solution : We have $\rho = \frac{ds}{d\psi} = a \frac{1}{\tan\left(\frac{\pi}{4} + \frac{\psi}{2}\right)} \sec^2 \left(\frac{\pi}{4} + \frac{\psi}{2} \right) \cdot \frac{1}{2}$

$$= \frac{a}{2 \sin\left(\frac{\pi}{4} + \frac{\psi}{2}\right) \cos\left(\frac{\pi}{4} + \frac{\psi}{2}\right)} = \frac{a}{\sin\left(\frac{\pi}{2} + \psi\right)} = \frac{a}{\cos\psi} = a \sec\psi.$$

5 Cartesian Formula for Radius of Curvature (Gorakhpur 2005)

Let the equation of the curve be $y = f(x)$.

We know that $\frac{dy}{dx} = \tan\psi$.

Differentiating with respect to x, we get

$$\frac{d^2 y}{dx^2} = \sec^2 \psi \cdot \frac{d\psi}{dx} = \sec^2 \psi \frac{d\psi}{ds} \cdot \frac{ds}{dx}.$$

$$\therefore \quad \frac{d\psi}{ds} = \frac{\frac{d^2 y}{dx^2}}{\sec^2 \psi \frac{ds}{dx}}. \qquad \therefore \quad \frac{ds}{d\psi} = \frac{(1 + \tan^2 \psi) \cdot \frac{ds}{dx}}{\frac{d^2 y}{dx^2}}.$$

But we have $\frac{ds}{dx} = \sqrt{\left\{ 1 + \left(\frac{dy}{dx} \right)^2 \right\}}$.

Hence $$\boldsymbol{\rho = \frac{ds}{d\psi} = \frac{\left\{ 1 + \left(\frac{dy}{dx} \right)^2 \right\}^{3/2}}{\frac{d^2 y}{dx^2}} = \frac{(1 + y_1^2)^{3/2}}{y_2}}.$$ **(Bundelkhand 2008)**

Note 1 : The radius of curvature ρ can come out to be positive or negative. If in the relation

$$\frac{ds}{dx}=\sqrt{\left\{1+\left(\frac{dy}{dx}\right)^2\right\}},$$

we take the positive sign before the radical, the value of ρ is positive or negative according as $\frac{d^2y}{dx^2}$ is positive or negative. However, if we define the radius of curvature in such a way that it is to be always positive, then we should ignore the sign whenever we get a negative value for ρ.

Note 2 : Since the radius of curvature is a length therefore its value is independent of the choice of x-axis and y-axis. Hence interchanging x and y, we obtain

$$\rho=\frac{\left\{1+\left(\frac{dx}{dy}\right)^2\right\}^{3/2}}{\frac{d^2x}{dy^2}}.$$

This formula is specially useful when (dy/dx) is infinite *i.e.*, when the tangent is perpendicular to x-axis.

Illustrative Examples

Example 1 : *Find the curvature at the point* $(3a/2, 3a/2)$ *of the curve* $x^3+y^3=3axy.$ **(Meerut 2010; Agra 05; Kumaun 12; Kashi 14; Avadh 14)**

Solution : The curve is $x^3+y^3=3axy.$ ...(1)

Differentiating with respect to x, we get

$$3x^2+3y^2\frac{dy}{dx}=3ay+3ax\frac{dy}{dx}$$

or $$x^2+y^2\frac{dy}{dx}=ay+ax\frac{dy}{dx}. \qquad \ldots(2)$$

$$\therefore \quad \frac{dy}{dx}=\frac{x^2-ay}{ax-y^2}. \qquad \therefore \quad \left[\frac{dy}{dx}\right]_{\left(\frac{3}{2}a,\,\frac{3}{2}a\right)}=-1.$$

Again, differentiating (2), with respect to x, we get

$$2x+2y\left[\frac{dy}{dx}\right]^2+y^2\frac{d^2y}{dx^2}=a\frac{dy}{dx}+a\frac{dy}{dx}+ax\frac{d^2y}{dx^2}$$

or $$(ax-y^2)\frac{d^2y}{dx^2}=2x+2y\left(\frac{dy}{dx}\right)^2-2a\frac{dy}{dx}. \qquad \ldots(3)$$

Putting $x=\frac{3a}{2}, y=\frac{3a}{2}$ and $\left[\frac{dy}{dx}\right]_{(3a/2,\,3a/2)}=-1$ in (3), we get

$$\left[\frac{d^2y}{dx^2}\right]_{(3a/2,\,3a/2)}=-\frac{32}{3}\cdot\frac{1}{a}.$$

Hence the radius of curvature ρ at $\left(\frac{3a}{2},\frac{3a}{2}\right)$

$$= \left[\frac{\left\{1+\left(\frac{dy}{dx}\right)^2\right\}^{3/2}}{\frac{d^2y}{dx^2}}\right]_{(3a/2,\,3a/2)} \qquad = \frac{(1+1)^{3/2}}{-\frac{32}{3}\cdot\frac{1}{a}} = -\frac{3a}{8\sqrt{2}}.$$

$\therefore$ Curvature at $\left(\frac{3a}{2}, \frac{3a}{2}\right) = \frac{1}{\rho} = -\frac{8\sqrt{2}}{3a}$.

If we ignore the negative sign, the value of curvature at $\left(\frac{3a}{2}, \frac{3a}{2}\right) = \frac{8\sqrt{2}}{3a}$.

Example 2 : *If a curve is defined by the equations* $x = f(t)$ *and* $y = \phi(t)$, *prove that the radius of curvature* ρ *is equal to* $\frac{(x'^2 + y'^2)^{3/2}}{x'y'' - y'x''}$, *where accents (i.e., dashes) denote differentiation with respect to t.* **(Kumaun 2007)**

Solution : We have $\frac{dy}{dx} = \frac{dy/dt}{dx/dt} = \frac{\phi'(t)}{f'(t)} = \frac{y'}{x'}$.

Also $\frac{d^2y}{dx^2} = \frac{d}{dx}\left(\frac{y'}{x'}\right) = \left\{\frac{d}{dt}\left(\frac{y'}{x'}\right)\right\}\cdot\frac{dt}{dx}$.

$$= \frac{y''x' - x''y'}{x'^2}\cdot\frac{1}{x'} \qquad \left[\because \frac{dx}{dt} = x' \text{ and } \frac{dt}{dx} = \frac{1}{x'}\right]$$

$$= \frac{y''x' - x''y'}{x'^3}.$$

Hence $\rho = \frac{\left\{1+\left(\frac{dy}{dx}\right)^2\right\}^{3/2}}{\frac{d^2y}{dx^2}} = \frac{\left\{1+\frac{y'^2}{x'^2}\right\}^{3/2}}{\frac{y''x' - x''y'}{x'^3}} = \frac{(x'^2 + y'^2)^{3/2}}{y''x' - x''y'}.$

Example 3 : *In the cycloid* $x = a(t + \sin t)$, $y = a(1 - \cos t)$, *prove that* $\rho = 4a\cos\frac{1}{2}t$. **(Lucknow 2005, 09, 10; Bundelkhand 07, 12, 14; Kumaun 07, 10)**

Solution : Here $\frac{dx}{dt} = a(1 + \cos t)$ and $\frac{dy}{dt} = a\sin t$.

$$\therefore \quad \frac{dy}{dx} = \frac{dy/dt}{dx/dt} = \frac{a\sin t}{a(1+\cos t)} = \frac{2\sin t/2\cos t/2}{2\cos^2 t/2} = \tan\frac{t}{2}.$$

Also $\frac{d^2y}{dx^2} = \frac{d}{dx}\left(\frac{dy}{dx}\right) = \frac{d}{dx}\left(\tan\frac{t}{2}\right) = \frac{1}{2}\cdot\sec^2\frac{t}{2}\cdot\frac{dt}{dx}$

$$= \frac{1}{2}\sec^2\frac{t}{2}\cdot\frac{1}{a(1+\cos t)} = \frac{1}{2}\sec^2\frac{t}{2}\cdot\frac{1}{2a\cos^2 t/2} = \frac{1}{4a}\sec^4\frac{t}{2}.$$

Hence $\rho = \frac{\left\{1+\tan^2\frac{t}{2}\right\}^{3/2}}{\frac{1}{4a}\sec^4\frac{t}{2}} = \frac{4a\sec^3\frac{t}{2}}{\sec^4\frac{t}{2}} = 4a\cos\frac{1}{2}t\cdot$

Example 4 : *If CP, CD be a pair of conjugate semi-diameters of an ellipse, prove that the radius of curvature at P is CD^3/ab, a and b being the lengths of the semi-axes of the ellipse.* **(Meerut 2001, 05B; Rohilkhand 11)**

Solution : (Note. Two perpendicular diameters are called **conjugate diameters**)

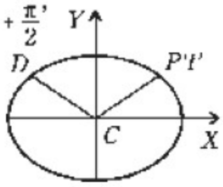
Let CP and CD be a pair of conjugate semi-diameters of the ellipse $\dfrac{x^2}{a^2}+\dfrac{y^2}{b^2}=1$, the centre C is origin.

Let 't' be the eccentric angle of the point P. Then the co-ordinates of P are $x = a\cos t$, $y = b\sin t$.

The eccentric angle of D will be $t+\frac{1}{2}\pi$, so that the co-ordinates of D are

$$\left[a\cos\left(\tfrac{1}{2}\pi+t\right), b\sin\left(\tfrac{1}{2}\pi+t\right)\right] \text{ i.e., } (-a\sin t, b\cos t).$$

Now for the point P we have $x = a\cos t$ and $y = b\sin t$.



$$\therefore \quad \frac{dx}{dt} = -a\sin t,\ \frac{dy}{dt} = b\cos t.$$

$$\text{Hence} \quad \frac{dy}{dx} = -\frac{b}{a}\cot t.$$

$$\text{Also} \quad \frac{d^2y}{dx^2} = \frac{d}{dx}\left(\frac{dy}{dx}\right) = \frac{d}{dx}\left(-\frac{b}{a}\cot t\right)$$

$$= \left\{\frac{d}{dt}\left(-\frac{b}{a}\cot t\right)\right\}\cdot\frac{dt}{dx}$$

$$= \left(\frac{b}{a}\operatorname{cosec}^2 t\right)\cdot\left(-\frac{1}{a}\operatorname{cosec} t\right) = -\frac{b}{a^2}\operatorname{cosec}^3 t\cdot$$

$\therefore$ Radius of curvature of the point 't'

$$= \rho = \frac{\left\{1+\dfrac{b^2\cos^2 t}{a^2\sin^2 t}\right\}^{3/2}}{-\dfrac{b}{a^2}\operatorname{cosec}^3 t} = -\frac{(a^2\sin^2 t+b^2\cos^2 t)^{3/2}}{ab}.$$

Neglecting the negative sign, we have $\rho = \dfrac{(a^2\sin^2 t+b^2\cos^2 t)^{3/2}}{ab}$.

$$\text{Now} \quad CD = \sqrt{\{(-a\sin t-0)^2+(b\cos t-0)^2\}} = (a^2\sin^2 t+b^2\cos^2 t)^{1/2}.$$

$$\therefore \quad \frac{CD^3}{ab} = \frac{(a^2\sin^2 t+b^2\cos^2 t)^{3/2}}{ab} = \rho.$$

Example 5 : *For the curve* $y=\dfrac{ax}{a+x}$, *if* ρ *is the radius of curvature at any point* (x, y), *show that* $(2\rho/a)^{2/3} = (y/x)^2+(x/y)^2$.

(Kumaun 2008, 09; Rohilkhand 10B, 13, 14; Avadh 10, 13)

Solution : We have $y=\dfrac{ax}{a+x}$ ...(1)

$$\therefore \quad \frac{dy}{dx} = a\frac{(a+x)-x}{(a+x)^2} = \frac{a^2}{(a+x)^2} = a^2(a+x)^{-2},$$

and $$\frac{d^2y}{dx^2}=\frac{d}{dx}\left(\frac{dy}{dx}\right)=-2a^2(a+x)^{-3}=\frac{-2a^2}{(a+x)^3}=\frac{-2a^2}{(ax/y)^3}=-\frac{2y^3}{ax^3}.$$

Now $$1+\left(\frac{dy}{dx}\right)^2=1+\frac{a^4}{(a+x)^4}=1+\frac{a^4}{(ax/y)^4}=1+\frac{y^4}{x^4}=\frac{x^4+y^4}{x^4}.$$

$$\therefore \quad \rho=\frac{[1+(dy/dx)^2]^{3/2}}{d^2y/dx^2}=\frac{[(x^4+y^4)/x^4]^{3/2}}{(2y^3/ax^3)},$$

(negative sign being neglected)

$$=\frac{a(x^4+y^4)^{3/2}}{2x^6(y^3/x^3)}=\frac{a}{2}\frac{(x^4+y^4)^{3/2}}{x^3y^3}.$$

Hence $$\left(\frac{2\rho}{a}\right)^{2/3}=\frac{x^4+y^4}{x^2y^2}=\frac{x^4}{x^2y^2}+\frac{y^4}{x^2y^2}=\frac{x^2}{y^2}+\frac{y^2}{x^2}=\left(\frac{x}{y}\right)^2+\left(\frac{y}{x}\right)^2.$$

6 Radius of Curvature at the Origin (Another Method)

Radius of curvature at the origin can be found by substituting $x=0, y=0$ in the value of ρ obtained from the formula of article 5. Here we shall give an alternative method.

Since the curve passes through the origin, therefore $(y)_0=0$ *i.e.*, the value of y at $x=0$ is 0.

Let $$\left(\frac{dy}{dx}\right)_{(0,0)}=(y_1)_0=p \quad \text{and} \quad \left(\frac{d^2y}{dx^2}\right)_{(0,0)}=(y_2)_0=q.$$

Then ρ (at origin) $=\dfrac{(1+p^2)^{3/2}}{q}$. ...(1)

To get the values of p and q, we know by Maclaurin's theorem that

$$y=(y)_0+(y_1)_0x+\frac{(y_2)_0}{2!}x^2+\dots \qquad \dots(2)$$

Since the curve passes through origin, therefore (2) becomes

$$y=px+\tfrac{1}{2}qx^2+\dots\dots$$

Thus to get the values of p and q, we should get from the equation of the curve an expansion for y in ascending powers of x by algebraic or trigonometric methods. The coefficient of x in this expansion will be equal to p and the coefficient of x^2 will be equal to $\frac{1}{2}q$. Putting the values of p and q in (1), we shall get ρ at origin.

7 Newton's Method for Radius of Curvature at the Origin

Suppose a curve passes through the origin and the x-axis is tangent to the curve at origin.

Then $(y)_0=0$ and $\left(\dfrac{dy}{dx}\right)_{(0,0)}$ *i.e,* $(y_1)_0=0$.

Therefore in this case by Maclaurin's expansion, we have

$$y = 0 + 0 . x + \frac{q}{2} . x^2 + \frac{(y_3)_0}{3\,!} x^3 + \ldots \qquad \ldots(1)$$

where $(y_2)_0 = q$.

Multiplying (1) by $\frac{2}{x^2}$, we get $\frac{2y}{x^2} = q + \frac{2}{3!} (y_3)_0 \, x + \ldots \qquad \ldots(2)$

Taking limit as $x \to 0$ of both sides of (2), we get $\lim\limits_{x \to 0} \frac{2y}{x^2} = q$.

Also in this case ρ at origin $= \frac{(1 + 0)^{3/2}}{q} = \frac{1}{q} = \lim\limits_{x \to 0} \frac{x^2}{2y}$.

Therefore *when x-axis is tangent to the curve at the origin,*

$$\rho \text{ (at origin)} = \lim_{x \to 0} \left(\frac{x^2}{2y} \right).$$

Similarly it can be shown that if y-axis is tangent to the curve at the origin, then

$$\rho \text{ (at origin)} = \lim_{x \to 0} \frac{y^2}{2x}.$$

These two formulae are known as **Newton's formulae.**

Illustrative Examples

Example 1 : *Find the radius of curvature at origin for the curve*

$$x^3 + y^3 - 2x^2 + 6y = 0.$$

Solution : The curve passes through origin. Equating to zero the lowest degree terms we get $y = 0$, *i.e.,* x-axis as tangent to the curve at origin

$\therefore$ By Newton's method ρ (at origin) $= \lim\limits_{x \to 0} \frac{x^2}{2y}$.

Dividing by $2y$, the equation of the curve can be written as

$$x \cdot \frac{x^2}{2y} + \frac{1}{2} y^2 - 2 . \frac{x^2}{2y} + 3 = 0.$$

Taking limit as $x \to 0$, $y \to 0$ and $\lim\limits_{x \to 0} \frac{x^2}{2y} = \rho$, we get

$$0\rho + 0 - 2\rho + 3 = 0 \ \ i.e., \ \ \rho = 3/2.$$

Example 2 : *Show that the radii of curvature of the curve* $y^2 = x^2 (a + x)/(a - x)$ *at the origin are* $\pm\, a\sqrt{2}$. **(Gorakhpur 2006; Kumaun 13)**

Solution : The curve passes through the origin and the tangents at origin are $y^2 = x^2$ *i.e.,* $y = \pm\, x$. Thus neither of the coordinate axes is tangent at the origin. Therefore we cannot apply Newton's method. But the equation of the curve can be written as

$$y = \frac{\pm\, x (a + x)^{1/2}}{(a - x)^{1/2}} \quad \text{or} \quad y = \pm\, x \left(1 + \frac{x}{a} \right)^{1/2} \left(1 - \frac{x}{a} \right)^{-1/2}$$

or $$y = \pm\, x \left\{ 1 + \frac{1}{2} \frac{x}{a} + \ldots\ldots \right\} \left\{ 1 + \frac{1}{2} \frac{x}{a} + \ldots\ldots \right\}$$

expanding by Binomial Theorem

or $$y = \pm\, x \left[1 + \frac{x}{a} + \ldots\ldots \right].$$

Comparing this equation with the equation

$$y = px + q\frac{x^2}{2} + \ldots, \text{ we get } p = 1, q = \frac{2}{a} \quad \text{or} \quad p = -1, q = -\frac{2}{a}.$$

But ρ at origin $= \dfrac{(1+p^2)^{3/2}}{q}$.

$\therefore$ When $p = 1, q = \dfrac{2}{a}$, ρ at origin $= \dfrac{(1+1)^{3/2}}{\dfrac{2}{a}} = a\sqrt{2}$.

Also when $p = -1, q = -\dfrac{2}{a}$, ρ at origin $= \dfrac{(1+1)^{3/2}}{-2/a} = -a\sqrt{2}$.

Example 3 : *Find the radii of curvature at the origin for the curve*

$$y^2 - 3xy - 4x^2 + x^3 + x^4 y + y^5 = 0.$$

Solution : The curve passes through the origin and the tangents at origin are $y^2 - 3xy - 4x^2 = 0$. Thus neither of the co-ordinate axes is tangent at the origin. Therefore Newton's method cannot be applied. Also we cannot put the equation of the curve in the form $y = px + \dfrac{qx^2}{2} + \ldots\ldots$

Hence substituting $px + \dfrac{qx^2}{2} + \ldots$ for y in the equation of the curve, we get the identity,

$$\left(px + \frac{qx^2}{2} + \ldots\ldots\right)^2 - 3x\left(px + \frac{qx^2}{2} + \ldots\ldots\right)$$
$$- 4x^2 + x^3 + x^4\left(px + \frac{qx^2}{2} + \ldots\ldots\right) + \ldots = 0.$$

Equating to zero the coefficients of x^2 and x^3, we get

$$p^2 - 3p - 4 = 0 \quad \text{and} \quad pq - \frac{3q}{2} + 1 = 0.$$

Solving these we get $p = 4, -1$.

When $p = 4, q = -2/5$ and when $p = -1, q = 2/5$.

Now ρ (at origin) $= \dfrac{(1+p^2)^{3/2}}{q}$.

$\therefore$ When $p = 4, q = 2/5$, ρ at origin $= \dfrac{(1+16)^{3/2}}{-2/5} = -\dfrac{85\sqrt{17}}{2}$

and when $p = -1, q = 2/5$, ρ at origin $= \dfrac{(1+1)^{3/2}}{2/5} = 5\sqrt{2}$.

Comprehensive Exercise 1

1. Find the radius of curvature at the point (s, ψ) on the following curves :

(i) $s = c \tan \psi$ (Catenary)

(ii) $s = 8a \sin^2 \frac{1}{6}\psi$ (Cardioid)

(iii) $s = 4a \sin \psi$ (Cycloid) **(Bundelkhand 2001; Rohilkhand 08; Kashi 11)**

(iv) $s = c \log \sec \psi$ (Tractrix). **(Kashi 2012)**

2. Find the radius of curvature at the point (x, y) on the following curves :

(i) $a^2 y = x^3 - a^3$ (ii) $y^2 = 4ax$

(iii) $xy = c^2$ (iv) $ay^2 = x^3$

(v) $y = \frac{1}{2} a \left(e^{x/a} + e^{-x/a}\right)$ **(Agra 2007)**

(vi) $y = c \log \sec (x/c)$ **(Kanpur 2007; Purvanchal 09)**

(vii) $x^{1/2} + y^{1/2} = a^{1/2}$.

(viii) $x^{2/3} + y^{2/3} = a^{2/3}$ **(Rohilkhand 2009B; Kashi 12)**

(ix) $x^m + y^m = 1$.

3. (i) Find the radius of curvature of the curve $y = e^x$, at the point where it crosses the y-axis. **(Agra 2014)**

(ii) Find the radius of curvature of the curve $\sqrt{x} + \sqrt{y} = 1$ at the point $\left(\frac{1}{4}, \frac{1}{4}\right)$.

4. (i) Prove that at the point $x = \frac{1}{2}\pi$ of the curve $y = 4 \sin x - \sin 2x$, $\rho = \frac{5\sqrt{5}}{4}$.

(ii) Prove that for the curve $s = a \log \cot \left(\frac{\pi}{4} - \frac{\psi}{2}\right) + a \sin \psi \sec^2 \psi$, $\rho = 2a \sec^3 \psi$;

and hence that $\frac{d^2 y}{dx^2} = \frac{1}{2a}$. **(Lucknow 2008)**

5. In the curve $y = ae^{x/a}$, prove that

$$\rho = a \sec^2 \theta \operatorname{cosec} \theta, \text{ where } \theta = \tan^{-1}(y/a).$$

6. Show that the radius of curvature at a point $(a \cos^3 \theta, a \sin^3 \theta)$ on the curve

$x^{2/3} + y^{2/3} = a^{2/3}$ is $3a \sin \theta \cos \theta$. **(Meerut 2000, 05; Kashi 13)**

7. Prove that for the ellipse $x^2/a^2 + y^2/b^2 = 1$,

$\rho = \frac{a^2 b^2}{p^3}$, p being the perpendicular from the centre upon the tangent at (x, y). **(Meerut 2002, 04B, 07; Avadh 05, 09)**

8. In the ellipse $x^2/a^2 + y^2/b^2 = 1$, show that the radius of curvature at an end of the major axis is equal to the semi-latus rectum of the ellipse.

9. If ρ and ρ' be the radii of curvature at the extremities of two conjugate diameters of an ellipse, prove that $(\rho^{2/3} + \rho'^{2/3})(ab)^{2/3} = a^2 + b^2$.

(Meerut 2001, 03, 04, 06, 11; Bundelkhand 06; Kanpur 11; Lucknow 07; Rohilkhand 13B; Kashi 14)

10. Prove that if ρ be the radius of curvature at any point P on the parabola $y^2 = 4ax$ and S be its focus, then ρ^2 varies as $(SP)^3$.

11. If the co-ordinates of a point on a curve be given by the equations

$$x = c \sin 2\theta (1 + \cos 2\theta), y = c \cos 2\theta (1 - \cos 2\theta),$$

show that the radius of curvature at the point is $4c \cos 3\theta$.

12. If the co-ordinates of a point on a curve be given by the equations

$$x = a \sin t - b \sin (at/b), y = a \cos t - b \cos (at/b),$$

show that the radius of curvature at the point is $\frac{4ab}{a + b} \sin \frac{a - b}{2b} t$.

13. Prove that for the curve $s = ae^{x/a}$, $a\rho = s(s^2 - a^2)^{1/2}$.

Show that for the curve $s^2 = 8ay$, $\rho = 4a\sqrt{\left(1 - \frac{y}{2a}\right)}$. **(Kanpur 2009)**

14. Find the radius of curvature at the origin of the following curves :

(i) $y = x^4 - 4x^3 - 18x^2$. (ii) $y = x^3 + 5x^2 + 6x$.

15. Show that the radii of curvature of the curve $a(y^2 - x^2) = x^3$ at the origin are $\pm 2a\sqrt{2}$.

Answers 1

1. (i) $c \sec^2 \psi$ (ii) $\frac{4}{3} a \sin \frac{1}{3} \psi$ (iii) $4a \cos \psi$ (iv) $c \tan \psi$.

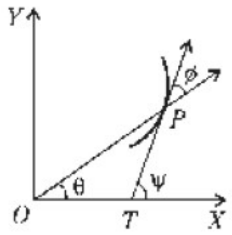
2. (i) $\frac{(a^4 + 9x^4)^{3/2}}{6a^4 x}$ (ii) $\left(\frac{2}{\sqrt{a}}\right)(x + a)^{3/2}$ (iii) $\frac{(x^2 + y^2)^{3/2}}{2c^2}$

(iv) $\frac{1}{6a}(4a + 9x)^{3/2} x^{1/2}$ (v) y^2/a (vi) $c \sec(x/c)$

(vii) $\frac{2(x + y)^{3/2}}{\sqrt{a}}$ (viii) $3a^{1/3} x^{1/3} y^{1/3}$ (ix) $\frac{(x^{2m-2} + y^{2m-2})^{3/2}}{(1 - m)x^{m-2} y^{m-2}}$.

3. (i) $\sqrt{8}$. (ii) $\frac{1}{\sqrt{2}}$. **14.** (i) $1/36$, (ii) $37\sqrt{(37)}/10$.

8 Pedal Formula for Radius of Curvature



We have the relation $\psi = \theta + \phi$, ...(1)

as is obvious from the adjoining figure.

Differentiating (1) w.r.t. s, we get

$$\frac{d\psi}{ds} = \frac{d\theta}{ds} + \frac{d\phi}{ds} \quad \text{or} \quad \frac{d\psi}{ds} = \frac{d\theta}{ds} + \frac{d\phi}{dr} \cdot \frac{dr}{ds}$$

or $$\frac{1}{\rho} = \frac{1}{r} \sin\phi + \cos\phi \frac{d\phi}{dr}$$

$$\left[\because \rho = \frac{ds}{d\psi}, \sin\phi = r\frac{d\theta}{ds} \text{ and } \cos\phi = \frac{dr}{ds}\right]$$

or $$\frac{1}{\rho} = \frac{1}{r}\left(\sin\phi + r\cos\phi \frac{d\phi}{dr}\right) = \frac{1}{r}\frac{d}{dr}(r\sin\phi) = \frac{1}{r}\frac{dp}{dr}. \qquad [\because p = r\sin\phi]$$

Hence $\boldsymbol{\rho = r\frac{dr}{dp}}$. **(Meerut 2003, 07B)**

9 Polar Formula for Radius of Curvature

We know that $\frac{1}{p^2} = \frac{1}{r^2} + \frac{1}{r^4}\left(\frac{dr}{d\theta}\right)^2$. ...(1)

Differentiating (1) with respect to r, we get

$$-\frac{2}{p^3}\frac{dp}{dr} = -\frac{2}{r^3} - \frac{4}{r^5}\left(\frac{dr}{d\theta}\right)^2 + \frac{1}{r^4}\left\{\frac{d}{dr}\left(\frac{dr}{d\theta}\right)^2\right\}$$

$$= -\frac{2}{r^3} - \frac{4}{r^5}\left(\frac{dr}{d\theta}\right)^2 + \frac{1}{r^4}\left\{\frac{d}{d\theta}\left(\frac{dr}{d\theta}\right)^2\right\} \cdot \frac{d\theta}{dr}$$

$$= -\frac{2}{r^3} - \frac{4}{r^5}\left(\frac{dr}{d\theta}\right)^2 + \frac{1}{r^4} \cdot 2\left(\frac{dr}{d\theta}\right) \cdot \frac{d^2 r}{d\theta^2} \cdot \frac{d\theta}{dr}$$

$$= -\frac{2}{r^3} - \frac{4}{r^5}\left(\frac{dr}{d\theta}\right)^2 + \frac{2}{r^4}\frac{d^2 r}{d\theta^2}$$

$$\therefore \qquad \frac{1}{p^3}\frac{dp}{dr} = \frac{1}{r^5}\left\{r^2 + 2\left(\frac{dr}{d\theta}\right)^2 - r\frac{d^2 r}{d\theta^2}\right\}$$

Therefore $$\rho = r\frac{dr}{dp} = \frac{r \cdot \dfrac{1}{p^3}}{\dfrac{1}{r^5}\left\{r^2 + 2\left(\dfrac{dr}{d\theta}\right)^2 - r\dfrac{d^2 r}{d\theta^2}\right\}}.$$

But from (i), $$\frac{1}{p^3} = \left\{\frac{1}{r^2} + \frac{1}{r^4}\left(\frac{dr}{d\theta}\right)^2\right\}^{3/2} = \frac{1}{r^6}\left\{r^2 + \left(\frac{dr}{d\theta}\right)^2\right\}^{3/2}.$$

Hence $$\rho = \frac{r^6 \cdot \dfrac{1}{r^6}\left\{r^2 + \left(\dfrac{dr}{d\theta}\right)^2\right\}^{3/2}}{r^2 + 2\left(\dfrac{dr}{d\theta}\right)^2 - r\dfrac{d^2 r}{d\theta^2}}.$$

Therefore, $$\boldsymbol{\rho = \frac{\left\{r^2 + \left(\dfrac{dr}{d\theta}\right)^2\right\}^{3/2}}{r^2 + 2\left(\dfrac{dr}{d\theta}\right)^2 - r\dfrac{d^2 r}{d\theta^2}}}.$$ **(Kumaun 2011)**

Corollary : If we put $u = \dfrac{1}{r}$ or $r = \dfrac{1}{u}$, then

$$\frac{dr}{d\theta} = -\frac{1}{u^2}\frac{du}{d\theta} \quad \text{and} \quad \frac{d^2 r}{d\theta^2} = \frac{2}{u^3}\left(\frac{du}{d\theta}\right)^2 - \frac{1}{u^2}\frac{d^2 u}{d\theta^2}.$$

Putting these values in the polar formula for ρ, we get

$$\rho = \frac{\left\{\dfrac{1}{u^2} + \dfrac{u'^2}{u^4}\right\}^{3/2}}{\dfrac{1}{u^2} + \dfrac{2u'^2}{u^4} - \dfrac{2u'^2}{u^4} + \dfrac{u''}{u^3}} = \boldsymbol{\frac{(u^2 + u'^2)^{3/2}}{u^3(u + u'')}},$$

where dashes denote differentiation with respect to θ.

Note : We see that the pedal formula for ρ is simpler than the polar formula. Therefore in case the equation of the curve is given in polar form, it is often convenient to change it first to pedal equation and then to find ρ with the help of the pedal formula.

Illustrative Examples

Example 1 : *Show that for the cardioid* $r = a(1 + \cos\theta)$, $\rho = \frac{2}{3}\sqrt{(2ar)}$.

(Purvanchal 2006, 11; Rohilkhand 09B, 10; Agra 14)

Solution : The curve is $r = a(1 + \cos\theta)$.

$$\therefore \qquad \frac{dr}{d\theta} = -a\sin\theta \quad \text{and} \quad \frac{d^2r}{d\theta^2} = -a\cos\theta.$$

$$\text{Now} \quad \rho = \frac{\{r^2 + (dr/d\theta)^2\}^{3/2}}{r^2 + 2(dr/d\theta)^2 - r(d^2r/d\theta^2)}$$

$$= \frac{\{a^2(1 + \cos\theta)^2 + a^2\sin^2\theta\}^{3/2}}{a^2(1 + \cos\theta)^2 + 2(-a\sin\theta)^2 - a(1 + \cos\theta)(-a\cos\theta)}$$

$$= \frac{\left(4a^2\cos^4\frac{1}{2}\theta + 4a^2\cos^2\frac{1}{2}\theta\sin^2\frac{1}{2}\theta\right)^{3/2}}{a^2 + 2a^2(\cos^2\theta + \sin^2\theta) + 3a^2\cos\theta}$$

$$= \frac{(4a^2\cos^2\frac{1}{2}\theta)^{3/2}[\cos^2\frac{1}{2}\theta + \sin^2\frac{1}{2}\theta]^{3/2}}{3a^2(1 + \cos\theta)} = \frac{8a^3\cos^3\frac{1}{2}\theta}{6a^2\cos^2\frac{1}{2}\theta} = \left[\frac{4a}{3}\right]\cos\frac{1}{2}\theta.$$

$$\text{But} \qquad r = a(1 + \cos\theta) = 2a\cos^2\frac{1}{2}\theta.$$

$$\therefore \qquad \cos\frac{1}{2}\theta = \sqrt{(r/2a)}.$$

$$\text{Hence} \quad \rho = \frac{4a}{3}\sqrt{\left[\frac{r}{2a}\right]} = (2/3)\sqrt{(2ar)}.$$

Note : We could have solved this problem more easily by changing the equation of the curve to pedal form.

Example 2 : *Show that in the rectangular hyperbola* $r^2\cos 2\theta = a^2$, $\rho = r^3/a^2$.

Solution : The curve is $r^2\cos 2\theta = a^2$. …(1)

Taking logarithm of both sides of (1), we get $2\log r + \log\cos 2\theta = 2\log a$.

Differentiating with respect to θ, we get

$$\frac{2}{r}\frac{dr}{d\theta} + \frac{1}{\cos 2\theta}(-2\sin 2\theta) = 0$$

$$\text{or} \qquad \frac{1}{r}\frac{dr}{d\theta} = \cot\phi = \tan 2\theta = \cot\left[\frac{\pi}{2} - 2\theta\right].$$

$$\therefore \qquad \phi = \frac{\pi}{2} - 2\theta.$$

$$\text{Now} \quad p = r\sin\phi = r\sin\left[\frac{\pi}{2} - 2\theta\right] = r\cos 2\theta. \qquad \text{But} \ \cos 2\theta = \frac{a^2}{r^2}\cdot$$

Hence the pedal equation of the curve is

$$p = r\,.\,\frac{a^2}{r^2} \quad \text{or} \quad p = \frac{a^2}{r}\cdot$$

$$\therefore \qquad \frac{dp}{dr} = -\frac{a^2}{r^2}\cdot$$

Hence $\rho = r\dfrac{dr}{dp} = -\dfrac{r^3}{a^2}$.

Neglecting the negative sign, we have $\rho = \dfrac{r^3}{a^2}$.

Example 3 : *Find the radius of curvature at the point* (p, r) *on the ellipse*

$$\frac{1}{p^2} = \frac{1}{a^2} + \frac{1}{b^2} - \frac{r^2}{a^2 b^2}.$$

Solution : Differentiating the given equation with respect to r, we get

$$-\frac{2}{p^3}\frac{dp}{dr} = -\frac{2r}{a^2 b^2}. \qquad \therefore \quad \frac{dp}{dr} = \frac{rp^3}{a^2 b^2}.$$

Hence $\rho = r\dfrac{dr}{dp} = r \cdot \dfrac{a^2 b^2}{rp^3} = \dfrac{a^2 b^2}{p^3}$.

10 Tangential Polar Formula for Radius of Curvature

A relation between p and ψ holding for every point of a curve, is called tangential polar equation of the curve. Thus the tangential polar equation of the curve is of the form $p = f(\psi)$.

We have $\dfrac{dp}{d\psi} = \dfrac{dp}{dr} \cdot \dfrac{dr}{ds} \cdot \dfrac{ds}{d\psi} = \dfrac{dp}{dr}\cos\phi \,.\, \rho$

$$= \frac{dp}{dr}\cos\phi \,.\, r\frac{dr}{dp} \qquad \left[\because \frac{dr}{ds} = \cos\phi \text{ and } \rho = \frac{ds}{d\psi} = r\frac{dr}{dp}\right]$$

$= r\cos\phi$.

Also $p = r\sin\phi$.

$$\therefore \quad p^2 + \left(\frac{dp}{d\psi}\right)^2 = r^2(\sin^2\phi + \cos^2\phi) \text{ or } p^2 + \left(\frac{dp}{d\psi}\right)^2 = r^2. \qquad \ldots(1)$$

Differentiating (1) with respect to p, we get

$$2p + 2\left(\frac{dp}{d\psi}\right) \cdot \frac{d^2p}{d\psi^2} \cdot \frac{d\psi}{dp} = 2r\frac{dr}{dp} \qquad \text{or} \qquad r\frac{dr}{dp} = p + \frac{d^2p}{d\psi^2}.$$

Hence $\rho = \boldsymbol{p + \dfrac{d^2 p}{d\psi^2}}$.

Illustrative Examples

Example 1 : *Show that for the epi-cycloid* $p = a\sin b\psi$, ρ *varies as* p.

Solution : We have $\dfrac{dp}{d\psi} = ab\cos b\psi$ and $\dfrac{d^2p}{d\psi^2} = -ab^2\sin b\psi = -b^2 p$.

$$\therefore \quad \rho = p + \frac{d^2p}{d\psi^2} = p - b^2 p = (1 - b^2)\,p.$$

Hence ρ varies as p.

Comprehensive Exercise 2

1. Find the radius of curvature at the point (p, r) on the following curves :

(i) $p^2 = ar$ (parabola). (ii) $2ap^2 = r^3$ (cardioid).

(iii) $a^2 p = r^3$ (Lemniscate). (iv) $p^2 = \dfrac{r^4}{(r^2 + a^2)}$.

2. Prove that for any curve $\dfrac{r}{\rho} = \sin\phi\left(1 + \dfrac{d\phi}{d\theta}\right)$, where ρ is the radius of curvature and $\tan\phi = r\dfrac{d\theta}{dr}$. **(Gorakhpur 2005; Lucknow 10)**

3. In the curve $p = r^{n+1}/a^n$, show that the radius of curvature varies inversely as the $(n-1)^{th}$ power of the radius vector.

4. Find the radius of curvature at the point (r, θ) on each of the following curves :

(i) $r = a\cos\theta$. **(Kanpur 2006)**

(ii) $r(1 + \cos\theta) = 2a$.

(iii) $r^n = a^n \cos n\theta$. **(Rohilkhand 2005; Kumaun 15)**

(iv) $r^n = a^n \sin n\theta$ **(Agra 2006; Rohilkhand 12; Avadh 12)**

(v) $r = a(1 - \cos\theta)$. **(Avadh 2010; Kumaun 14)**

(vi) $r^2 = a^2\cos 2\theta$.

5. Forming the pedal equation of the curve

$$\theta = a^{-1}(r^2 - a^2)^{1/2} - \cos^{-1}\left(\frac{a}{r}\right), \text{ show that } \rho = \sqrt{(r^2 - a^2)}.$$

(Meerut 2006B, 08; Rohilkhand 06; Kashi 11)

6. For the rectangular hyperbola $xy = c^2$, prove that $\rho = \frac{1}{2} r^3/c^2$, r being the central radius vector of the point considered.

7. Show that at any point on the equiangular spiral $r = ae^{\theta\cot\alpha}$, $\rho = r\operatorname{cosec}\alpha$, and that it subtends a right angle at the pole.

8. If ρ_1, ρ_2 be radii of curvature at the extremities of any chord of the cardioid $r = a(1 + \cos\theta)$, which passes through the pole, then show that

$\rho_1{}^2 + \rho_2{}^2 = 16a^2/9$. **(Kanpur 2008)**

9. Show that the radius of curvature at any point on the curve $r = a(1 \pm \cos\theta)$ varies as square root of the radius vector.

10. Find the radius of curvature of the cardioid $r = a(1 - \cos\theta)$ at the pole (origin).

Answers 2

1. (i) $\dfrac{2p^3}{a^2}$ (ii) $\frac{2}{3}\sqrt{(2ar)}$ (iii) $a^2/3r$

(iv) $(r^2 + a^2)^{3/2}/(r^2 + 2a^2)$. **2.** $\dfrac{a^2 b^2}{p^3}$.

4. (i) $a/2$ (ii) $2\sqrt{(r^3/a)}$ (iii) $\dfrac{a^n}{(n+1)\, r^{n-1}}$

(iv) $\dfrac{a^n}{(n+1)\,r^{n-1}}$ (v) $\frac{2}{3}\sqrt{(2ar)}$ (vi) $\dfrac{a^2}{3r}$.

10. 0.

11 Co-ordinates of Centre of Curvature (Meerut 2008)

Let the equation of the curve be $y = f(x)$.

Let P be the given point (x, y) on this curve and Q the point $(x + \delta x, y + \delta y)$ in the neighbourhood of P. (See the fig. of article 11.3). Let N be the point of intersection of the normals at P and Q. As $Q \to P$, suppose $N \to C$. Then C is the centre of curvature of P.

Suppose co-ordinates of C are (α, β).

From the equation of the curve, we have $\dfrac{dy}{dx} = f'(x) = \phi(x)$, say.

The equation of normal at P is

$$(Y - y)\,\phi(x) + (X - x) = 0. \qquad \text{...(1)}$$

The equation of normal at Q is

$$\{Y - (y + \delta y)\}\,\phi(x + \delta x) + \{X - (x + \delta x)\} = 0. \qquad \text{...(2)}$$

Subtracting (1) from (2), we get

$$(Y - y)\,\{\phi(x + \delta x) - \phi(x)\} - \phi(x + \delta x)\,\delta y - \delta x = 0.$$

Dividing by δx, we get

$$(Y - y)\left\{\frac{\phi(x + \delta x) - \phi(x)}{\delta x}\right\} - \phi(x + \delta x)\,\frac{\delta y}{\delta x} - 1 = 0. \qquad \text{...(3)}$$

The value of Y obtained from this equation will give us the y co-ordinate of the point of intersection of (1) and (2).

Now as $Q \to P$, $\delta x \to 0$ and Y obtained from (3)$\to \beta$.

Therefore taking limit of (3) as $\delta x \to 0$, we get

$$(\beta - y)\lim_{\delta x \to 0}\left\{\frac{\phi(x + \delta x) - \phi(x)}{\delta x}\right\} - \lim_{\delta x \to 0}\phi(x + \delta x)\,.\,\lim_{\delta x \to 0}\frac{\delta y}{\delta x} - 1 = 0$$

or $$(\beta - y)\,\frac{d}{dx}\,\phi(x) - \phi(x)\cdot\frac{dy}{dx} - 1 = 0$$

or $$(\beta - y)\,\frac{d}{dx}\left(\frac{dy}{dx}\right) - \frac{dy}{dx}\cdot\frac{dy}{dx} - 1 = 0. \qquad \left[\because\ \phi(x) = \frac{dy}{dx}\right]$$

or $$(\beta - y)\,\frac{d^2 y}{dx^2} - \left\{\left(\frac{dy}{dx}\right)^2 + 1\right\} = 0.$$

$$\therefore \qquad \boldsymbol{\beta = y + \frac{1 + \left(\dfrac{dy}{dx}\right)^2}{\dfrac{d^2 y}{dx^2}}}.$$

Also (α, β) lies on (1). Therefore, we get

$$(\beta - y)\frac{dy}{dx} + (\alpha - x) = 0$$

i.e.,
$$(\alpha - x) = -(\beta - y)\frac{dy}{dx} = -\frac{dy}{dx}\frac{1 + \left(\frac{dy}{dx}\right)^2}{\frac{d^2y}{dx^2}}.$$

$$\therefore \qquad \boldsymbol{\alpha = x - \frac{\frac{dy}{dx}\left\{1 + \left(\frac{dy}{dx}\right)^2\right\}}{\frac{d^2y}{dx^2}}}.$$

12 Evolute of a Curve

The locus of the centre of curvature of a curve is called its evolute.

13 Equation of the Circle of Curvature

If (α, β) be the co-ordinates of the centre of curvature and ρ the radius of curvature at any point (x, y) on a curve, then the equation of the circle of curvature at that point is $(X - \alpha)^2 + (Y - \beta)^2 = \rho^2$.

Illustrative Examples

Example 1 : *Find the co-ordinates of the centre of curvature for the point* (x, y) *on the parabola* $y^2 = 4ax$. **(Lucknow 2008)**

Also find the equation of the evolute of the parabola.

Solution : Here $2y\frac{dy}{dx} = 4a$, *i.e.,* $\frac{dy}{dx} = \frac{2a}{y} = a^{1/2}x^{-1/2} = \sqrt{\left(\frac{a}{x}\right)}$.

$$\therefore \qquad \frac{d^2y}{dx^2} = -\frac{1}{2}a^{1/2}x^{-3/2}.$$

If (α, β) be the centre of curvature for the point (x, y), then

$$\alpha = x - \frac{\frac{dy}{dx}\left\{1 + \left(\frac{dy}{dx}\right)^2\right\}}{\frac{d^2y}{dx^2}} = x - \frac{\sqrt{\left(\frac{a}{x}\right)}\left\{1 + \frac{a}{x}\right\}}{-\frac{1}{2}\frac{1}{x}\sqrt{\left(\frac{a}{x}\right)}} = x + 2x(1 + a/x)\cdot$$

$$\therefore \qquad \alpha = 3x + 2a, \qquad \text{...(1)}$$

and
$$\beta = y + \frac{1 + \left(\frac{dy}{dx}\right)^2}{\frac{d^2y}{dx^2}} = y + \frac{1 + \left(\frac{a}{x}\right)}{-\frac{1}{2}\frac{1}{x}\sqrt{\left(\frac{a}{x}\right)}}$$

$$= 2a^{1/2}x^{1/2} - 2a^{-1/2}x^{3/2}(1 + a/x)$$
$$= 2a^{1/2}x^{1/2} - 2a^{-1/2}x^{3/2} - 2a^{1/2}x^{1/2}$$

$$\therefore \qquad \beta = -2x\sqrt{\left(\frac{x}{a}\right)}. \qquad \ldots(2)$$

Therefore the required centre of curvature is $\left((3x + 2a), -2x\sqrt{\left(\frac{x}{a}\right)}\right)$.

Evolute of the parabola : Let us eliminate x between (1) and (2). From (2), we get

$$\beta^2 = \frac{4x^3}{a} \quad \text{or} \quad x^3 = \frac{a\beta^2}{4}.$$

From (i), we get $x = \dfrac{\alpha - 2a}{3}$.

$$\therefore \qquad \left(\frac{\alpha - 2a}{3}\right)^3 = \frac{a\beta^2}{4} \quad \text{or} \quad 27\,a\beta^2 = 4(\alpha - 2a)^3.$$

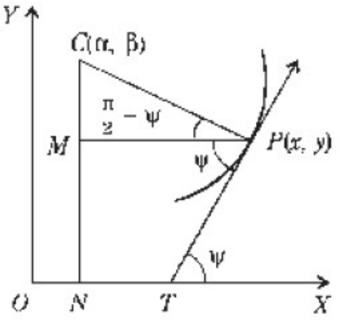
Hence the locus of (α, β) is $27\,ay^2 = 4(x - 2a)^3$, which is the evolute of parabola.

Example 2 : *Prove that the co-ordinates* (α, β) *of the centre of curvature at any point* (x, y) *can be expressed in the form*

$$\alpha = x - \frac{dy}{d\psi} \text{ and } \beta = y + \frac{dx}{d\psi}.$$

Solution : Let $C(\alpha, \beta)$ be the centre of curvature of the point $P(x, y)$ on the curve $y = f(x)$. The line TP is tangent to the curve at P and obviously PC is normal at P to the curve, since the centre of curvature is a point on the normal.

ρ = radius of curvature at $P = PC$ and CN is the ordinate of C. Draw PM perpendicular to CN. Obviously



$$\angle CPM = \tfrac{1}{2}\pi - \psi.$$

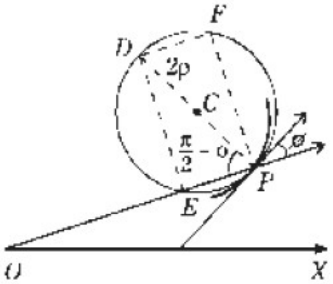
$$\text{Then} \qquad \alpha = x - PM = x - \rho\sin\psi$$
$$= x - \frac{dy}{ds}\cdot\frac{ds}{d\psi} \qquad \left[\because\ \rho = \frac{ds}{d\psi} \text{ and } \frac{dy}{ds} = \sin\psi\right]$$
$$= x - \frac{dy}{d\psi}.$$

$$\text{Also} \qquad \beta = y + CM = y + \rho\cos\psi$$
$$= y + \frac{dx}{ds}\cdot\frac{ds}{d\psi} \qquad \left[\because\ \cos\psi = \frac{dx}{ds}\right]$$
$$= y + \frac{dx}{d\psi}.$$

14 Chord of Curvature through the Origin (Pole)

Let C be the centre of curvature at the point P on any given curve.

Then $CP = \rho$ = radius of curvature at P. O is the pole. Join OP to meet the circle of curvature in E. Then PE is the chord of curvature through the origin.



PD is the diameter of the circle of curvature. We have $PD = 2\rho$

and $\angle PED = 90^{\circ}$, being an angle in a semi-circle.

Also *PD* is normal to the curve at *P*.

$\therefore \quad \angle EPD = \frac{1}{2}\pi - \phi.$

Hence from the right-angled triangle *PED*, we have

$$PE = PD \cos\left(\frac{1}{2}\pi - \phi\right) = 2\rho \sin \phi.$$

$\therefore$ *chord of curvature through pole* = $\mathbf{2\rho \sin \phi}$.

Corollary : Chord of curvature perpendicular to the Radius Vector :

Suppose a line through *P*, perpendicular to the radius vector *OP*, meets the circle of curvature in *F*.

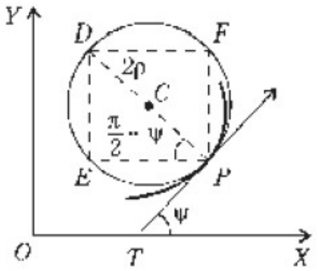
Then *PF* is the chord of curvature perpendicular to the radius vector.

We have $PF = ED = 2\rho \sin\left(\frac{1}{2}\pi - \phi\right) = 2\rho \cos \phi.$

$\therefore$ *Chord of curvature perpendicular to the radius vector* = $2\rho\,\mathbf{\cos}\,\phi$.

15 Chord of Curvature Parallel to the Axes

(i) Chord of Curvature Parallel to the *x*-axis :



Let *C* be the centre of curvature at the point *P* on any given curve. Suppose a line through *P*, drawn parallel to the axis of *x*, meets the circle of curvature in *E*. Then *PE* is the chord of curvature parallel to *x*-axis.

PD is the diameter of the circle of curvature. We have $PC = 2\rho$ and $\angle PED = 90^{\circ}$.

Obviously $\angle EPD = \frac{1}{2}\pi - \psi.$

Hence from the right angled triangle *PED*, we have

$$PE = 2\rho \cos\left(\frac{1}{2}\pi - \psi\right) = 2\rho \sin \psi.$$

$\therefore$ *Chord of curvature parallel to x-axis* = $\mathbf{2\rho \sin \psi}$.

(ii) Chord of Curvature Parallel to *y*-axis :

Draw a line through *P*, parallel to *y*-axis, to meet the circle of curvature in *F*.

Then PF = chord of curvature parallel to *y*-axis

$$= ED = 2\rho \sin\left(\frac{\pi}{2} - \psi\right) = \mathbf{2\rho \cos \psi}.$$

Illustrative Examples

Example 1 : *Show that the chord of curvature through the pole of the curve* $r^n = a^n \cos n\theta$ *is* $2r/(n+1)$. **(Lucknow 2005; Purvanchal 14)**

Solution : The curve is $r^n = a^n \cos n\theta$. ...(1)

Taking logarithm of both sides, we get $n \log r = n \log a + \log \cos n\theta$.

Differentiating with respect to θ, we get $\frac{n}{r}\frac{dr}{d\theta} = -\frac{n}{\cos n\theta}\sin n\,\theta$

i.e., $$\cot\phi = -\tan n\,\theta = \cot\left(\tfrac{1}{2}\pi + n\,\theta\right)\cdot$$

$$\therefore \quad \phi = \tfrac{1}{2}\pi + n\,\theta.$$

Now $p = r\sin\phi = r\sin\left(\frac{1}{2}\pi + n\,\theta\right) = r\cos n\,\theta.$

Therefore the pedal equation of the given curve is $p = r^{n+1}/a^n$.

$$\therefore \quad \frac{dp}{dr} = \frac{(n+1)\,r^n}{a^n}.$$

Also $$\rho = r\frac{dr}{dp} = \frac{a^n}{(n+1)\,r^{n-1}}.$$

Hence the chord of curvature through the pole

$$= 2\rho\sin\phi = 2\rho\sin\left(\frac{1}{2}\pi + n\,\theta\right) = 2\rho\cos n\,\theta$$

$$= 2\cdot\frac{a^n}{(n+1)\,r^{n-1}}\cdot\frac{r^n}{a^n} = \frac{2r}{(n+1)}\cdot$$

Example 2 : *In the curve $y = a\log\sec(x/a)$, prove that the chord of curvature parallel to the axis of y is of constant length.* **(Rohilkhand 2009; Lucknow 11)**

Solution : Differentiating the equation of the curve with respect to x, we get

$$\frac{dy}{dx} = a\,.\,\frac{1}{\sec(x/a)}\,.\,\sec(x/a)\tan(x/a)\,(1/a) = \tan(x/a).$$

$$\therefore \quad \frac{d^2y}{dx^2} = (1/a)\sec^2(x/a).$$

Chord of curvature parallel to y-axis

$$= 2\rho\cos\psi = \frac{2\rho}{\sec\psi} = \frac{2\rho}{\sqrt{\left\{1 + \left(\frac{dy}{dx}\right)^2\right\}}}$$

$$= 2\cdot\frac{\left\{1 + \left(\frac{dy}{dx}\right)^2\right\}^{3/2}}{\frac{d^2y}{dx^2}}\cdot\frac{1}{\sqrt{\left\{1 + \left(\frac{dy}{dx}\right)^2\right\}}}$$

$$= 2\cdot\frac{\left\{1 + \left(\frac{dy}{dx}\right)^2\right\}}{\frac{d^2y}{dx^2}}$$

$$= 2\cdot\frac{\left(1 + \tan^2\frac{x}{a}\right)}{\frac{1}{a}\sec^2\left(\frac{x}{a}\right)} = 2a, \text{ which is constant.}$$

Comprehensive Exercise 3

1. In the parabola $x^2 = 4ay$, prove that the co-ordinates of the centre of curvature are $\left(-\dfrac{x^3}{4a^2}, 2a + \dfrac{3x^2}{4a}\right)$.

2. In the catenary $y = c \cosh(x/c)$, show that the centre of curvature (α, β) is given by $\alpha = x - y\{(y^2/c^2) - 1)\}^{1/2}, \beta = 2y$.

3. For the curve $a^2 y = x^3$, show that the centre of curvature (α, β) is given by

$$\alpha = \frac{x}{2}\left\{1 - \frac{9x^4}{a^4}\right\}, \quad \beta = \frac{5x^3}{2a^2} + \frac{a^2}{6x}.$$

4. Show that the centre of curvature (α, β) at the point determined by t on the ellipse $x = a\cos t, y = b \sin t$, is given by $\alpha = \dfrac{a^2 - b^2}{a}\cos^3 t, \beta = -\dfrac{a^2 - b^2}{b}\sin^3 t$.

(Lucknow 2007, 10)

Also show that the evolute of the ellipse is $(ax)^{2/3} + (by)^{2/3} = (a^2 - b^2)^{2/3}$.

5. Prove that the centre of curvature (α, β) for the curve $x = 3t, y = t^2 - 6$ is $\alpha = -\frac{4}{3}t^3, \beta = 3t^2 - \frac{3}{2}$.

6. Show that in any curve the chord of curvature perpendicular to the radius vector is $2\rho\sqrt{(r^2 - p^2)}/r$.

7. Show that the chord of curvature through the pole of the equiangular spiral $r = ae^{m\theta}$ is $2r$.

8. Show that the chord of curvature, through the pole, for the cardioid

$$r = a(1 + \cos\theta) \text{ is } \frac{4}{3}r.$$

9. Show that the circle of curvature at the point $(am^2, 2am)$ of the parabola $y^2 = 4ax$ has for its equation

$$x^2 + y^2 - 6am^2 x - 4ax + 4am^3 y - 3a^2 m^4 = 0.$$

10. If C_x and C_y be the chords of curvature parallel to the axes at any point of the curve $y = ae^{x/a}$, prove that $\dfrac{1}{C_x^{\,2}} + \dfrac{1}{C_y^{\,2}} = \dfrac{1}{2aC_x}$.

(Agra 2007; Rohilkhand 07; Purvanchal 07)

Objective Type Questions

Fill in the Blanks:

Fill in the blanks "…… ", so that the following statements are complete and correct.

1. The relation between s and ψ for any curve is called its …… equation.

2. By definition the curvature of the curve at any point P is equal to …… .

3. For a curve $y = f(x)$, we have $\rho =$ …… .

4. Intrinsic formula for the radius of curvature is …… .

5. The radius of curvature at any point of the cycloid

$x = a(t + \sin t), y = a(1 - \cos t)$ is …… .

6. For a curve defined by the equations $x = f(t)$ and $y = \phi(t)$ the radius of curvature is …… .

Multiple Choice Questions:

Indicate the correct answer for each question by writing the corresponding letter from (a), (b), (c) *and* (d).

7. If y-axis is the tangent to the given curve at the origin, then radius of curvature at the origin is equal to

(a) $\lim\limits_{x \to 0} \dfrac{x^2}{2y}$ (b) $\lim\limits_{x \to 0} \dfrac{y^2}{2x}$ (c) $\lim\limits_{x \to 0} \dfrac{x^2}{y}$ (d) $\lim\limits_{x \to 0} \dfrac{y^2}{x}$

(Kumaun 2013)

8. Pedal formula for radius of curvature is

(a) $\dfrac{1}{r}\dfrac{dr}{dp}$ (b) $r\dfrac{dr}{dp}$ (c) $\dfrac{1}{r}\dfrac{dp}{dr}$ (d) $r\dfrac{dp}{dr}$

9. Chord of curvature parallel to y-axis is

(a) $2\rho \sin \phi$ (b) $2\rho \cos \phi$ (c) $2\rho \sin \psi$ (d) $2\rho \cos \psi$

10. Radius of curvature of the curve $p^2 = ar$ is :

(a) p^2/a^2 (b) $2p/a^2$ (c) $2p^3/a^3$ (d) $p^3/2a^2$

(Kumaun 2015)

True or False:

Write 'T' for true and 'F' for false statement.

11. There is no difference between curvature of the circle and circle of curvature. **(Meerut 2003)**

12. The curvature of the curve at any point is equal to the reciprocal of the radius of curvature at that point.

13. The polar formula for radius of curvature is : $\rho = \dfrac{\left\{r^2 + \left(\dfrac{dr}{d\theta}\right)^2\right\}^{3/2}}{r^2 + 2\left(\dfrac{dr}{d\theta}\right)^2 - r\dfrac{d^2 r}{d\theta^2}}.$

14. The tangential polar formula for radius of curvature is $\rho = p + \dfrac{d^2 p}{d\psi^2}.$

15. Pedal formula for radius of curvature is $\rho = r\dfrac{dr}{dp}.$ **(Agra 2006)**

Answers

1. intrinsic. **2.** $\dfrac{d\psi}{ds}.$ **3.** $\dfrac{\left[1 + \left(\dfrac{dy}{dx}\right)^2\right]^{3/2}}{\dfrac{d^2 y}{dx^2}}.$ **4.** $\dfrac{ds}{d\psi}.$

5. $4a \cos \frac{1}{2} t.$ **6.** $\dfrac{(x'^2 + y'^2)^{3/2}}{x'y'' - y'x''}$, where $x'y'' - y'x'' \neq 0$.

Geometry Background

"Let no one ignorant of Geometry enter" — At entrance to Plato's Academy

2.1 Preliminaries

2.1.1 In the Beginning ...

The Nile's flooding in Egypt used to destroy landmarks and position markers, raising the need for reliable measurements and originating the development of geometry *Geo*-$\Gamma\epsilon\omega$ (for land) *metry* (for measure-$\mu\epsilon\tau\rho\iota\alpha$).[10] The Rhind Papyrus, which is in the British Museum, was written by an Egyptian priest named Ahmes about 1,800 B.C.E. It treats the measurement of planar regions and solids. It contains the remarkable approximation of $\pi \approx (\frac{16}{9})^2 = 3.1604$. The contemporary Babylonians, as well as Chinese, used 3 for the value of π. The value of 3 for π is also mentioned in the Hebrew scriptures (see I Kings 7:23). A rabbi called Nehemia (p. 5 [74]) proposed the value of $\frac{22}{7}$ for π, but apparently it was not accepted. By the way, only in 1789 was it first proved by J. Lambert that π is an irrational number and in 1882, F. Lindemann proved that π is transcendental (i.e., it is not the root of any algebraic equation with rational coefficients). For more enjoyable folklore on π the reader is referred to [12].

It is fair to consider the Egyptians more as surveyors, who used a collection of geometrical formulas, mostly approximations, rather than geometers. For proper attribution, *deductive* geometry was accomplished by the Greeks, probably beginning with Thales of Miletus ($\approx$ 640–545 B.C.E.), who was familiar with Egyptian

---

[10] This story was reported by Proclus in the fifth century C.E., who wrote the early history of geometry.

A. Inselberg, *Parallel Coordinates*, DOI 10.1007/978-0-387-68628-8_2,
© Springer Science+Business Media, LLC 2009

and Babylonian mathematics. Pythagoras, Hippocrates (not the physician of the same name), Menaechmus, Archimedes, Apollonius, Plato, Archytas, Eudoxus and Theaetetus continued the development until it was codified by Euclid in his *Elements* $\Sigma\tau o\iota\chi\epsilon\iota\alpha$ ($\approx$ 300 B.C.E.). Entirely novel, and characteristic of Greek mathematics, is the *axiomatic method* whereby theorems are established by proof. Particularly relevant to computer science are the *constructions* of Euclidean geometry. They consist of a finite set of well-defined operations and provide an unambiguous procedure that terminates for all inputs! Truly the first *algorithms ... and with proofs*. The constructions of Euclidean geometry involved ruler and compass. A remarkable discovery was made in 1672 by the Danish geometer G. Mohr (1640–1697) and independently in 1797 by the Italian L. Mascheroni (1750–1800).[11] They showed that *all* of these constructions can be accomplished by *compass alone!* [38]. The proofs were, in the true spirit of computer science, by simulation. It was demonstrated that any operation involving a ruler can be replaced by a finite number of compass operations; a real equivalence proof like those in automata theory. Alternatively, J. Steiner and J.V. Poncelet showed that all constructions in Euclidean geometry can be accomplished with a straightedge when in addition, a single circle and its center are also given. Continuing in this vein, it is natural to ask what is left if the compass is discarded and only the ruler is left. What remains is *projective geometry*, an elegant branch of geometry simpler than Euclid's but rich and interesting in its own right. It deals with points, lines, planes, and spaces where distance between two points or angles between two lines are *not* measured and there are *no parallel lines* in the plane! For a modern treatment of projective geometry see [154].

Exercises

1. To get a feel for the Mohr–Mascheroni result, using compass *only* write (and prove) an algorithm for:
    (a) constructing 3 collinear points,
    (b) given a segment $\overline{OA}$ construct a point B such that $\overline{OB}$ is twice as long as $\overline{OA}$,
    (c) bisecting a segment,
    (d) trisecting a segment,
    (e) given a circle C and two points determining a line l, construct the point of intersection $C \cap l$ (be careful here, the line l is *not given*, but only two points on the line l are. This is what makes the problem *hard*).
    (f) constructing the point of intersection between two lines (*hard*).

---

[11] For a short exposition on the *geometry of compasses* see [145, (pp. 23–25)] and [36, (pp. 145–151)], quoted in [38].

2. Given an angle A, provide a construction for finding an angle = 1/2 A using the Steiner–Poncelet constraint, i.e., with a straightedge, a single circle, and its center.

   To recall and rejuvenate some Euclidean geometry skills try some of the following[12]:

3. Provide a Euclidean geometry construction (i.e., using circle and ruler only) that transforms a rectangle into a square of equal area.
4. One of the three famous unsolvable problems in Euclidean geometry is "squaring the circle." Given a square with area **A** construct, using ruler and compass only, a square having area **2A**. What other shapes can this be generalized to?
5. Prove that a triangle ABC is isosceles if the bisectors AD and BE of the two angles A and B are equal. Here D and E are the points of intersection of the angle bisectors with the sides BC and AC respectively. This is a deceptively *hard* problem.

2.2 ♣ *FT-1* Why Projective Geometry?

We begin the formal aspects with an excursion into projective geometry, but why? There are two important concepts and tools that we will need and that are also widely used in many other fields and applications. They are:

- *duality* and
- *homogeneous coordinates* (see [146] for applications of homogeneous coordinates to computer graphics).

Both of these are projective concepts and can be properly understood only in this context. The experience is quite broadening and will get us "unglued" from the narrow mindset of Euclidean geometry. For example, entirely new notions, such as finite geometries, arise naturally. Projective geometry was initially motivated by the fine arts. The Italian architect Brunelleschi in 1425 first proposed a geometrical theory of perspective that was formalized by Alberti a few years later. It included the idea of "points at infinity" and influenced art in a profound way, as shown by contrasting prior "flat" paintings such as Martini's *Annunciation* with those where "depth" is perceived, such as Leonardo's *Last Supper* and Raphael's *Athens*, shown in the chapter on projective geometry by Morris Kline [140, vol. **1**, 622–641]. In the absence of photography, realism in drawings had not only artistic but also great practical value.

---

[12] See also the delightful short paper by Hudson [90].

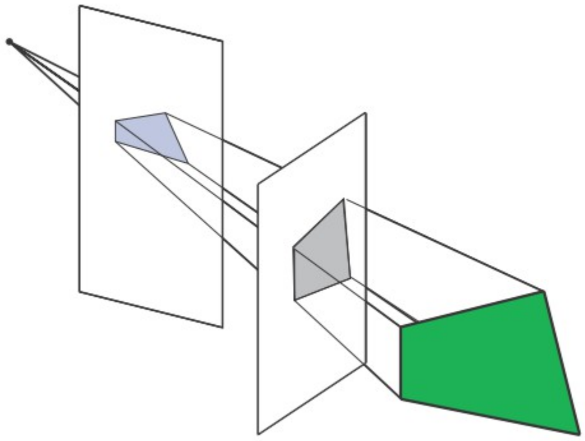

Figure 2.1. Projections and Sections.

2.2.1 Projective Plane Model

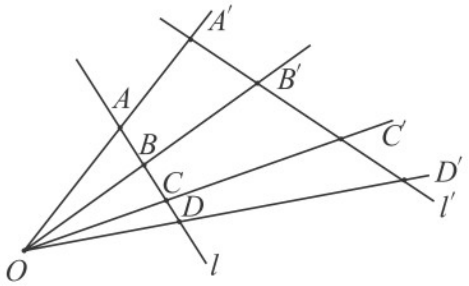

Figure 2.2. Points and lines in Perspective.

Projective geometry deals with properties that are invariant under projections and sections, see Fig. 2.1, such as "incidence" and "collinearity." A beautiful projective theorem, discovered by the French architect Desargue in 1640, states that two triangles, ABC and $A'B'C'$, are in perspective from a point O if and only if they are in perspective from a line *TSR*; see Fig. 2.4 (left) in the Euclidean plane and Fig. 2.4 (right), where O is a "point at infinity" in the vertical direction. Note the role of *duality* in the interchange between the words *point* and *line*. Of course, we have not explained what is meant by "perspective"; see Fig. 2.2 for an indication, but we are on the way.

It will help our intuition to have a model for visualizing the projective space, and only afterward do we present the more formal axiomatic treatment. Our "building blocks," otherwise called *primitives*, are concepts and objects with which we are already familiar. The notation commonly used in geometry appears in the list below; points and lines are denoted by capital and lowercase Latin letters (preferably in *italics*) respectively, while planes are denoted by lowercase Greek letters.

Primitives

- *points* - P, Q, A
- *lines* - ℓ, *r*, *s*
- *planes* - π, α, β
- *incidence* relation - P is *incident* to ℓ, or P is *on* ℓ.

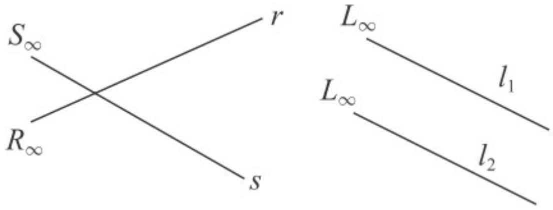

Figure 2.3. Ideal points and augmented lines.

Of course, incidence and containment are not equivalent, since P is *incident* to ℓ if and only if ℓ is *incident* to P; $P \in \ell$ is true and $\ell \in P$ is not.

We start with the Euclidean space $\mathbb{R}^3$ and add something new. Let $\pi \subset \mathbb{R}^3$ be a plane. To each line $\ell \subset \pi$ we associate an *ideal point* ("point at infinity") L_∞ such that distinct intersecting lines have distinct ideal points while parallel lines have the *same* ideal point. Effectively, then, ideal points signify direction. Since no

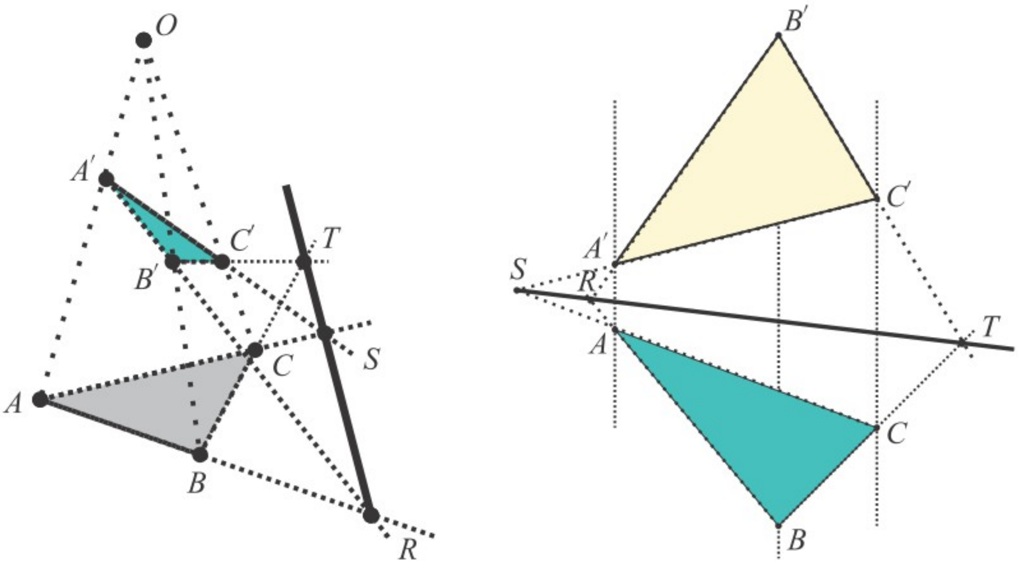

Figure 2.4. Desargue's theorem. The three points T, S, R, $T = B'C' \cap BC$, $S = A'C' \cap AC$, $R = A'B' \cap AB$, are always collinear for when the triangles are in perspective with respect to an ordinary point (left) or an ideal point ("point at infinity") (right).

distinction is made between the "+" and "−" directions for each line ℓ, one and not two L_∞ need to be appended.

On occasion, the notation P_m^∞ is used for ideal points, with m being the slope of the corresponding direction. The points of $\mathbb{R}^3$ are called *regular* to distinguish them from the "*ideal*" ones. Proceeding, we call the pair (ℓ, L_∞) an *augmented line*. Then for $r, s \subset \pi$,

$$(r, R_\infty) \cap (s, S_\infty) = \begin{cases} P \text{ ordinary point} & \Longleftrightarrow \text{r not} \parallel \text{s}, \\ R_\infty & \Longleftrightarrow \text{r} \parallel \text{s}. \end{cases}$$

For a given plane $\pi \subset \mathbb{R}^3$, let $p_\infty = \{L_\infty | \ell \subset \pi, (\ell, L_\infty)\}$ be the collection of all ideal points (directions) on π. We will see that p_∞ satisfies the axioms for a line, and for this reason it is called an *ideal line*. The pair (π, p_∞) is called an *augmented plane* for, as will be seen, it satisfies the axioms for a plane. Proceeding, the ideal lines for each plane $\pi \subset \mathbb{R}^3$ are collected and denoted by $\pi_\infty = \{p_\infty | \pi \subset \mathbb{R}^3, (\pi, p_\infty)\}$; we refer to π_∞ as the *ideal plane* and the pair $(\mathbb{R}^3, \pi_\infty)$ as the *augmented space*. All in all, then, "points" are either ordinary or ideal, "lines" are either augmented or ideal, and "planes" are either augmented planes or the ideal plane.

Hilbert [85] proposed an elegant model of the projective plane whose construction (actually a modified version) is shown in Fig. 2.6. A hemisphere S together with the disk D capping it is placed in a Euclidean plane π, with its south pole tangent to the origin. A *stereographic* projection is established such that a point $P \in \pi$ is connected to the center C of S. The point $P' = CP \cap S$ is the image of P. All points of π (i.e., "ordinary points") are mapped uniquely onto the surface points of S. As the point $P = (a_1, a_2)$ goes farther and farther away from the origin in the constant direction having slope $m = a_2/a_1$, it approaches the ideal point[13] P_m^∞. Then the line CP approaches the line parallel to π that includes the diameter d_m of the disk D having slope m. This establishes a one-to-one correspondence $d_m \longleftrightarrow P_m^\infty$. The points on the hemisphere's surface are the images of the ordinary points, while the diameters of D are the images of the ideal points providing the image of all of $\mathbb{P}^2$ as described above.[14] It is a very helpful visual model. For example, a line $\ell \subset \pi$ is mapped into a great semicircle (see exercise below), and the augmented line $(l, \mathbb{P}_m^\infty)$ includes the diameter d_m. Parallel augmented lines, as shown in Fig. 2.7, "intersect" at their common ideal point. Two points on a projective line specify *two*

---

[13] The subscript m, in the notation of an ideal point, indicates the corresponding direction, and it is included only when the direction is relevant.

[14] We use homogeneous coordinates only with real values so there is no need to use $\mathbb{RP}^2$ as seen elsewhere, the $\mathbb{R}$ distinguishing the *real* projective plane from others.

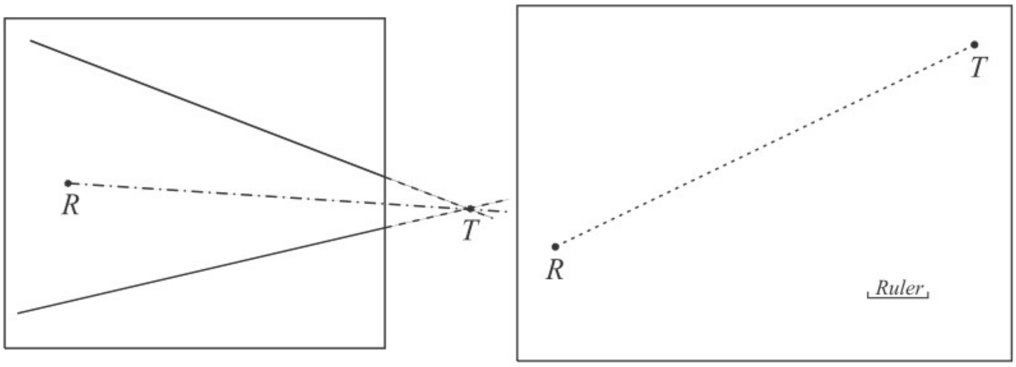

Figure 2.5. On the left, figure for Exercise 4; and on the right, figure for Exercise 5.

intervals; one containing the ideal point and its complement being the "ordinary" interval of the Euclidean line.

A very basic though often unfamiliar property of $\mathbb{P}^2$ is that it is not *orientable*. That is, it is not possible to assign a consistent sense of left and right ([18] p. 372). This matter arises in various topics in our development, and we shall learn how to cope with it when the need arises.

Exercises

1. Show that lines are mapped into great semicircles by stereographic projection.
2. Show that stereographic projection preserves angles (i.e., is isogonal)
3. How are circles mapped by stereographic projection?
4. On a piece of paper, as shown in Fig. 2.5 (left), there is a point R and portions of two lines intersecting at some point T outside the paper. Using only a straightedge (ruler), draw the line joining the points R and T (Hint: Use Desargues's theorem). From [13, vol. I, p. 119].
5. Given two points R and T and a short ruler, as shown in Fig. 2.5 (right), not long enough to reach both points, draw the line joining R and T (Hints: Use the result of the previous exercise and slide the ruler along a line segment.) From [13, vol. I, p. 119].

2.2.2 Axioms for Projective Geometry

The time has come to describe projective 3-space more formally in terms of the axioms, i.e., the properties of the primitives: points, lines, planes, and the *incidence* (or "*on*") relation.

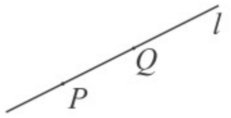
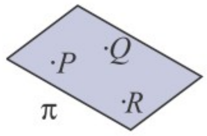
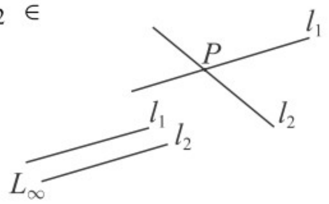
Axioms for 2-D and 3-D



1. (2-D) Two distinct points are *on* (or incident to) a unique line. That is, if $P \neq Q$ then $P, Q \in \ell_1$ and $P, Q \in \ell_2 \Rightarrow \ell_1 = \ell_2$.

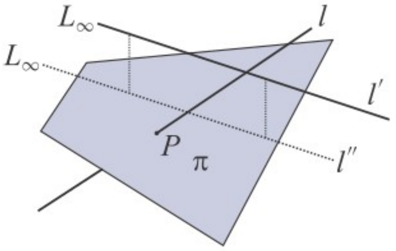


2. (3-D) Three distinct noncollinear points are *on* a unique plane. That is, if $P \neq Q, Q \neq R, P \neq R$, and there is no line $\ell \ni \{P, Q, R\} \subset \ell$, then $\{P, Q, R\} \subset \pi_i$, $i = 1, 2 \Rightarrow \pi_1 = \pi_2$.



3. (* 2-D) Two distinct coplanar lines are *on* (i.e., intersect or determine) a unique point. With the "ideal" elements we always have $\ell_1 \cap l_2 \neq \emptyset$ and $P_1, P_2 \in \ell_1 \cap \ell_2 \Rightarrow P_1 = P_2$.

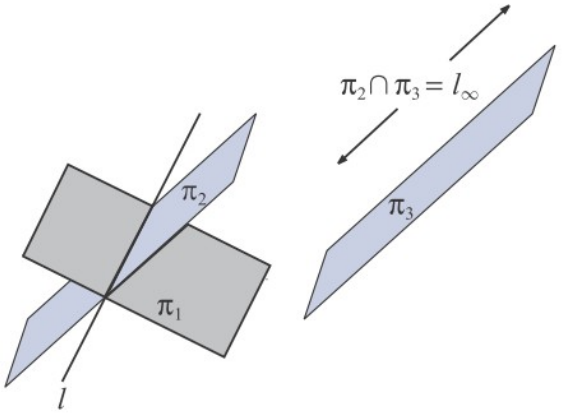
This axiom and the remaining axioms are marked with an asterisk $(*)$, for they differ from their corresponding Euclidean cousins. Specifically, this axiom corresponds to Euclid's famous fifth postulate, which postulated the existence of parallel lines.



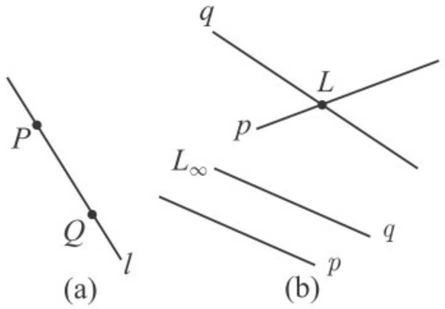
4. (* 3-D) A plane π and a line ℓ not contained in π are *on* (i.e., intersect at) a unique point $\ell \cap \pi \neq \emptyset$ always and $P_1, P_2 \in \ell \cap \pi \Rightarrow P_1 = P_2$.

5. (* 3-D) Two distinct planes are *on* (i.e., intersect in) a unique line $\pi_1 \cap \pi_2 \neq \emptyset$ and $\pi_1 \cap \pi_2 = \ell$, where ℓ is unique.

It is not difficult to prove that the Euclidean plane together with the ideal and augmented elements satisfies the projective plane axioms. Let us assume that ideal points and augmented lines satisfy the axioms (see exercises) and study an example.



Theorem 2.2.1. *The ideal line p_∞ of an augmented plane (π, p_∞) is a line.*



(a) (b)

Figure 2.8. Axiom 1 is illustrated in (a) and its dual axiom (3) in (b).

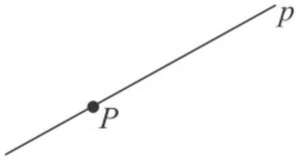


Figure 2.9. Self-dual: *point on line* and *line on point*.

Proof. We need to show that p_∞ satisfies the axioms for lines, namely axioms 3 and 4.

Let (ℓ, L_∞) be any augmented line on (π, p_∞). Since p_∞ is the collection of all ideal points on the augmented plane, $(\ell, L_\infty) \cap p_\infty = L_\infty$, so axiom 3 is satisfied.

Let (π', p'_∞) be an augmented plane not containing p_∞; therefore π' is not $\|$ to π. Hence $\pi \cap \pi' = \ell \Rightarrow (\pi, p_\infty) \cap (\pi', p'_\infty) = (\ell, L_\infty)$, where L_∞ is the ideal point associated with ℓ. ■

Two excellent references for projective geometry are [7] and [39].

Exercises

1. Show that the ideal points satisfy the axioms of points.
2. Show that augmented lines satisfy the axioms of lines.
3. Show that augmented planes satisfy the axioms of planes.
4. Show that the ideal plane π_∞ satisfies the axioms of a plane.

2.2.3 Principle of Duality

The axioms yield a principle not found in Euclidean geometry. In 2-D there is a point ↔ line duality stemming from (axiom 1) two *points* are on a *line* ℓ and (axiom 3) two *lines* are on a *point* L. As a result, planar figures can be "dualized" by switching the words point and line. For example, three distinct noncollinear (i.e., not on the same *line*) *points P, Q, and R* determine a triangle. Dually, three distinct nonintersecting (i.e., not on the same *point*) *lines p, q, r* also determine a triangle. That is, triangles are self-dual. Note also the projective cases in Fig. 2.11: (left)

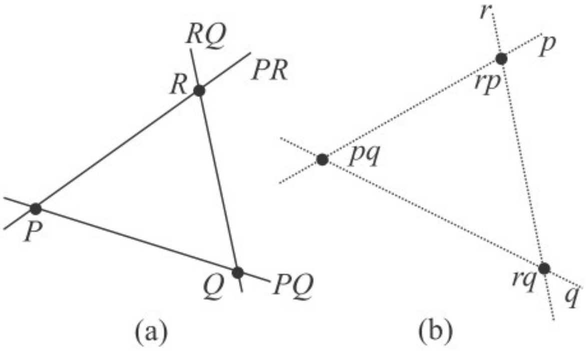

Figure 2.10. Self-dual 2: Triangle (a) and "triline" in (b).

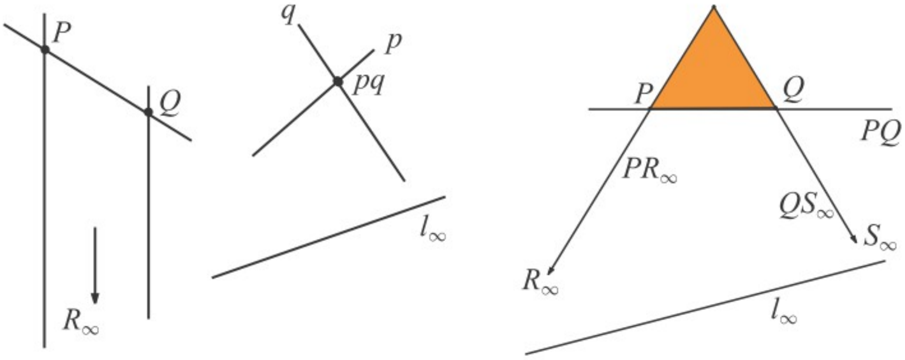

Figure 2.11. Projective triangles (left) and quadrangle (right).

triangles and (right) the four points P, Q, R_∞, S_∞, which form a quadrilateral ("quadrangle") with edges $PQ, PR_\infty, QS_\infty, \ell_\infty$.

The 3-D duality is point ↔ plane and results from axiom 2, whose dual is that three noncollinear *planes* π_1, π_2, π_3 are on a point P; Fig. 2.12. By the way, this is the reason why point ↔ line dualities do not generalize to higher dimensions. Other examples of the point ↔ plane duality are that two *planes* π_1, π_2 are on a line, whose dual is axiom 1, and two *points* P_1, P_2 are on a line. Also axiom 4: a *plane* π and a line l not on π are on (determine) a *point* is dualized to a *point* P and a line l not on P are on (determine) a *plane*.

The implications of duality are far deeper than those just indicated. For if a (projective) theorem involves points and lines in 2-D or points and planes in 3-D, its dual is also true. We illustrate this with the earliest known projective theorem,

proved by Pappus in the third century C.E. Using the notation $\cdot$, instead of $\cap$, for intersection Pappus's theorem states that for any distinct *points* A_i on a *line* r and any distinct *points* B_i on a *line* s, where $i = 1, 2, 3$, the *points* C_i, where $C_i = A_j B_k \cdot A_k B_j$ for $j \neq k \neq i$, are always on a *line* p. The dual theorem is obtained simply by interchanging the *words* point ↔ line. In our notation it is equivalent to switching lowercase ↔ capital letters as follows: for any distinct *lines* a_i on a *point* R and any distinct *lines* b_i on a *point* S, where $i = 1, 2, 3$, the *lines* c_i, where $c_i = a_j b_k \cdot a_k b_j$ for $j \neq k \neq i$, are always on a *point* P. No further proof is needed!

Fun and Games with the ILM

Open the ILM: set *Chapter = 2D Point Line duality*.

Move the point and watch the line.

Next set *Subject = Point ↔ Line*.
Draw a point on the left and see the corresponding line on the right.

2.3 ** Finite Geometries

Let a *finite* set of points and a nonempty collection of point subsets called *lines* satisfy the following axioms:

1. Any two distinct points A and B are *on* a unique line ℓ.
2. If p and q are distinct lines, there is a unique point *on* both.
3. There are at least three distinct points *on* any line.
4. Not all points are *on* the same line.

Such a set is called a *finite geometry*. It exemplifies the stark contrast with Euclidean geometry. *Point, line*, and the *on* relation are primitives specified by the above axioms only. Additional properties can be introduced to enrich the geometry.

2.3.1 Seven-Point Geometry

From the third axiom there are $n \geq 3$ points on a line. The smallest geometry, with $n = 3$ points on each line and a total of $n^2 - n + 1 = 7$ (see Exercise 3 below) points or lines is illustrated in Fig. 2.14. The lines are $a = [A, D, B]$, $b = [A, E, C]$, $c = [C, F, B]$, $d = [A, G, F]$, $e = [B, G, E]$, $f = [C, G, D]$, $g = [D, E, F]$. Observe that the projective plane axioms are satisfied (i.e., two distinct points are on a unique line and vice versa) for ∀ lines $x \in \{a, \dots, g\}$

Figure 2.16. Incidence matrix for the 13-point geometry.

2.3.2 Finite Geometry with 13 Points

Finite geometries can be pictured in different ways, as in Figure 2.15, and specified by an incidence matrix for points and lines as for the 13-point geometry. Here, it is more convenient to denote the points and lines by numbers rather than letters. Those interested in pursuing the fascinating subject of finite geometries are referred to [116] and [117].

Exercises

1. Prove the 3-D dual shown in Fig. 2.12, i.e., that three noncollinear planes are on a point, using only the projective 3-D space axioms.
2. The second axiom may be weakened to 2a: "If p and q are distinct lines, there is *at least* one point on *on* both lines." Prove that with axiom 2 replaced by 2a above, the resulting set of points and lines also satisfies the projective plane axioms.
3. Prove that in a finite geometry with n points on any line there are $n^2 - n + 1$ points (or lines) altogether.
4. Construct diagrams for the geometries with $n = 5$ and 6 points and try to generalize. This is hard: you may want to look up a topic in combinatorics called "Latin squares."

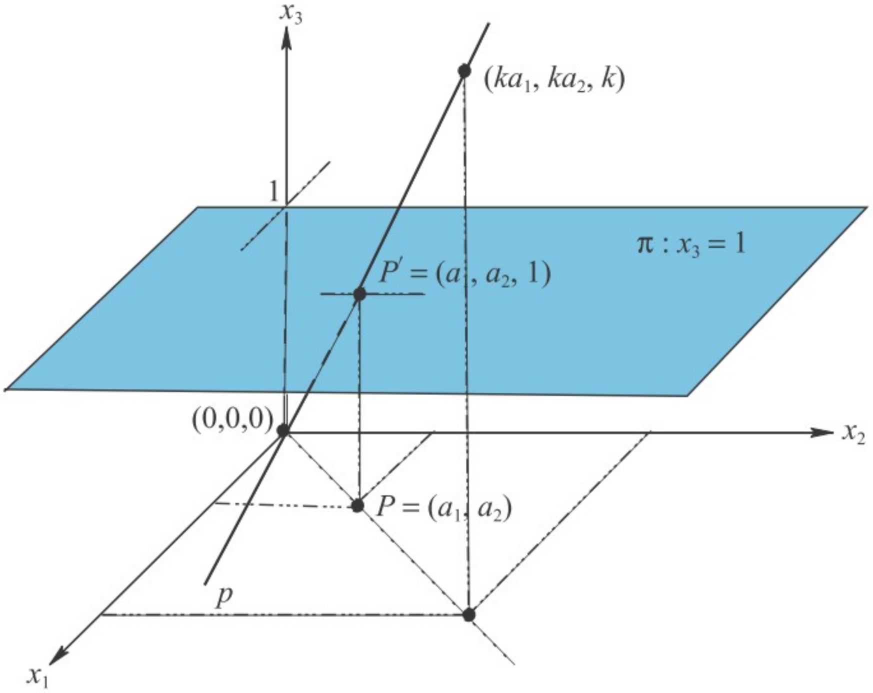

Figure 2.17. Homogeneous coordinates. Correspondence between points P in the x_1x_2-plane and lines p through the origin in 3-D.

2.4 ♣ *FT-2* Analytic Projective Geometry

Even though there is no notion of distance in projective space, it is possible to introduce a very useful coordinate system. The geometric development here is for the plane and can be generalized to projective N-space $\mathbb{P}^N$.

We consider the x_1x_2 plane in $\mathbb{R}^3$ with Cartesian coordinates as shown in Fig. 2.17 and the plane $\pi : x_3 = 1$. The point $P = (a_1, a_2)$ in the x_1x_2-plane is identified with the point $P' = (a_1, a_2, 1)$ in the plane π. The line p through the points $(0, 0, 0)$ and P' is constructed and is described by the equations

$$p : \begin{cases} x_2 = \frac{a_2}{a_1} x_1, \\ x_3 = \frac{1}{a_2} x_2. \end{cases}$$

In this way, the point-to-line correspondence

$$
\begin{aligned}
&P = (a_1, a_2) \in x_1x_2\text{-}plane \\
&\quad \longleftrightarrow\ p \subset x_1x_2x_3\text{-}space,\ p\ \ on\ \ (a_1, a_2, 1), (0, 0, 0),
\end{aligned}
$$

is established. Since p can be identified by any one of its points (ka_1, ka_2, k) for $k \neq 0$, the correspondence can be alternatively written as

$$P : (a_1, a_2) \longleftrightarrow (ka_1, ka_2, k),\ \ 0 \neq k \in \mathbb{R}.$$

That is, (k_1a_1, k_1a_2, k_1) and any other multiple (k_2a_1, k_2a_2, k_2) for $k_1 \neq k_2$ represent the *same* point, since they both lie on the *same line* p. These triples are the *point coordinates* of P.

Let us return to Fig. 2.17 and imagine the point P moving farther away from the origin but always in the direction with slope $m = \frac{a_2}{a_1}$ approaching the ideal point in this direction. The point coordinates of P are $(a_1, a_2, 1)$ or $(1, m, \frac{1}{a_1})$, and as $a_1 \to \infty$ the ideal point is represented by the triples $(ka_1, ka_2, 0)$ for $k \neq 0$. The important realization is that the 0 in the third component identifies ideal points. This system is called *homogeneous coordinates*, allowing the representation both ordinary *and* ideal points, something that cannot be done with Cartesian coordinates; it has other nice properties as well.

Appealing to duality, a *line* x can be represented as an ordered triple of real numbers that is distinguished from a triple representing *points* using capitals for the coordinates themselves and "[ ]" instead of "( )" as

$$x : [X_1, X_2, X_3] \neq [0, 0, 0],$$

again with the convention that $[kX_1, kX_2, kX_3]$, $\forall k \neq 0$, represents the same line. These triples are called *line coordinates*. So $(1, 2, 3)$ represents a point and $[1, 2, 3]$ a line. Actually, this is quite reasonable, for consider a line described in Cartesian coordinates by

$$A_1x_1 + A_2x_2 + A_3 = 0. \tag{2.1}$$

For $A_3 \neq 0$ the same line is also given by

$$\frac{A_1}{A_3}x_1 + \frac{A_2}{A_3}x_2 + 1 = 0. \tag{2.2}$$

In either case, the three constants A_1, A_2, A_3 completely specify the line. So taking the triple $[A_1, A_2, A_3]$ with the understanding that A_i is the coefficient of x_i for

$i = 1, 2$ and A_3 is the constant completely describes the line in (2.1). Equivalently, the triple $[\frac{A_1}{A_3}, \frac{A_2}{A_3}, 1]$ describes the line as given by (2.2), and hence these two triples and their multiples identify the same line.

There remains to define the *on* relation. We say that a point $X = (x_1, x_2, x_3)$ is *on* the line $x = [X_1, X_2, X_3]$, and dually the line x is *on* the point if and only if

$$X \cdot x = x \cdot X = x_1 X_1 + x_2 X_2 + x_3 X_3 = 0.$$

Consider now the three points $Y = (y_1, y_2, y_3), Z = (z_1, z_2, z_3), W = (w_1, w_2, w_3)$, all on the line $x = [X_1, X_2, X_3]$. Then

$$\begin{aligned} y_1 X_1 + y_2 X_2 + y_3 X_3 &= 0, \\ z_1 X_1 + z_2 X_2 + z_3 X_3 &= 0, \\ w_1 X_1 + w_2 X_2 + w_3 X_3 &= 0. \end{aligned}$$

This system of linear homogeneous equations has a nontrivial solution $[X_1, X_2, X_3]$ if and only if the deteterminant of the coefficients is zero. That is, Y, Z, W are on a line x if and only if

$$\begin{vmatrix} y_1 & y_2 & y_3 \\ z_1 & z_2 & z_3 \\ w_1 & w_2 & w_3 \end{vmatrix} = 0. \tag{2.3}$$

This condition provides the line coordinates of x as

$$\left[\begin{vmatrix} y_2 & y_3 \\ z_2 & z_3 \end{vmatrix}, \begin{vmatrix} y_3 & y_1 \\ z_3 & z_1 \end{vmatrix}, \begin{vmatrix} y_1 & y_2 \\ z_1 & z_2 \end{vmatrix} \right]. \tag{2.4}$$

A direct consequence is that the points X, Y, and $\lambda X + \mu Y$ for $\lambda, \mu \in \mathbb{R}$ are collinear.

What are the line coordinates of the ideal line? We can find out by substituting two distinct ideal points in (2.4), i.e., $z_3 = y_3 = 0$. This yields $[0, 0, y_1 z_2 - y_2 z_1]$ or $[0, 0, 1]$. So far, it is all falling into place: we have a coordinate system that provides coordinates for every regular point (from which its Cartesian coordinates can be recovered) and *also* coordinates for the ideal elements (points and line). In addition, homogeneous coordinates can be extended to projective N-space and finite geometries. ♣ *FT-2e*

Consider now the 7-point geometry (i.e., $n = 3$) described earlier and take the algebra J_2, the integers modulo 2, with elements $\{1, 0\}$. The binary operations $+$ and $\times$ are defined by

$$\begin{array}{c|cc} + & 0 & 1 \\ \hline 0 & 0 & 1 \\ 1 & 1 & 0 \end{array} \qquad \begin{array}{c|cc} \times & 0 & 1 \\ \hline 0 & 0 & 0 \\ 1 & 0 & 1 \end{array}.$$

Now we collect all triples (x_1, x_2, x_3) except $(0, 0, 0)$ and label them:

$$A = (0, 0, 1), \quad B = (0, 1, 0), \quad C = (1, 0, 0),$$
$$D = (0, 1, 1), \quad E = (1, 0, 1), \quad F = (1, 1, 0), \quad G = (1, 1, 1).$$

A pair of points is chosen specifying a line $x = [X_1, X_2, X_3]$ whose coordinates are computed from (2.4) for $X_i \in J_2$, yielding

$$a = [1, 0, 0] \quad b = [0, 1, 0] \quad c = [0, 0, 1]$$
$$d = [1, 1, 0] \quad e = [1, 0, 1] \quad f = [0, 1, 1] \quad g = [1, 1, 1].$$

Note that each point is on two lines; for example A is *on* the lines having $X_3 = 0$. Similarly, other finite geometries can be coordinatized using the appropriate algebra J_p of integers modulo p, that is, the set of integers $\{1, 2, \dots, p-1\}$ with addition and multiplication analogously defined (see a book on modern algebra). To clarify, let us use J_3 to coordinatize the 13-point geometry. Excluding $(0, 0, 0)$, there are 26 triples (a_1, a_2, a_3), $a_i \in J_3$, with the multiples $k(a_1, a_2, a_3)$, $k \neq 0 \in J_3$, also representing the same point. The only multiple of interest is $2(a_1, a_2, a_3)$, which equals (a_1, a_2, a_3) for $a_i \in J_3$, yielding 13 distinct triples. Similarly, with J_4 there 63 nonzero triples whose multiples by 2 or 3 are the same in that algebra, yielding 21 distinct triples, which can therefore serve as the homogeneous coordinates of the 21-point geometry (Exercise 3 below).

2.4.1 Homogeneous Coordinates on a Line

Let us specialize homogeneous coordinates to a line o, which for convenience we take as being on the two points

$$O = (0, 1, 1), \quad U = (1, 1, 1).$$

The coordinates of a point $X = (x_1, x_2, x_2) \in o$ together with those of O and U satisfy the collinearity condition of (2.3); therefore $x_2 = x_3$, so $X = (x_1/x_2, 1, 1)$, with $X = (x_1, 0, 0)$ being the line's ideal point if $x_2 = 0$. Since there is no variation in the third component, the coordinates of regular points can be simplified to $O = (0, 1)$, $U = (1, 1)$ and in general, $X = (x_1, x_2)$, as indicated in Fig. 2.18. We can write

$$X : (x_1, x_2) = a_2(1, 1) + a_1(0, 1) = a_2 U + a_1 O$$

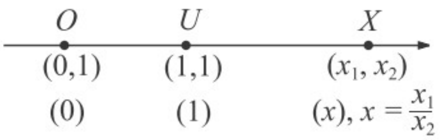

Figure 2.18. Homogeneous coordinates on the line.

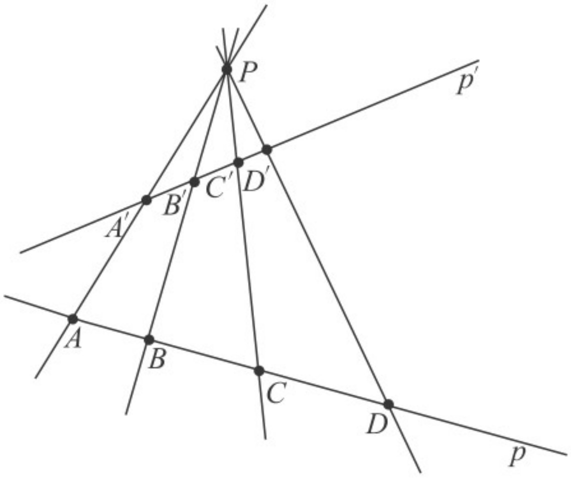

Figure 2.19. Two lines p, p' in perspective from the point P.

for $x_1 = a_2$, $x_2 = a_1 + a_2$, and O, U acting as a basis. The point O can be thought of as the "origin," and U establishes the "unit"; recall that we do not have a metric in the projective plane. There is a further simplification obtained by dividing by x_2 to represent the point X by the single value $x = x_1/x_2$.

2.5 The Fundamental Transformations of Projective Geometry

A short diversion into the basic transformations of projective geometry is needed in order to prove a fundamental property of homogeneous coordinates. Consider two *directed* (in the Euclidean plane) lines p, p' and a point P not on the lines, as shown in Fig. 2.19. A line on P intersecting p at the point A and p' at A' establishes a one-to-one correspondence called *perspectivity* between the points of p and p'. It is denoted by

$$p(A, B, C, D, \dots) \overset{P}{\underset{\wedge}{=}} p'(A', B', C', D', \dots).$$

The two lines are said to be in perspective with respect to the point P, which may be indicated above the $\underset{\wedge}{=}$ symbol. Of course, there is the dual concept, shown in Fig. 2.20, of two points P, P' being in perspective with respect to a line p denoted by

$$P(a, b, c, d, \dots) \underset{\wedge}{=} P'(a', b', c', d', \dots).$$

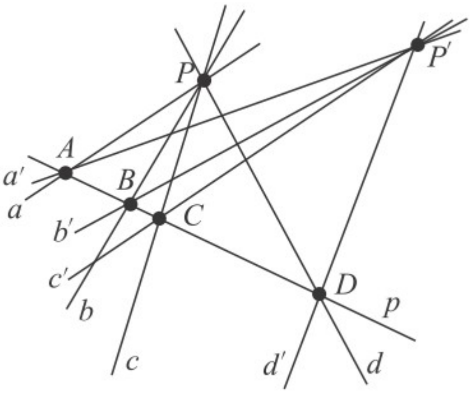

Figure 2.20. Two points P, P' in perspective from the line p.

Consider now a perspectivity $p(A, B, C, D, \dots) \underset{\wedge}{=} p'(A', B', C', D', \dots)$ as shown in Fig. 2.21 and the *cross-ratio*

$$(A, B; C, D) = \frac{AC/BC}{AD/BD}.$$

Theorem 2.5.1. *The cross-ratio is invariant under perspectivity.*

Proof. We give an elementary proof in the Euclidean plane, leaving the projective aspects for the exercises. With reference to Fig. 2.21,

$$(A, B; C, D) = \frac{\frac{IP \cdot AC}{IP \cdot BC}}{\frac{IP \cdot AD}{IP \cdot BD}} = \frac{\frac{\text{area}\triangle APC}{\text{area}\triangle BPC}}{\frac{\text{area}\triangle APD}{\text{area}\triangle BPD}} = \frac{\frac{AP \cdot CP \sin(APC)}{BP \cdot CP \sin(BPC)}}{\frac{AP \cdot DP \sin(APD)}{BP \cdot DP \sin(BPD)}},$$

or

$$(A, B; C, D) = \pm \frac{\sin(APC) \cdot \sin(BPD)}{\sin(BPC) \cdot \sin(APD)}. \tag{2.5}$$

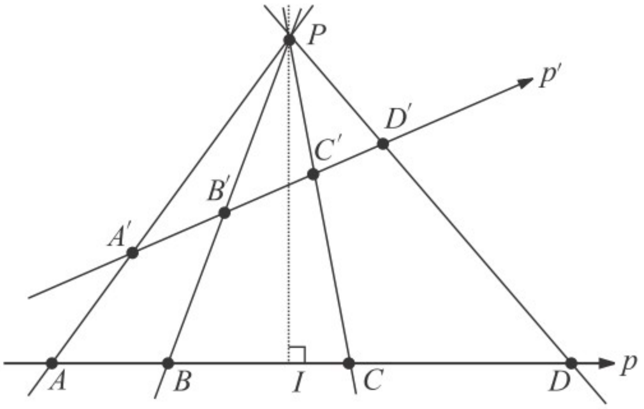

Figure 2.21. Diagram for the cross-ratio property.

Similarly, it can be shown that $(A', B'; C', D')$ also equals the right-hand-side of (2.5). There remains to show that the signs match (see exercises below). As stated, this definition of the cross-ratio applies only to the Euclidean plane, but it can be appropriately generalized to the augmented plane (π, p_∞), the cross-section invariance being a *projective* property. ■

The set of all points on a line is called a *pencil of points*, and dually, the set of all lines on a point is called a *pencil of lines*. A pencil of points may undergo successive perspectivities, as in

$$p_1 \overset{P_1}{\doublebarwedge} p_2 \overset{P_2}{\doublebarwedge} \cdots \overset{P_{n-1}}{\doublebarwedge} p_n.$$

A sequence of perspectivities is called a *projectivity* and is denoted by $p \barwedge p_n$. In projective geometry we study the properties that remain invariant under projectivities. We state without proof a couple of important results.

Theorem 2.5.2. *A projectivity is determined by the correspondence between two triples of distinct points. That is, if the triples* (A, B, C) *and* (A', B', C') *correspond under a projectivity* $p \barwedge p_n$*, then the correspondence between any* $X \in p$ *and* $X' \in p'$ *is uniquely determined (i.e., projectivity is determined by just three points).*

This does not determine the actual sequence of perspectivities from which the projectivity resulted. Rather, it just determines the correspondence between the original and final pencils of points.

Theorem 2.5.3. *A projectivity can be expressed by at most two perspectivities.*

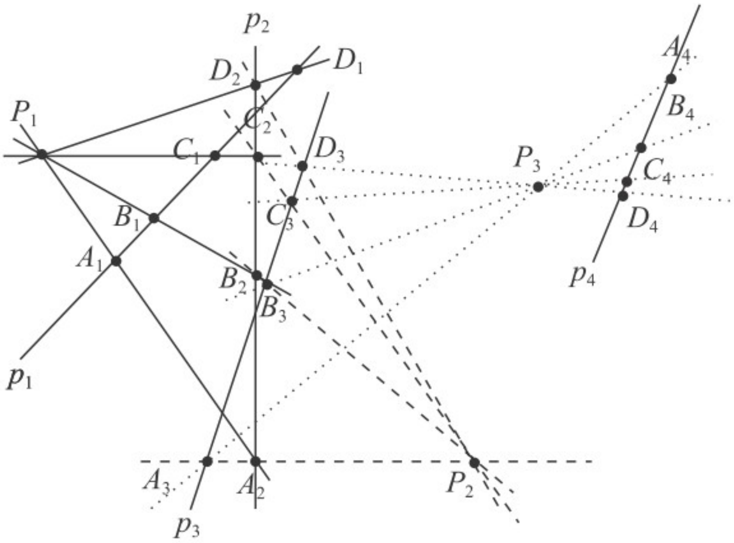

Figure 2.22. A projectivity composed of four perspectivities.

Exercises

1. Show that the 24 distinct permutations of four symbols A, B, C, and D result in exactly six different values of the cross-ratios as formed from these four symbols (corresponding to four points on a line)
2. Prove Theorem 2.5.1 when the perspectivity is with respect to an ideal point.
3. Prove Theorem 2.5.2 in the Euclidean plane and also with a perspectivity with respect to an ideal point.
4. Prove Theorem 2.5.3 in the Euclidean plane and also with a perspectivity with respect to an ideal point.

2.6 More on Homogeneous Coordinates

2.6.1 Linearizability of Projective Transformations

It is easy to see that the cross-ratio remains invariant under a projectivity and in fact, completely characterizes (determines) the projectivity. This invariance leads to a very important result and the reason homogeneous coordinates are so widely used in fields such as computer graphics. It is proved first for the plane $\mathbb{P}^2$ and then generalized to higher dimensions. For a projectivity $s \barwedge s'$ between two directed lines

s and s' (as in Fig. 2.21, see lines p and p'), four points and their corresponding single homogeneous coordinates indicated by (), $P : (p)$, $Q : (q)$, $R : (r)$, $X : (x)$ are chosen to form the cross-ratio

$$(P, Q; R, X) = \frac{(p - r)(q - x)}{(p - x)(q - r)}.$$

Similarly, the cross-ratio

$$(P', Q'; R', X') = \frac{(p' - r')(q' - x')}{(p' - x')(q' - r')}$$

is formed with the corresponding points $P' : (p')$, $Q' : (q')$, $R' : (r')$, $X' : (x')$ on s'. By the cross-ratio invariance, under a projectivity, we have

$$(P, Q; R, X) = (P', Q'; R', X'), \tag{2.6}$$

yielding

$$x' = \frac{ax + b}{cx + d}. \tag{2.7}$$

The a, b, c, d are given in terms of the coordinates p, q, r, p', q', and r', and their actual values are immaterial to the development. This is a *linear fractional transformation*, also called a *Möbius transformation*, completely specifying the projectivity $s \,\overline{\wedge}\, s'$. Reverting back to the ratio obtained from the homogeneous coordinates, i.e., $x = x_1/x_2$ and $x' = x'_1/x'_2$, we obtain from (2.7),

$$\frac{x'_1}{x'_2} = \frac{ax_1 + bx_2}{cx_1 + dx_2}. \tag{2.8}$$

Then rewriting the homogeneous coordinates of a point on a line in terms of two components as $X = (x_1, x_2)$, see Fig. 2.18, we get

$$k\left(\frac{x'_1}{x'_2}, 1\right) = \left(\frac{ax_1 + bx_2}{cx_1 + dx_2}, 1\right).$$

Here k is an arbitrary proportionality constant, which is needed, since *multiples* of a triple (the 1 in the third position is not shown; see Fig. 2.18) represent the same point. Eliminating the fractions yields

$$k(x'_1, x'_2) = (ax_1 + bx, cx_1 + dx_2),$$

from which we obtain the *linear* relations

$$kx'_1 = ax_1 + bx_2, kx'_2 = cx_1 + dx_2 \tag{2.9}$$

between the coordinates on the directed lines s and s'. The transformation (2.8) is called *projective*, and this is the most general class of *nonlinear* transformations that can be linearized by homogeneous coordinates. It is worth examining this in greater detail. Rewrite the transformation as

$$T(x) = \frac{ax+b}{cx+d} = \left(\frac{bc-ad}{c^2}\right) \cdot \left(\frac{1}{x+d/c}\right) + \left(\frac{a}{c}\right),$$

which provides the decomposition of T into

$$T = T_4 \circ T_3 \circ T_2 \circ T_1,$$

where $\circ$ denotes the transformation composition and

$$T_1(x) = x + \frac{d}{c}, \quad T_2(x) = \frac{1}{x}, \quad T_3(x) = \frac{bc-ad}{c^2}x, \quad T_4(x) = x + \frac{a}{c}.$$

That is, T is composed of two translations T_1, T_4, a scaling T_3, and an inversion T_2. Inversions and translations, being nonlinear, are linearized, and this property makes homogeneous coordinates especially useful in applications, since the *projective* transformations, translation, perspective, rotation, and scaling, can all be described in terms of matrices. Hence, a sequence of such transformations can be expressed as a matrix product and computed in a convenient and efficient way (e.g., see [146]).

For n-dimensional projective space $\mathbb{P}^N$ and projectivities there, the linear fractional transformation (2.7) generalizes to

$$x_i'' = \frac{a_{1i}x_1' + a_{2i}x_2' + \cdots + a_{N,i}x_N' + a_{(N+1),i}}{b_{1i}x_1' + b_{2i}x_2' + \cdots + b_{N,i}x_N' + b_{(N+1),i}}, \quad i = 1, 2, \ldots, n, \qquad (2.10)$$

where we have reverted to homogeneous coordinates by

$$x_i'' = \frac{x_i'}{x_{(N+1)}'}, \quad x_j' = \frac{x_j}{x_{(N+1)}}, \quad j = 1, 2, \ldots, (n+1).$$

Here the x_i are Cartesian coordinates, while the x_i' and x_i'' are homogeneous coordinates.

2.7 ** The Linearized Projective Transformations

To recap, the projective transformation

$$T(x) = ax \qquad (2.11)$$

is linear and is called *scaling* when $a > 0, a \neq 1$; then it is a *contraction* for $a < 1$ and a *stretching*, or *magnification*, when $a > 1$. For complex $a = r(\cos\theta + i\sin\theta)$, the result is a *rotation* of x by an angle θ about the origin as well as a scaling by r. By contrast, *translation*

$$T(x) = x + a \tag{2.12}$$

and *inversion* or *perspective*

$$T(x) = \frac{1}{x} \tag{2.13}$$

are not linear, and for these the linearization, accomplished via homogeneous coordinates, enables the transformations to be expressed in matrix form. This is of importance in such applications as *computer graphics* and *geometric modeling*.

2.7.1 Projective Transformations in the Plane $\mathbb{P}^2$

For notational convenience, a point $P = (x_1, x_2, x_3)$ and its transform $P' = (x_1', x_2', x_3')$, expressed in homogeneous coordinates, are taken as row vectors, while the transformations are denoted by two capital letters. We take $x_3' = c'$ and $x_3 = c$, such that for ordinary points, $c, c' \neq 0$, and $c, c' = 0$ for ideal points. Many references in computer graphics, geometric modeling, robotics, and other fields consider only the case $x_3 = 1$, which unnecessarily excludes the ideal points.

The scaling transformation $P' = PS(s_1, s_2)$, where $x_i' = s_i x_i$ and $x_3' = x_3 = c$, in matrix form is

$$PS: \quad (x_1', x_2', c) = (x_1, x_2, c)\begin{pmatrix} s_1 & 0 & 0 \\ 0 & s_2 & 0 \\ 0 & 0 & 1 \end{pmatrix}. \tag{2.14}$$

The rotation $P' = PR(\theta)$ by an angle θ about the origin is

$$PR: \quad (x_1', x_2', c) = (x_1, x_2, c)\begin{pmatrix} \cos\theta & \sin\theta & 0 \\ -\sin\theta & \cos\theta & 0 \\ 0 & 0 & 1 \end{pmatrix}. \tag{2.15}$$

For the translation $P' = PT(t_1, t_2)$, with $x_i' = x_i + t_i$, we can set $c = 1$, since translation of ideal points is not meaningful, to obtain

$$PT: \quad (x_1', x_2', 1) = (x_1, x_2, 1)\begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ t_1 & t_2 & 1 \end{pmatrix}. \tag{2.16}$$

Successive scaling or rotation transformations result in successive multiplications of the corresponding matrices, as they should, since these are linear transformations. The fun and beauty is that it also works with translations. For $P' = PT_1(t_1^1, t_2^1)$ and $P'' = P'T_2(t_1^2, t_2^2)$, the result is $P'' = PT_1T_2 = PT_2T_1$ so that $x_i'' = x_i + t_i^1 + t_i^2$. The matrices commute with respect to multiplication, as they should, since the result of successive translations does not depend on their order.

The composition of scalings, rotations, and translations is obtained by the multiplication of the corresponding matrices. In addition, the matrices are sparse (i.e., they have many zeros), and the computational advantage is tremendous.

2.7.2 Projective Transformations in $\mathbb{P}^3$

The generalizations of these transformations to 3-D are straightforward, with the previous remarks regarding $x_3 = c$ now pertaining to $x_4 = c$. For scaling, $P' = PS(s_1, s_2, s_3)$,

$$PS: \quad (x_1', x_2', x_3', c) = (x_1, x_2, x_3, c)\begin{pmatrix} s_1 & 0 & 0 & 0 \\ 0 & s_2 & 0 & 0 \\ 0 & 0 & s_3 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}. \tag{2.17}$$

Let the matrices for the rotation about the x_i-axes by an angle θ be denoted by $PR_i(\theta)$, $i = 1, 2, 3$. The rotation about x_3 is given by

$$PR_3: \quad (x_1', x_2', x_3', c) = (x_1, x_2, x_3, c)\begin{pmatrix} \cos\theta & \sin\theta & 0 & 0 \\ -\sin\theta & \cos\theta & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}, \tag{2.18}$$

and is a direct extension of the 2-D rotation. The two other rotation matrices are

$$\begin{gathered} PR_1(\theta) = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & \cos\theta & \sin\theta & 0 \\ 0 & -\sin\theta & \cos\theta & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}, \\ PR_2(\theta) = \begin{pmatrix} \cos\theta & 0 & -\sin\theta & 0 \\ 0 & 1 & 0 & 0 \\ \sin\theta & 0 & \cos\theta & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}. \end{gathered} \tag{2.19}$$

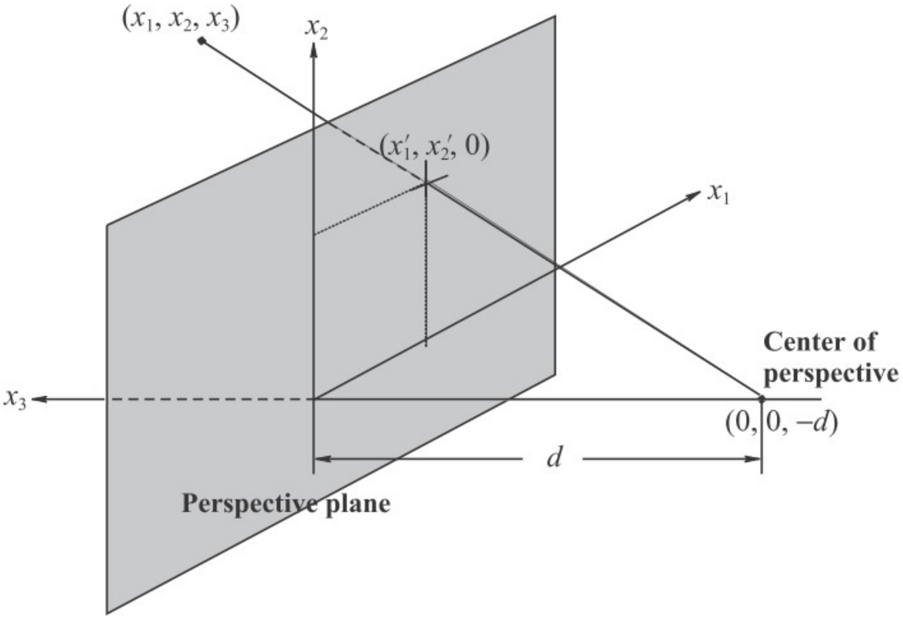

Figure 2.23. Perspective with respect to the x_3-axis.

For 3-D translations $P' = PT(t_1, t_2, t_3)$, $c = 1$ as in 2-D, and

$$PT: \quad (x_1', x_2', x_3', 1) = (x_1, x_2, x_3, 1)\begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ t_1 & t_2 & t_3 & 1 \end{pmatrix}. \tag{2.20}$$

In 3-D, the perspective transformation is important, for it provides images with a sense of depth and realism. It is convenient to choose the center of the perspective transformation on the negative x_3-axis at a distance d behind the perspective plane, as shown in Fig. 2.23. The transformation equations, obtained by similar triangles, are

$$x_1' = \frac{x_1}{x_3/d + 1}, \quad x_2' = \frac{x_2}{x_3/d + 1}, \quad x_3' = 0. \tag{2.21}$$

Denote the perspective transformation matrix by $V[\pi_{per}, C_{per}]$, where π_{per} and C_{per} are the perspective plane and center respectively. For the setup in Fig. 2.23, $P' = PV[x_3 = 0, (0, 0, -d)]$, and explicitly,

$$(x'_1, x'_2, 0, w) = (x_1, x_2, x_3, c)\begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1/d \\ 0 & 0 & 0 & 1 \end{pmatrix}, \tag{2.22}$$

with the relation between c and w emerging next. The perspective image of an ideal point $P = (1, x_2/x_1, x_3/x_1, 0)$, called a *vanishing point*, is the *ordinary point* $P' = (x'_1, x'_2, 0, x_3/d) = (dx_1/x_3, dx_2/x_3, 0, 1)$. Hence

$$w = \frac{x_3}{d} + c, \quad x'_1 = \frac{x_1}{w}, \quad x'_2 = \frac{x_2}{w}, \quad x'_3 = 0.$$

All projective transformations can now be performed successively by matrix multiplication. The matrix of the perspective transformation, unlike those of other projective transformations, is singular, confirming that an object cannot be uniquely retrieved from its perspective image.

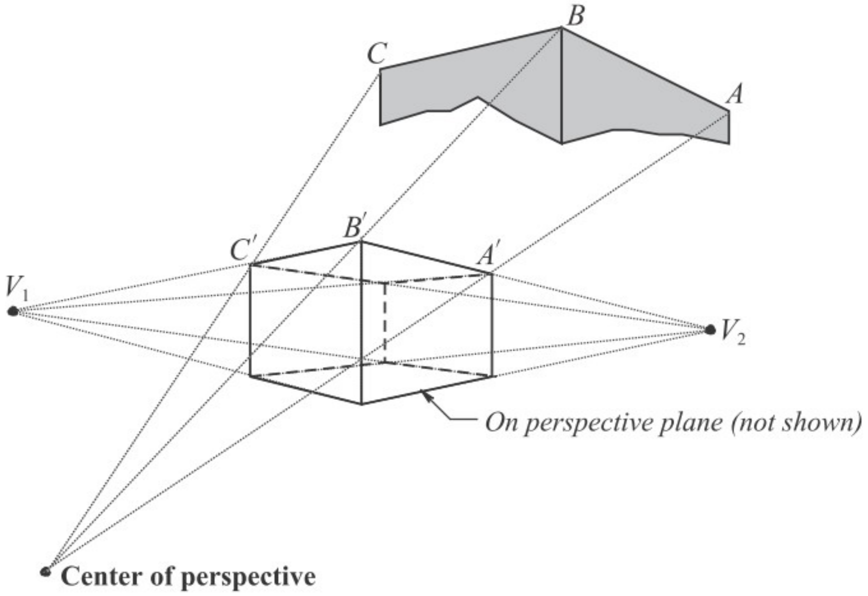

Figure 2.24. The perspective image of an object (partially shown).
In the figure, the perspective transformation of three vertices A, B, C is traced, showing their images A', B', C'. This is sometimes called a *2-point perspective*, having two *vanishing points* V_1 and V_2, the images of ideal points, giving the image "3-dimensionality." Actually, the ideal point in the vertical direction is the "third vanishing point." It would have been a *3-point perspective* had the perspective plane not been parallel to the front (vertical) face of the object. All lines joining the object's points with their images intersect at the *center of perspective*.

2.8 ** Coordinate System Rotations

This section, complementing the discussion of rotations about one axis above, is adapted from an old gem [161, pp. 240–241] (the textbook from which I learned analytic geometry). In $\mathbb{R}^3$ with a positive direction assigned to a line ℓ, translate the coordinate system to any point $Q \in \ell$, denoting by α, β, γ the *direction angles* between the positive direction of ℓ and the translates of the axes x_1, x_2, x_3 respectively. Their cosines, called *direction cosines*, have the property

$$\cos^2\alpha + \cos^2\beta + \cos^2\gamma = 1. \tag{2.23}$$

Denoting by $\hat{\mathbf{e}}_\mathbf{i}$ the unit vectors in the x_i directions, we obtain that

$$\hat{\ell} = \hat{\mathbf{e}}_\mathbf{1}\cos\alpha + \hat{\mathbf{e}}_\mathbf{2}\cos\beta + \hat{\mathbf{e}}_\mathbf{3}\cos\gamma \tag{2.24}$$

is the unit vector in the positive direction of ℓ, with (2.23) equivalent to $\hat{\ell}\cdot\hat{\ell} = |\hat{\ell}|^2$. The cosine of the angle ϕ between two directed lines ℓ_1, ℓ_2 is given in terms of their corresponding unit vectors $\hat{\ell}_\mathbf{1}, \hat{\ell}_\mathbf{2}$, and their corresponding direction angles, subscripted by 1 and 2, respectively, are given by

$$\cos\phi = \hat{\ell}_\mathbf{1}\cdot\hat{\ell}_\mathbf{2} = \cos\alpha_1\cos\alpha_2 + \cos\beta_1\cos\beta_2 + \cos\gamma_1\cos\gamma_2, \tag{2.25}$$

with $\cos\phi = 0$ when the lines are perpendicular.

For a plane π, let n be the directed line through the origin O and perpendicular to π with direction angles α, β, γ. The normal form of the equation of π is

$$\pi : x_1\cos\alpha + x_2\cos\beta + x_3\cos\gamma = d, \tag{2.26}$$

with d the directed distance of π from O. It is an easy matter to verify that the directed distance p of π from the point $P = (p_1, p_2, p_3)$ is given by

$$p = p_1\cos\alpha + p_2\cos\beta + p_3\cos\gamma - d. \tag{2.27}$$

With reference to Fig. 2.25, the coordinate system x_1, x_2, x_3 is rotated about the origin O to the system x_1', x_2', x_3', all points remaining stationary with a point P having two sets of coordinates (x_1, x_2, x_3), (x_1', x_2', x_3'). Our task is to find the relationship between them. Letting the direction cosines of the x_i' axes with respect to x_i be $\cos\alpha_i, \cos\beta_i, \cos\gamma_i$ for $i = 1, 2, 3$ respectively, we obtain

$$\begin{aligned}&\cos^2\alpha_i + \cos^2\beta_i + \cos^2\gamma_i = 1,\\ &\cos\alpha_j\cos\alpha_k + \cos\beta_j\cos\beta_k + \cos\gamma_j\cos\gamma_k = 0,\end{aligned} \tag{2.28}$$

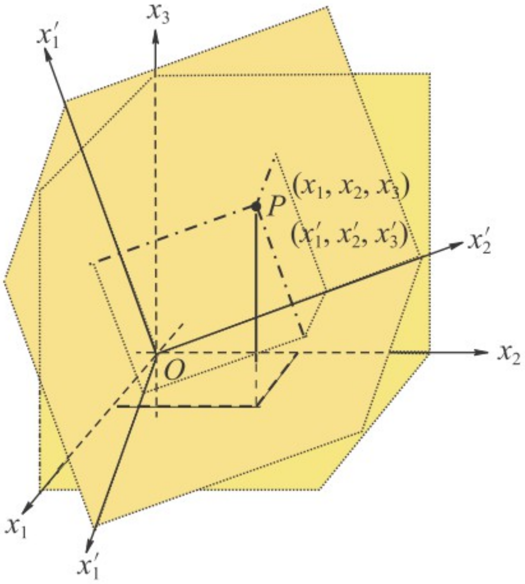

Figure 2.25. Rotation of the coordinate system $x_1x_2x_3$ about the origin.

where $j \neq k\, i,\, j, k = 1, 2, 3$, the first part corresponding to (2.23) for the x_i' and the second due to the orthogonality between the pairs x_j', x_k' of axes. The plane $x_2'x_3'$, which passes through the origin O, has equation

$$x_2'x_3' : x_1 \cos\alpha_1 + x_2 \cos\beta_1 + x_3 \cos\gamma_1 = 0,$$

with coefficients the direction cosines of the axis x_1', which is orthogonal to it. Similarly, for all the 2-planes,

$$x_j'x_k' : x_1 \cos\alpha_i + x_2 \cos\beta_i + x_3 \cos\gamma_i = 0, \quad i \neq j \neq k. \tag{2.29}$$

The directed distance of the point P from the plane $x_j'x_k'$ is its x_i' coordinate, $i \neq j \neq k$; hence by (2.27), (2.29),

$$x_i' = x_1 \cos\alpha_i + x_2 \cos\beta_i + x_3 \cos\gamma_i. \tag{2.30}$$

These describe the coordinate transformation $\{x_1, x_2, x_3\} \to \{x_1', x_2', x_3'\}$. Reversing the roles of x_i and x_i' in the previous reasoning, we obtain the inverse transformation $\{x_1', x_2', x_3'\} \to \{x_1, x_2, x_3\}$:

$$x_i = x_1 \cos\alpha_i + x_2 \cos\beta_j + x_3 \cos\gamma_k, \quad i \neq j \neq k. \tag{2.31}$$

For consistency with Section 2.7, (2.30) and (2.31) are rewritten in homogeneous coordinates and in matrix form:

$$(x_1', x_2', x_3', 1) = (x_1, x_2, x_3, 1)\begin{pmatrix} \cos\alpha_1 & \cos\beta_1 & \cos\gamma_1 & 0 \\ \cos\alpha_2 & \cos\beta_2 & \cos\gamma_2 & 0 \\ \cos\alpha_3 & \cos\beta_3 & \cos\gamma_3 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}, \tag{2.32}$$

$$(x_1, x_2, x_3, 1) = (x_1', x_2', x_3', 1)\begin{pmatrix} \cos\alpha_1 & \cos\alpha_2 & \cos\alpha_3 & 0 \\ \cos\beta_1 & \cos\beta_2 & \cos\beta_3 & 0 \\ \cos\gamma_1 & \cos\gamma_2 & \cos\gamma_3 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}. \tag{2.33}$$

The matrix A of the transformation in (2.30) has determinant $|A| = 1$, and the matrix of the inverse transformation (2.31) is the transpose A^T. These, and the matrices corresponding to the rotations about one axis in Section 2.7, are examples of *orthogonal* matrices (transformations), which also appear in the previous section. As a reminder, the above equations *together* with the six conditions of (9.47) specify the rotation of the coordinate system about the origin. By the way, such a rotation about an arbitrary point can be obtained by translating the origin first and then rotating, or equivalently, multiplying the matrix A in (9.48) by that in (2.20), with resulting matrix describing the combined transformation. That is,

$$(x_1', x_2', x_3', 1) = (x_1, x_2, x_3, 1)\begin{pmatrix} \cos\alpha_1 & \cos\beta_1 & \cos\gamma_1 & 0 \\ \cos\alpha_2 & \cos\beta_2 & \cos\gamma_2 & 0 \\ \cos\alpha_3 & \cos\beta_3 & \cos\gamma_3 & 0 \\ t_1 & t_2 & t_3 & 1 \end{pmatrix}. \tag{2.34}$$

From the vector and matrix form, the generalization to $\mathbb{R}^N$ is direct, with a slight change in notation denoting the direction angle between the x_i axis and a directed line $\ell \subset \mathbb{R}^N$ by α_i and the unit vector in the direction of ℓ:

$$\hat{\ell} = \sum_{i=1}^{N} \hat{\mathbf{e}}_{\mathbf{i}} \cos\alpha_i, \quad \sum_{i=1}^{N} \cos^2\alpha_i = 1. \tag{2.35}$$

Proceeding as above, the corresponding $(N+1)\times(N+1)$ transformation matrix is obtained *together* with the $(N^2+N)/2$ additional conditions analogous to (9.47): N conditions from the above equation and $N(N-1)/2$ more due to the orthogonality of all pairs of axes.

2.9 ** Analytic Proofs

$\mathcal{D}$esargues's theorem will be helpful in subsequent chapters. This is an oppurtune time to prove it and learn yet another nice way to utilize homogeneous coordinates.

2.9.1 Computational Proof

Three noncollinear points P_i, specified in homogeneous coordinates by triples $A_i, i = 1, 2, 3$, are chosen on the projective plane $\mathbb{P}^2$. Another point P, with triple A, is selected such that $A = c_1 A_1 + c_2 A_2 + c_3 A_3$ with all $c_i \neq 0$. Each point P_i is also represented by the triple $c_i A_i = A_i^*$, which are fixed from now on, leaving $A = A_1^* + A_2^* + A_3^*$. Any other point Q can be described as $Q = a_1 A_1^* + a_2 A_2^* + a_3 A_3^*$ with the A_i^* of the multiples now fixed. The coefficients can be used as a new set of coordinates, i.e., $Q = (a_1, a_2, a_3)$ and $P_1 = (1, 0, 0), P_2 = (0, 1, 0), P_3 = (0, 0, 1), P = (1, 1, 1)$. In this coordinate system it is easy to see that $Q = (a_1, a_2, a_3)$ and $Q' = k(a_1, a_2, a_3), k \neq 0$, represent the same point, allowing us to write $Q = Q'$. This is similar to homogeneous coordinates with 0 in the third position no longer implying that the point is ideal. This turns out to be a very useful tool.

To illustrate, we provide an analytic proof of Desargues's theorem. It is convenient to take the triangle's vertices A, B, C as the basis triples and $P = A + B + C$ or $P = (1, 1, 1)$ as the point of perspectivity, as shown in Fig. 2.26. The three lines from P through the vertices of the triangle are denoted by a', b', and c'. With $A = (1, 0, 0)$ and $P = (1, 1, 1)$ on a', from (2.4) we find that

$$a' = \left[\begin{vmatrix} 1 & 1 \\ 0 & 0 \end{vmatrix}, \begin{vmatrix} 1 & 1 \\ 0 & 1 \end{vmatrix}, \begin{vmatrix} 1 & 1 \\ 1 & 0 \end{vmatrix} \right] = [0, 1, -1].$$

For a point $A' = (a, a_1, a_2) \in a'$, where $A \neq A'$, the collinearity of P, A, A' and (2.3) yield

$$\begin{vmatrix} a & a_1 & a_2 \\ 1 & 1 & 1 \\ 1 & 0 & 0 \end{vmatrix} = 0,$$

which shows that $a_1 = a_2$. Since these values are arbitrary, we can take $A' = (a, 1, 1)$. Similarly, we obtain the line coordinates $b' = [1, 0, -1]$, $c' = [1, -1, 0]$ and the point coordinates $B' = (1, b, 1)$, $C' = (1, 1, c)$. Let r be the line determined by A and B. Then

$$r = \left[\begin{vmatrix} 0 & 0 \\ 1 & 0 \end{vmatrix}, \begin{vmatrix} 0 & 1 \\ 0 & 0 \end{vmatrix}, \begin{vmatrix} 1 & 0 \\ 0 & 1 \end{vmatrix} \right] = [0, 0, 1].$$

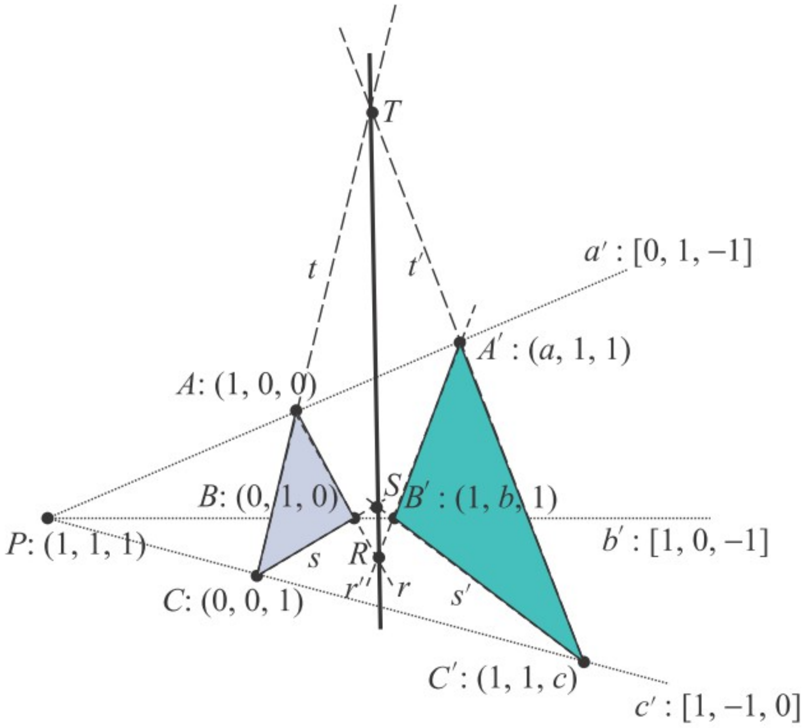

Figure 2.26. Diagram for analytic proof of Desargue's theorem.

Similarly, for the line r' determined by A' and B',

$$r' = \left[\begin{vmatrix} 1 & 1 \\ b & 1 \end{vmatrix}, \begin{vmatrix} a & 1 \\ 1 & 1 \end{vmatrix}, \begin{vmatrix} a & 1 \\ 1 & b \end{vmatrix} \right] = [1-b, a-1, ab-1].$$

To find the intersection $r \cap r' = R$, we can use the *dual* of (2.4). That is, in its original form, (2.4) yields the coordinates of the *line* determined by the coordinates of two of its points. In the dual, the same equation yields the coordinates of the *point* on the two lines from their coordinates. Namely,

$$R = \left(\begin{vmatrix} 0 & 1 \\ a-1 & ab-1 \end{vmatrix}, \begin{vmatrix} 1 & 0 \\ ab-1 & 1-b \end{vmatrix}, \begin{vmatrix} 0 & 0 \\ 1-b & a-1 \end{vmatrix} \right)$$

$$= (1-a, b-1, 0).$$

Continuing in the same way, we obtain

$$S = BC \cdot B'C' = s \cap s' = (0, 1 - b, c - 1),$$

$$T = AC \cdot A'C' = t \cap t' = (a - 1, 0, 1 - c).$$

Applying again (2.3) with the coordinates found for R, S, T yields

$$\begin{vmatrix} 1-a & b-1 & 0 \\ 0 & 1-b & c-1 \\ a-1 & 0 & 1-c \end{vmatrix} = 0,$$

showing that R, S, and T are always collinear, proving Desargues's theorem in the *projective plane*.

2.9.2 Algebraic Proof

When the coordinates of the points and lines are not explicitly needed, their computation can be avoided with an algebraic proof. In Fig. 2.26, let all points be identified by their homogeneous coordinate triples. By the collinearity of P, A, A' there exist nonzero constants c_1, c_2 such that

$$P = c_1 A + c_2 A'. \tag{2.36}$$

The multiple $c_1 A$ identifies the *same* point as A, and similarly, $c_2 A'$ identifies $-A'$. Without loss of generality we can take the triples $c_1 A, c_2 A'$ for the representation of the points $A, -A'$, simplifying (2.37) to

$$P = A - A'. \tag{2.37}$$

The new triples for A, A' then remain *fixe* as in the previous section. Similarly, there exist constant multiples of B, B', C, C' such that

$$P = B - B', \quad P = C - C'. \tag{2.38}$$

Then

$$A - B = A' - B'. \tag{2.39}$$

The point $A - B$ is on the line AB, and the point $A' - B'$ is on $A'B'$. Therefore,

$$A - B = A' - B' = R = AB \cap A'B'. \tag{2.40}$$

Continuing, we obtain

$$C - A = C' - A' = T = AC \cap A'C', \quad B - C = B' - C' = S = BC \cap B'C'. \tag{2.41}$$

Altogether,

$$R + S + T = A - B + C - A + B - C = 0, \tag{2.42}$$

showing that the intersection points R, S, and T are collinear.

It is worth contrasting these proofs with the synthetic proofs of Desargues's theorem, as illustrated in Fig. 2.27.

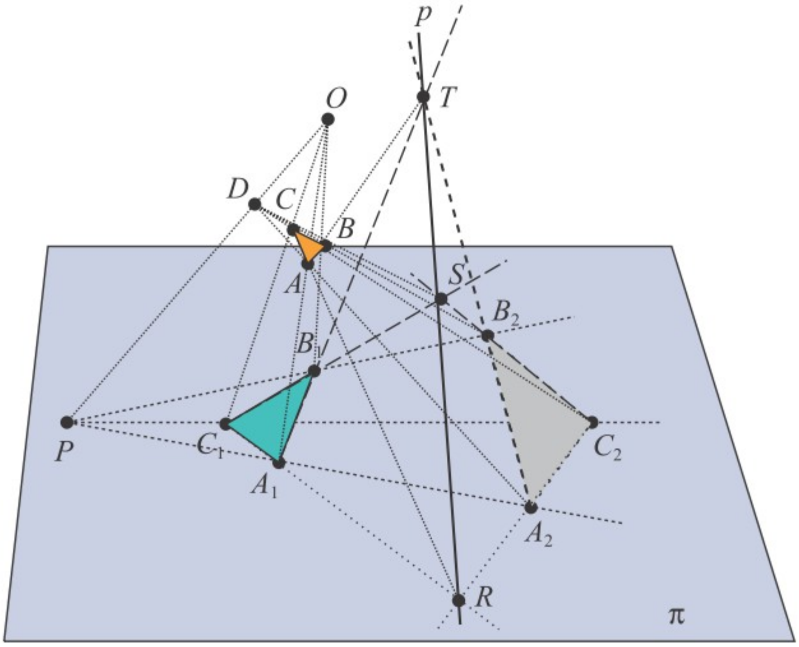

Figure 2.27. Diagram for the synthetic proof of Desargues theorem.
This proof involves embedding the 2-D perspectivity in 3-D. The theorem statement is that *two triangles in perspective from a point* P *are in perspective from a line* p.

Fun and Games with the ILM

Open the ILM: set *Chapter* = *Geometry* and click on *"Lock Guides."*
The display shows **Desargues's theorem** with the three intersection points R, S, T collinear.
Click and move any of the **red** triangle vertices along the lines.
The three points R, S, T remain collinear.

Next set *Example* = *Pappus* and click on *"Lock Guides."*
The display shows **Pappus's theorem**.
Again click on and move any of the six points A_i, B_i along the lines.
The three intersection points C_i remain collinear.

Exercises

1. Provide an analytic proof of Pappus's theorem.
2. Generalize and find the representation of the ideal elements of $(\mathbb{R}^3, p_\infty)$ in terms of ordered quadruples.
3. Generalize the representation of the ideal elements of $\mathbb{P}^N$ in terms of ordered $(N+1)$-tuples.

2.10 ** Conics on the Projective Plane

Curves can be considered as a collection of points and dually as a collection of lines whose *envelope* forms a curve, (see Fig. 2.28.) To distinguish them, they are referred to as *point-curves* and *line-curves* respectively. The duality of the projective plane enables us to treat them equivalently and leads to some nice results, illustrated here with conic point- and line-curves.

2.10.1 In the Projective Plane All Conics Are Ellipses

That all conics are ellipses in the projective plane can be observed on the right of Fig. 2.28, which relates to the position of an ellipse with respect to the ideal line l_∞. That is, an ordinary (Euclidean) ellipse has no ideal points, and a Euclidean parabola corresponds to an ellipse tangent to the ideal line and hence having one ideal point corresponding to the direction in which the parabola "opens toward

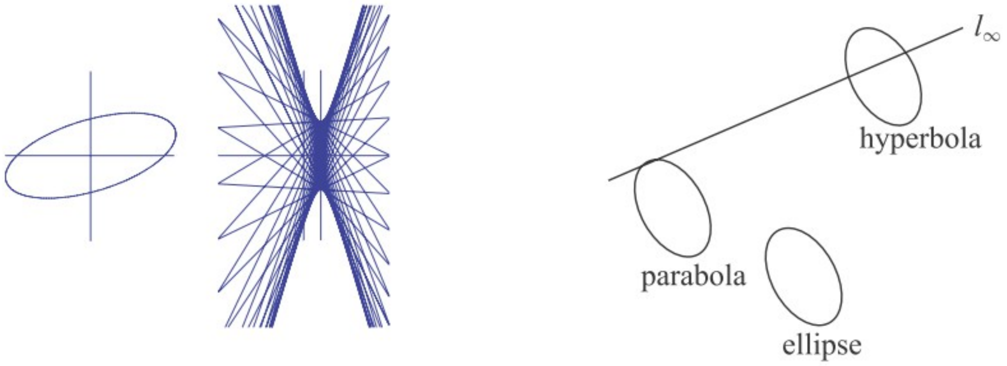

Figure 2.28. Ellipse (point-curve) and hyperbola (line-curve). Projective conics are ellipses.

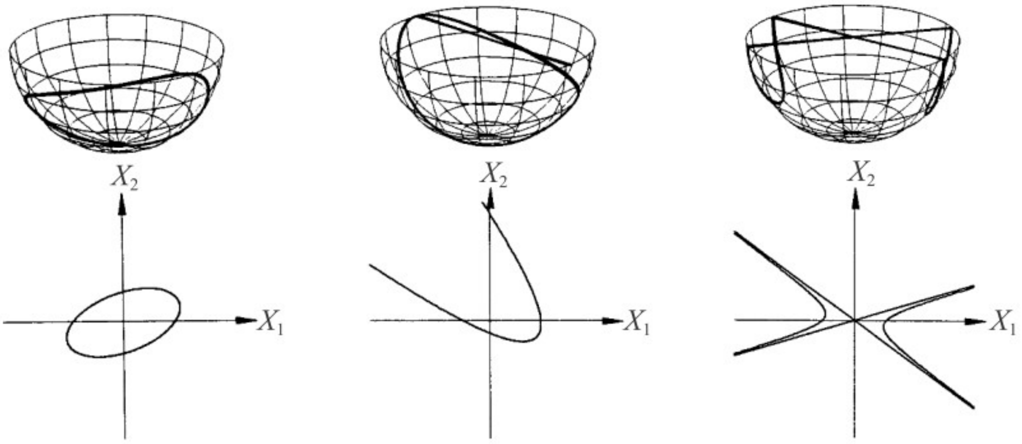

Figure 2.29. Ellipse (left), parabola (center), and hyperbola (right) in the projective plane model.

infinity." A Euclidean hyperbola is a projective ellipse intersecting l_∞ at two ideal points corresponding to the directions of its asymptotes. The three cases in Fig. 2.29 are shown in the projective plane model.

2.10.2 Generalizing Pappus's Theorem

In 1640, Pascal generalized Pappus's theorem to conics.

Theorem 2.10.1 **(Pascal)** *If a simple hexagon* $A_1A_2A_3B_1B_2B_3$ *is inscribed in a conic, the intersections* $C_i = A_jB_k \cdot A_kB_j$, $i \neq j \neq k$, *are collinear.*

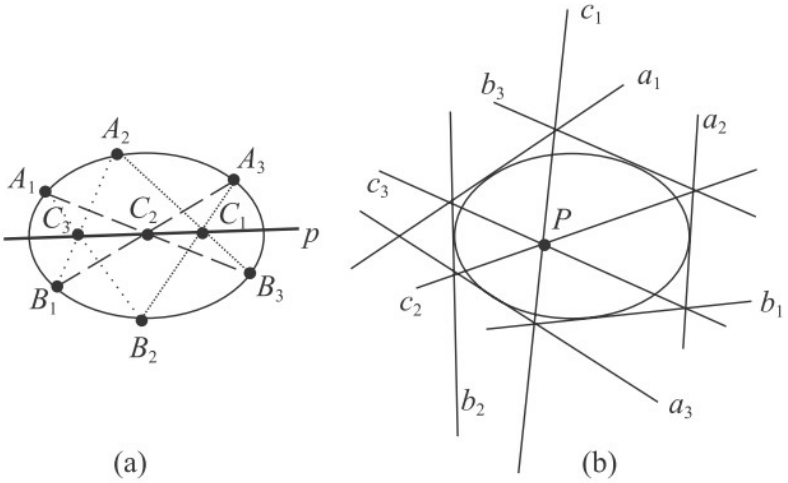

Figure 2.30. Pascal's theorem (a) and its dual, Briachnon's theorem (b).

Briachnon proved the result depicted in Fig. 2.30 in 1806, which turned out to be the *dual* of Pascal's theorem.

2.11 ** Geometries and Invariants

As already mentioned in connection with (2.10), homogeneous coordinates can be extended to higher dimensions. Specifically, a point $P \in \mathbb{P}^N$ is represented by an (N+1)-tuple, the *point* coordinates

$$P = (x_1, x_2, \dots, x_N, x_{N+1}) \text{ or } (kx_1, kx_2, \dots, kx_N, kx_{N+1}), k \neq 0,$$

where not all components are zero. Dually, a hyperplane π is represented by the $(N+1)$-tuple

$$\pi = [X_1, X_2, \dots, X_N, X_{N+1}], \text{ or } [kX_1, kX_2, \dots, kX_N, kX_{N+1}],$$

where again not all components are zero, these being the *hyperplane* coordinates of π. The *on* relation as before is defined by the inner product of the coordinates, i.e.,

$$P \text{ } on \text{ } \pi \iff \sum_{i=1}^{N+1} x_i X_i = 0.$$

A projective transformation in $\mathbb{P}^N$ is expressed by (2.10) and can be linearized by homogeneous coordinates. Projective transformations leave the cross-ratio invariant, and they are the most general transformations employed in projective geometry.

Various geometries were developed during the nineteenth century in addition to the Euclidean: affine, projective, spherical and inversive. Felix Klein proposed a way of classifying geometries that became known as the Erlangen Program, since he was a professor at the University of Erlangen. A geometry is regarded as a *space* together with a *group of transformations* acting on it. Geometrical properties are those remaining *invariant* under the group of transformations. As a reminder, a group is a set of elements G and a binary operation $\circ$ with

$a \circ b = c \in G \ \forall a, b \in G$ (closure property),
$(a \circ b) \circ c = a \circ (b \circ c)$ (associativity)
$\exists\, e \in G \ni a \circ e = e \circ a = a, \forall a \in G$ (identity)
$\forall a \in G \ \exists a^{-1} \ni a^{-1} \circ a = a \circ a^{-1} = e$ (inverse).

Exercises

Show that the set of all linear fractional transformations (i.e., the projective transformations) with the composition operation form a group.

The group of projective transformations has important special cases that form subgroups of transformations, i.e., subsets that are groups. With slight changes in the notation, consider the case of *translations*, for which the b's in the denominator of (2.10) are zero except for the last one, i.e.,

$$\mathbf{x}' = \mathbf{x}A + \mathbf{c},$$

with row vectors denoted in **bold**, e.g., $\mathbf{x}$, and A is an $N \times N$ matrix. In general, a mapping

$$L : D \to D$$

is a *linear transformation* if it preserves linear combinations, i.e.,

$$L(a\mathbf{x} + b\mathbf{y}) = aL(\mathbf{x}) + bL(\mathbf{y}).$$

A general *affine* transformation can be written as

$$T(\mathbf{u}) = L(\mathbf{u}) + \mathbf{c},$$

where $\mathbf{c}$ is a constant vector and L is a linear transformation. In this case,

$$T(a\mathbf{x}+b\mathbf{y}) = aL(\mathbf{x}) + bL(\mathbf{y}) + \mathbf{c} \neq aT(\mathbf{x}) + bT(\mathbf{y}) = aL(\mathbf{x}) + bL(\mathbf{y}) + 2\mathbf{c}.$$

In short, translations are not linear transformations. Affine transformations leave *convex* combinations $\left(\sum a_i x_i,\ \text{where } \sum a_1 = 1\right)$ invariant and also preserve *incidence* (i.e., the *on* relation).

Let us return to the representation

$$\mathbf{x}' = \mathbf{x}A + \mathbf{c}$$

and consider the case where the matrix has the property $AA^T = \lambda^2 I$, where λ is real and ^{T} denotes the transpose of a matrix. This is the *similarity* group. First take the case $\mathbf{c} = \mathbf{0}$. The square of the length, $|\mathbf{x}|$, of $\mathbf{x}$ is given by $\mathbf{x}\cdot\mathbf{x} = \mathbf{x}\mathbf{x}^T$ and is called the *norm* of $\mathbf{x}$. For the similarity transformation $\mathbf{x}' = \mathbf{x}A$, we have

$$\mathbf{x}'\cdot\mathbf{x}' = (\mathbf{x}A)\cdot(\mathbf{x}A) = \lambda^2\mathbf{x}\cdot\mathbf{x}.$$

Effectively, $|\mathbf{x}|$ has been amplified by $\pm\lambda$. For two vectors $\mathbf{x}$, $\mathbf{y}$, under similarity we obtain

$$\mathbf{x}'\cdot\mathbf{y}' = \lambda^2\mathbf{x}\cdot\mathbf{y} \quad \mathbf{x}\cdot\mathbf{y} = |\mathbf{x}|\cdot|\mathbf{y}|\cos(\mathbf{x},\mathbf{y}),$$

where $(\mathbf{x},\mathbf{y})$ is the angle between the two vectors. So

$$|\mathbf{x}'|\cdot|\mathbf{y}'|\cos(\mathbf{x}',\mathbf{y}') = \lambda^2|\mathbf{x}|\cdot|\mathbf{y}|\cos(\mathbf{x},\mathbf{y}).$$

Therefore, $\mathbf{x}\perp\mathbf{y} \iff \mathbf{x}'\perp\mathbf{y}'$, and in general, $\cos(\mathbf{x}',\mathbf{y}') = \cos(\mathbf{x},\mathbf{y})$. So under similarity, the ratio of distances and angles between vectors is preserved, or

$$\frac{|\mathbf{x}'|}{|\mathbf{y}'|} = \frac{|\mathbf{x}|}{|\mathbf{y}|}.$$

Specializing further to *orthogonal* matrices with $|A| = \pm 1$ or $|A||A^T| = |A|^2 = 1$, where $|A|$ denotes the determinant of A, we obtain the important group of orthogonal transformations.

The Euclidean distance between two vectors $\mathbf{x}, \mathbf{y}$ is given by $d(\mathbf{x},\mathbf{y}) = [(\mathbf{x}-\mathbf{y})\cdot(\mathbf{x}-\mathbf{y})^T]^{1/2}$:

$$\begin{aligned} d(\mathbf{x}',\mathbf{y}') &= [(\mathbf{x}'-\mathbf{y}')\cdot(\mathbf{x}'-\mathbf{y}')^T]^{1/2} = [(\mathbf{x}-\mathbf{y})AA^T(\mathbf{x}-\mathbf{y})^T]^{1/2} \\ &= [(\mathbf{x}-\mathbf{y})\cdot(\mathbf{x}-\mathbf{y})^T]^{1/2} = d(\mathbf{x},\mathbf{y}), \end{aligned}$$

showing that distance is also invariant under orthogonal transformations. Altogether then, areas, angles, and orthogonality are also preserved. All these together with the “pure” translation

$$\mathbf{x}' = \mathbf{x} + \mathbf{c}$$

form the *rigid motions*, which are the invariants of Euclidean geometry.

To recapitulate, as pointed out by Klein, the above geometries are projective geometries with additional conditions. For example, affine geometry is obtained by selecting any line in a projective geometry and considering only the transformations leaving that line invariant. This line plays the role of the ideal line and can be safely ignored. The reader is referred to [163], [157] for background and history of N-dimensional geometry, and to [152], [18] for learning more about the various geometries. Aspects of differential geometry, starting with a short chapter on the theory of envelopes, are covered later in the study of curves and surfaces.

3

♣ FT-1 The Plane with Parallel Coordinates

3.1 The Fundamental Duality

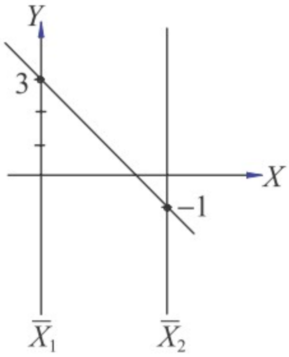

Figure 3.1. Points on the plane are represented by lines.

A point in the x_1x_2 plane is represented in parallel coordinates (abbreviated ∥-coords) by a line in the xy-plane (Fig. 3.1). To find out what a line "looks like" in ∥-coords, a set of collinear points is selected (Fig. 3.2, top right), and the lines representing them intersect (top left) at a point! Remarkably, this is true in general, and for the line

$$\ell : x_2 = mx_1 + b, \tag{3.1}$$

the corresponding point is

$$\bar{\ell} : \left(\frac{d}{1-m}, \frac{b}{1-m} \right), \quad m \neq 1, \tag{3.2}$$

where d is the distance between the parallel axes. As will be appreciated later, the interaxis distance is *directed*, so that interchanging the axes makes the sign of d negative. The point $\bar{\ell}$ is said to *represent* the line ℓ. It is evident that a point ↔ line duality[15] is at work here, which must be properly considered in the *projective* $\mathbb{P}^2$ rather than the Euclidean $\mathbb{R}^2$ plane. In (3.2), as

degree. This was the case with Rhind's discovery. The scroll was 1 foot wide and 18 feet long but missing its middle portions. The content of the scroll that remained was seen to be written in the ancient Egyptian writing called **hieratic**. Beginning as a simple modification of hieroglyphics, hieratic later became a language in which each syllable is represented as a symbol and each symbol represents a particular idea. Because of this connection to hieroglyphics, the Rosetta Stone made possible the translation of the scroll that we know as the **Rhind Mathematical Papyrus** (Kline 1972, 15–16).

About four years after Rhind found his papyrus, the American Edwin Smith was studying in Egypt when he purchased what he believed to be a scroll on ancient Egyptian medicine. However, it was a fraud. Someone had taken pieces from a papyrus and created what looked like a scroll, but only the outside layers were ancient Egyptian. The inside was fake. Smith was an expert on Egypt, and it seems that it would be unlikely for someone in his position to be fooled by a forgery. We must remember, however, that the condition of any found papyri will be very fragile. It takes time and care to open an ancient scroll. Fortunately for posterity, Smith kept his find, and it went with the rest of his collection to the New York Historical Society after his death. In 1922 experts at the museum determined that the fraudulent scroll was assembled using the lost pieces of Rhind's papyrus! The pieces were shipped to the British Museum, where experts were able to fit together most of the missing section and complete its translation (Burton 1985, 36).

Other papyri discovered are the Golenischev Papyrus, usually called the **Moscow Papyrus** because it is now a part of the collection of the Museum of Fine Arts in Moscow, and a second purchase of Rhind's, which we know as the **Egyptian Mathematical Leather Scroll**. All of these finds have greatly aided our understanding of ancient Egyptian mathematics. The ancient Egyptian's wrote their mathematics in the form of questions followed by answers. The goal was to calculate values associated with government and commerce, specifically the computation of areas and volumes. They used specific numbers to solve problems, and they did not generalize their results. Any formulas that they did use were not deduced from first principles but were discovered empirically by trial and error. Because of this, some of their formulas were not accurate but only approximations, which, considering their needs, often sufficed. The greatest mystery regarding the mathematics of the ancient Egyptians is that for about two millennia they made very little progress beyond their initial work (Burton 1985, 36, 52, 57, 64).

Approximations

The mathematical scrolls show that the Egyptians did not distinguish between algebra and geometry. They viewed mathematics simply as a tool by which to obtain needed values. They had formulas for basic areas and volumes. This included the volumes of a cube and a cylinder. There is some debate in academic circles as to whether the Egyptians ever gave any justifications for any of the steps in their solutions. None have been discovered, but it is clear that the Egyptians did not consider geometry to be a logical system (Kline 1972, 19–20).

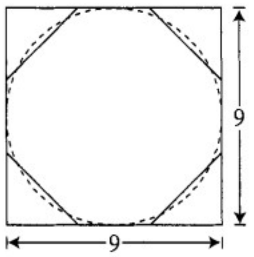

Figure 1.1 Using a 9 × 9 square to estimate the area of a circle.

The Rhind Mathematical Papyrus provides an example of an ancient Egyptian formula that did satisfactorily approximate its intended value. Take a square with sides of length 9. Trisect each of the sides, and then by joining consecutive points at the corners, create a regular octagon. This is illustrated in Figure 1.1, but we must note that the diagram found in the papyrus was a simple sketch of this diagram without the circle. The scribe of the papyrus considered the octagon a good estimate for the area of the circle. To find the octagon's area, we simply remove the four equilateral triangles from the square. Therefore, its area is

$$9^2 - 4 \cdot \frac{9}{2} = 63.$$

It is conjectured that this provided the ancient Egyptians a reason to believe that for a circle of diameter d,

$$A \approx \left(\frac{8d}{9}\right)^2. \tag{1.1}$$

The Egyptians could have relied on the octagonal estimate in support of Equation 1.1 because it yields an area of 64 square units when $d = 9$, which is close to the Rhind approximation. Furthermore, notice what Equation 1.1 implies about the Egyptian value of π. Since $A = \pi d^2/4$, we substitute Equation 1.1 to find

$$\pi \approx 3\frac{13}{81} = 3.16049\ldots. \tag{1.2}$$

This is very close to the common approximation of $3\frac{1}{7}$ (Burton 1985, 58).

An example of an equation from ancient Egypt that did not provide very good estimates is one that was found at the temple of Horus at Edfu. The priests of the temple received gifts in the form of patches of land. Each plot was in the form of a quadrilateral but was not necessarily rectangular. If we let a, b, c, and d represent the lengths of consecutive sides of the quadrilateral, their formula is

$$A = \frac{1}{4}(a + c)(b + d).$$

Notice that this amounts to multiplying the average of opposite sides together. It is not a bad estimate for regions that are nearly rectangular, but for most quadrilaterals it is an example of an instance when the Egyptians did try to generalize a result but did it poorly (Burton 1985, 57).

Pyramids

Herodotus recounts an encounter that he had with one of the priests (Burton 1985, 62–63). He claims that he was told that the Great Pyramid was designed so that the area of a square with side equal to the height of the pyramid is equal to the area of one of the faces of the pyramid. Using Figure 1.2, this is equivalent to writing

$$h^2 = \frac{1}{2}(2ba) = ab,$$

where $2b$ is the length of one of the sides of its square base, a is the altitude of one of the faces, and h is the height of the pyramid. From this we can calculate the ratio b/a by first noting that since

$$h^2 + b^2 = a^2,$$

we have

$$a^2 - b^2 = ab.$$

Dividing through by a^2 and a little rearranging yields

$$\left(\frac{b}{a}\right)^2 + \frac{b}{a} - 1 = 0.$$

This is a quadratic equation with b/a serving as the unknown. Thus, since both a and b are positive,

$$\frac{b}{a} = \frac{\sqrt{5} - 1}{2}. \tag{1.3}$$

Geometrically, a **pyramid** is a solid consisting of a collection of polygons joined at their edges. Recall that a **polygon** is a closed plane figure consisting of line segments called **sides**. An endpoint of a side is called a **vertex**. A polygon with n sides is often called an ***n*-gon**. If all the sides of the polygon are of the same magnitude and if the same can be said of the interior angles, the polygon is **regular**. In a pyramid one

EXERCISE

Dualize Theorem 4.31 and Figure 4.3B.

4.4 Pappus and Desargues

We are now ready to prove one of the oldest of all projective theorems. Pappus of Alexandria, living in the fourth century A.D., used a laborious development of Euclid's methods (see Reference **21**, pp. 286–290, and **8a**, pp. 66–69).

4.41 PAPPUS'S THEOREM: *If the six vertices of a hexagon lie alternately on two lines, the three pairs of opposite sides meet in collinear points.*

PROOF. Let the hexagon be $AB'CA'BC'$, as Figure 4.4A (which shows two of the many different ways in which it can be drawn). Since alternate vertices are collinear, there is a projectivity $ABC \barwedge A'B'C'$. The pairs of opposite sides, namely

$$B'C, BC'; \qquad C'A, CA'; \qquad A'B, AB',$$

are just the cross-joins of the pairs of corresponding points

$$BB', CC'; \qquad CC', AA'; \qquad AA', BB'.$$

By Theorem 4.31, their points of intersection

$$L = B'C \cdot BC', \qquad M = C'A \cdot CA', \qquad N = A'B \cdot AB'$$

all lie on the axis of the projectivity.

Alternatively, using further points

$$J = AB' \cdot CA', \qquad E = AB \cdot A'B', \qquad K = AC' \cdot CB',$$

we have

$$ANJB' \overset{A'}{\barwedge} ABCE \overset{C'}{\barwedge} KLCB'.$$

Thus B' is an invariant point of the projectivity $ANJ \barwedge KLC$. By Theorem 4.22, this projectivity is a perspectivity, namely

$$ANJ \overset{M}{\barwedge} KLC.$$

Thus M lies on NL; that is, L, M, N are collinear.

Similarly, since Theorem 4.22 is a consequence of the five axioms 2.13, 3.11, 3.12, 2.17, 2.18, we could have proved 2.32 (Desargues's theorem) as follows.

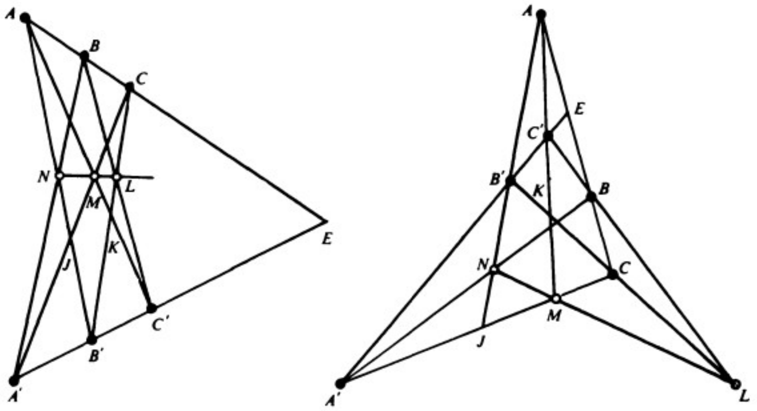

FIGURE 4.4A

Assuming that the lines PP', QQ', RR' all pass through O, as in Figure 2.3A, we define $D = QR \cdot Q'R'$, $E = RP \cdot R'P'$, $F = PQ \cdot P'Q'$ and three further points

$$A = OP \cdot DE, \qquad B = OQ \cdot DE, \qquad C = OR \cdot DE.$$

Then

$$OPAP' \overset{E}{\barwedge} ORCR' \overset{D}{\barwedge} OQBQ',$$

so that O is an invariant point of the projectivity $PAP' \barwedge QBQ'$. By 4.22, this projectivity is a perspectivity. Its center, F, lies on AB, which is DE; that is, D, E, F are collinear.

This procedure (see Reference **20**, p. 16) has the advantage of allowing us to omit 2.32 from the list of two-dimensional axioms proposed in Section 3.1. (The list is thus seen to be redundant: only five of the six are really needed.) It has the disadvantage of making Theorem 3.51 depend on Axiom 2.18, so that the theorem can no longer be used to make the axiom plausible!

We saw, in Section 3.2, that the figure for Desargues's theorem is a self-dual configuration 10_3. Somewhat analogously, the figure for Pappus's theorem is a self-dual configuration 9_3: nine points and nine lines, with three points on each line and three lines through each point. This fact becomes evident as soon as we have made the notation more symmetrical by calling the nine points

$$A_1 = A,\ \ B_1 = B,\ \ C_1 = C,\ \ A_2 = A',\ \ B_2 = B',\ \ C_2 = C',$$
$$A_3 = L,\ \ B_3 = M,\ \ C_3 = N$$

and the nine lines

$$a_1 = BL,\quad b_1 = AM,\quad c_1 = A'B',\quad a_2 = CM,\quad b_2 = CL,\quad c_2 = AB,$$
$$a_3 = AN,\quad b_3 = BN,\quad c_3 = LM.$$

The three triangles

$$A_1B_1C_2,\ A_2B_2C_3,\ A_3B_3C_1 \quad \text{or} \quad a_1b_1c_2,\ a_3b_3c_1,\ a_2b_2c_3$$

provide an instance of *Graves triangles:* a cycle of three triangles, each inscribed in the next. (See page 130 of Graves's paper mentioned in Exercise 2 of Section 3.2. This aspect of the Pappus configuration was rediscovered by G. Hessenberg.)

EXERCISES

1. Using the "symmetrical" notation for the Pappus configuration, prepare a table showing which are the three points on each line and which are the three lines through each point. Observe that the three points A_i, B_j, C_k are collinear (and the three lines a_i, b_j, c_k are concurrent) whenever $i + j + k$ is a multiple of three. (Reference **12a**, p. 108.)
2. Given a triangle $A_1A_2A_3$ and two points B_1, B_2, locate a point B_3 such that the three lines A_1B_1, A_2B_3, A_3B_2 are concurrent while also the three lines A_1B_3, A_2B_2, A_3B_1 are concurrent. Then also the three lines A_1B_2, A_2B_1, A_3B_3 are concurrent; in other words, *if two triangles are doubly perspective, they are triply perspective.* (Reference **19**, p. 100.)
3. What can be said about the three "diagonals" of the hexagon $A_1B_3A_2B_2A_3B_1$?
4. State the dual of Pappus's theorem and name the sides of the hexagon in the notation of Exercise 1.
5. Consider your solution to Exercise 2 of Section 4.2. Could this be developed into a proof of Pappus's theorem?
6. If one triangle is inscribed in another, any point on a side of the former can be used as a vertex of a third triangle which completes a cycle of Graves triangles (each inscribed in the next).
7. Assign the digits 0, 1, . . . , 8 to the nine points of the Pappus configuration in such a way that 801, 234, 567 are three triads of collinear points while 012, 345, 678 is a cycle of Graves triangles. (E. S. Bainbridge.*)

CHAPTER ELEVEN

Parallelism

> Projective geometry was historically developed as a part of Euclidean geometry. . . . Von Staudt, for instance, still needed the parallel axiom in his study of the foundations of projective geometry. Klein, in his work on non-Euclidean geometry, established the independence of projective geometry from the theory of parallels (in 1871). This opened the possibility of an independent foundation for projective geometry. The pioneer work was done by Moritz Pasch (in 1882).

11.1 Is the Circle a Conic?

The attentive reader must have noticed that most of the conics appearing in our figures look like something that has been familiar ever since he first saw the full moon: they look like *circles*. This observation raises the important question: *Is the circle a conic*? We can answer *Yes* as soon as we have found a characteristic property of a conic that is also a property of the familiar circle. One way to do this is to give a Euclidean definition for the pole-and-polar relation with respect to a circle, and carry the discussion far enough to find that this relation satisfies the projective definition for a polarity. A quicker way is to give a Euclidean proof for the Braikenridge-MacLaurin construction (Figure 9.2B). More precisely, we select five points on a circle and prove that the unique conic that can be drawn through these points coincides with the circle. For convenience we shall take the five points A, P, B, Q, C

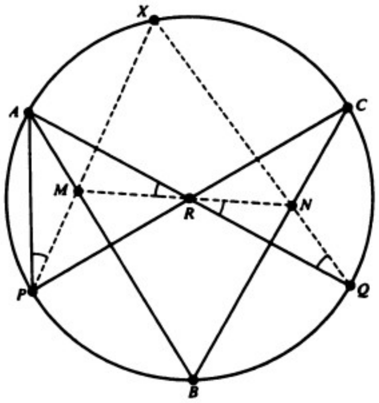

FIGURE 11.1A

(Figure 11.1A) to be five of the six vertices of a regular hexagon inscribed in the circle.

The following simple proof is due to S. L. Greitzer. Let AQ and CP meet in R (which is, of course, the center of the circle), let a variable diameter meet AB in M, BC in N, and let PM meet QN in X. Since AB, being a median of the equilateral triangle APR, is the perpendicular bisector of PR, and similarly BC is the perpendicular bisector of QR, we have

$$\angle XPA = \angle MPA = \angle ARM = \angle QRN = \angle NQR = \angle XQA.$$

By Euclid III.21 and 22, the locus of X is the circle APQ. By the Braikenridge-MacLaurin construction, the locus of X is the conic $APBQC$. Hence the conic coincides with the circle.

EXERCISES

1. What happens when the diameter is parallel to AB?
2. How does the proof have to be modified if A, P, B, Q, C are arbitrarily placed on the circle?

11.2 Affine Space

The time has come for us to investigate the connection between projective space, as determined by our axioms, and *affine* space, that is, the ordinary space of elementary solid geometry, in which two coplanar lines, or a line and a plane, or two planes, are said to be *parallel* if they do not meet. Instead of deliberately modifying the customary notions of space as we did in Section 1.1, let us now exploit the powerful theory of parallelism as Euclid did in his eleventh book. The idea of parallel lines leads immediately to that of a parallelogram, and thence to ratios of distances along parallel lines, or on one line (Reference **7**, pp. 2, 115–128; Reference **8**, pp. 175, 202, 222).

I. M. Yaglom, in the third volume of his *Geometric Transformations* (Reference **23**, pp. 10, 21), shows two sketches of a house. The former depicts the living-room on a sunny day. The window panes cast shadows on the floor. The rectangles are distorted into parallelograms, but those that are equal remain equal. Affine geometry deals with properties that are maintained by such "parallel projection." His other sketch is a night scene outside the house. A lamp inside casts shadows of the same window panes on the lawn. The rectangles are distorted into quadrangles of various sizes, but their sides are still straight. Projective geometry deals with properties that are maintained by such "central projection."

One way of expressing the connection is to regard affine space as *part of* projective space, namely, projective space minus one plane. For this purpose, we specialize any one plane of the projective space and call it "the plane at infinity." (It is still, of course, a *projective* plane.) Two lines, or a line and a plane, or two planes, are then said to be parallel if they meet on this special plane. We soon see that parallelism, so defined, has all its familiar properties.

Another way is to begin with the affine space, regarding its properties as known, and seeking certain figures which behave like the projective points and lines. Such a representation of the projective *plane* is easy: we can use the lines and planes through a fixed point O in the affine space. For instance, to verify 2.22 we merely have to observe that any two distinct planes α and β, through O, have just one common line, namely the line $\alpha \cdot \beta$. For projective *space*, the appropriate figures are bundles and axial pencils, defined as follows.

A *bundle* is the set of all lines and planes through a point.

An *axial pencil* is the set of all planes through a line.

When there is any possibility of confusion, the other kind of pencil (the set of all lines that lie in a plane and pass through a point) is called a *flat* pencil. In the terminology of Section 1.5, an axial pencil, like a flat pencil, is a "one-dimensional form." But a bundle is a combination of two two-dimensional forms: the set of *lines* through a point (which is the space-dual of the set of *lines* in a plane) and the set of *planes* through the same point (which is the space-dual of the set of *points* in a plane). What makes these forms useful in the present connection is that their description is precisely the same in affine space as in projective space.

Clearly, a range is determined by any two of its points, and these may be any two distinct points; a flat pencil is determined by any two of its lines, and these may be any two lines that meet; an axial pencil is determined by any two of its planes, and these may be any two planes that meet; finally, a bundle (like a flat pencil) is determined by any two of its lines.

EXERCISE

A range, a flat pencil, and an axial pencil are three kinds of one-dimensional form. Which two are space-duals of each other? Which one is its own dual (that is, which one is "self-dual")?

11.3 How Two Coplanar Lines Determine a Flat Pencil and a Bundle

If (in ordinary space) we are given a point P, and two coplanar lines a and b whose point of intersection O is inconveniently far away, how can we construct the line through P of the pencil or bundle determined by a and b? If O were available we could simply draw OP, but can we still locate this line without using O? If P is not in the plane ab, we merely have to draw the planes Pa and Pb; these meet in a line p through P, which is the desired line of the bundle (see Figure 11.3A). In a single symbol, the member through P (outside the plane ab) is the line

$$p = Pa \cdot Pb.$$

On the other hand, if P is in the plane ab, we can use an auxiliary point Q outside the plane, locate the member q through Q (which is the line OQ), and consider (as in Figure 11.3B) the line of intersection of the planes ab and Pq. In other words, the line through P (of the bundle or pencil) is now

$$p = ab \cdot Pq \quad \text{where} \quad q = Qa \cdot Qb.$$

This construction owes its importance to the fact that it remains valid when a and b are parallel, so that O does not exist! The lines a, b, q, p, which originally passed through O, are now all parallel.

A practical model for this new situation is easily made by dividing a rectangular card into four unequal strips (of widths roughly proportional to

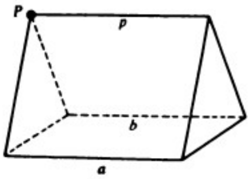

FIGURE 11.3A

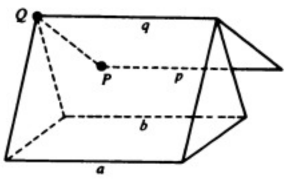

FIGURE 11.3B

4 : 6 : 7 : 5, as in Figure 11.3C) by three cuts made half-way through the thickness of the card. When suitably folded, this makes a solid version of Figure 11.3B.

Since we can derive p without inquiring whether a and b are parallel or not, we now feel justified in extending the meaning of the words *pencil* and *bundle* so as to allow the determining lines a and b to be *any two coplanar lines*. If a and b happen to be parallel, the bundle consists of all the lines and planes parallel to them, and the pencil consists of all the lines parallel to them in their own plane. Accordingly, we speak of a *bundle of parallels* and a (flat) *pencil of parallels*.

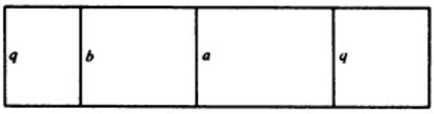

FIGURE 11.3C

It must be remembered that two planes may be parallel to a line without being parallel to each other. (For instance, in Figure 11.3B, the intersecting planes Qa and Qb are both parallel to the line p.) Thus a bundle of parallels contains a lot of lines, all parallel to one another, and a lot of planes, not all parallel to one another but each containing two (and therefore infinitely many) of the lines.

A familiar instance of a bundle of parallels is the set of all "vertical" lines and planes. If we take a cosmic standpoint and insist that two vertical lines are not strictly parallel but meet in the center of the earth, then we have an ordinary bundle instead of a bundle of parallels.

EXERCISE

Two lines parallel to the same line are parallel to each other. Does this remain true

(i) when the word "lines" is replaced by "planes,"
(ii) when the word "line" is replaced by "plane,"
(iii) when both substitutions are made simultaneously?

11.4 How Two Planes Determine an Axial Pencil

If we are given a point P, and two planes α and β whose line of intersection is far away, how can we construct the member through P of the axial pencil determined by α and β? This can be done by means of two applications of

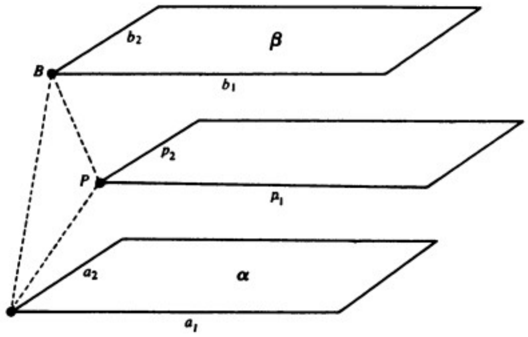

FIGURE 11.4A

the previous construction. We take any two intersecting lines a_1 and a_2 in α, and a point B in β (but not in either of the planes Pa_1, Pa_2), and draw the lines

$$b_1 = Ba_1 \cdot \beta, \qquad b_2 = Ba_2 \cdot \beta,$$
$$p_1 = Pa_1 \cdot Pb_1, \qquad p_2 = Pa_2 \cdot Pb_2,$$

as in Figure 11.4A. Then the desired plane through P is p_1p_2. For, if α and β meet in a line o, we may assume a_1 and a_2 to be chosen so as to meet o in two distinct points O_1 and O_2. Since $O_1 = o \cdot a_1$ lies in both the planes Ba_1 and β, it lies on their common line b_1. Since O_1 lies in both the planes Pa_1 and Pb_1, it lies on their common line p_1. Similarly O_2 lies on p_2. Therefore the join $o = O_1O_2$ lies in the plane p_1p_2.

If, on the other hand, α and β are parallel planes (conveyed by parallelograms in Figure 11.4A), the construction makes the lines b_1 and p_1 parallel to a_1, and the lines b_2 and p_2 parallel to a_2; therefore the plane p_1p_2 is parallel to α and β. Allowing P to take various positions, we thus obtain a *pencil of parallel planes*, consisting of all the planes parallel to a given plane.

A familiar instance is the set of all "horizontal"planes. If we insist that two horizontal planes are not strictly parallel but intersect in a line called the "horizon," then we have an ordinary axial pencil instead of a pencil of parallel planes.

EXERCISE

Can two lines be parallel to the same plane without being coplanar?

11.5 The Language of Pencils and Bundles

We have seen that a bundle can be derived from two of its lines, and an axial pencil from two of its planes, by constructions that remain valid when the two lines or planes are parallel.

Since an ordinary bundle consists of all the lines and planes through a point, and an ordinary axial pencil consists of all the planes through a line, any simple statement about points and lines can be "translated" into a corresponding statement about bundles and axial pencils. For instance, the statement

Any two distinct points lie on a line

becomes:

The common planes of any two distinct bundles form an axial pencil.

It is significant that the latter statement remains true when one of the bundles is replaced by a bundle of parallels, and again when *both* are replaced by bundles of parallels. In fact, the common planes of an ordinary bundle and a bundle of parallels form the ordinary axial pencil whose axis is the common line of the two bundles. (For instance, the bundle of lines and planes through any point O shares with the bundle of vertical lines and planes the vertical line through O and all the planes through this line.) Again, the common planes of two bundles of parallels form a pencil of parallel planes. (For instance, the bundle whose lines are horizontal in the north-south direction and the bundle whose lines are horizontal in the east-west direction have in common all the horizontal planes.)

EXERCISE

Translate the following statement into the language of pencils and bundles: *If two distinct lines have a common point they lie in a plane.*

11.6 The Plane at Infinity

These considerations serve to justify a convenient extension of space by the invention of an "ideal" plane whose points and lines represent the bundles of parallels and pencils of parallel planes, respectively. Remembering that an ordinary bundle consists of all the lines and planes through an ordinary point, we regard a bundle of parallels as consisting of all the lines and planes through an ideal point. Similarly, we regard a pencil of parallel planes as consisting of all the planes through an ideal line, and we say that an ideal point lies on an ideal line if the bundle contains the pencil. We can still assert that any two distinct points lie on a line. If one of the points is ordinary, so is the line; but if both are ideal, the line is ideal.

Since an ordinary bundle contains no pair of parallel planes, an ordinary point cannot lie on an ideal line; that is, all the "points" on an ideal line are ideal points. On the other hand, since a bundle of parallels contains ordinary axial pencils as well as pencils of parallel planes, an ideal point lies on some ordinary lines as well as on some ideal lines. Since any ordinary line belongs to just one bundle of parallels (consisting of all the lines and planes parallel to it), it contains just one ideal point, which we call its *point at infinity*. Thus we regard any two parallel lines as meeting in an ideal point: their common point at infinity. Since any plane belongs to just one pencil of parallel planes (consisting of all the planes parallel to it), it contains just one ideal line, which we call its *line at infinity*. Thus we regard any two parallel planes as meeting in an ideal line: their common line at infinity. In a given plane, each point on the line at infinity is the "center"of a pencil of parallel lines.

Since any two pencils of parallel planes belong to a bundle of parallels,

Any two ideal lines meet in an ideal point.

It follows that, if a and b are any two ideal lines, every other ideal line meets both a and b. This state of affairs resembles what happens in a plane. For, if a and b are two ordinary intersecting lines, every point in the plane ab lies on a line that meets both a and b. Accordingly, it is appropriate to regard the set of all ideal points and ideal lines as forming an ideal plane: *the plane at infinity*. This makes it possible to assert that any two intersecting (or parallel) lines determine a plane through both of them. If one of the lines is ordinary this is an ordinary plane; if both are ideal it is the plane at infinity.

Since each point (or line) at infinity is joined to an ordinary point O by an ordinary line (or plane), the points and lines of the projective *plane* may simply be regarded as a "new language" for the lines and planes (respectively) through O. In other words,

The projective plane is faithfully represented by a bundle.

Historically, points at infinity, lines at infinity, and the plane at infinity were first thought of by Kepler, Desargues, and Poncelet, respectively.

EXERCISE

Examine all the Axioms 2.11–2.18 for projective space, verifying that each is satisfied in our "extended" space, that is, in the ordinary affine space plus the plane at infinity with all its points and lines.

11.7 Euclidean Space

Although elementary solid geometry operates in affine space (Section 11.2), we must not imagine that affine geometry is merely another name for

Euclidean geometry! Affine geometry is the part of Euclidean geometry in which distances are compared only on the same line or on parallel lines.* Affine geometry becomes Euclidean geometry as soon as we have said what we mean by *perpendicular*. (For, right angles lead to circles and spheres, and thus enable us to compare distances.)

We have already referred to the set of all vertical lines as a familiar instance of a bundle of parallels, and to the set of all horizontal planes as a familiar instance of a pencil of parallel planes. More generally, every bundle of parallels in Euclidean space determines a unique axial pencil (of parallel planes), whose planes are perpendicular to the lines and planes of the bundle; and, conversely, every pencil of parallel planes determines a perpendicular bundle (of parallels). In the language of the plane at infinity, we thus have a special one-to-one correspondence between points at infinity and lines at infinity. As we have already remarked, the plane at infinity is a projective plane. Accordingly, we are not surprised to find that this correspondence between its points and lines is a polarity (called the *absolute polarity*). A line and a plane are perpendicular if the point at infinity on the line is the pole of the line at infinity in the plane. Two lines (or two planes) are perpendicular if their sections by the plane at infinity are conjugate points (or lines). Since no line or plane is perpendicular to itself, the polarity is elliptic. In fact, just as affine space can be derived from projective space by singling out a plane ("at infinity") and using it to define parallelism, so Euclidean space can be derived from affine space by singling out an elliptic polarity in the plane at infinity and using it to define perpendicularity.

EXERCISE

Let P and Q be two distinct points in Euclidean space. What is the locus of the point of intersection of a variable line through P and the perpendicular plane through Q?

Coordinates in an Affine Plane with Desargues and Pappus Properties

Foreword (The First Desargues Property)

For a reason that will be made clear later, an affine plane is said to have *the first Desargues property,* provided (whenever lines *AB*, *A′B′*, *A″B″* of the plane are pairwise mutually parallel) that when line *AA′* is parallel to line *BB′* and line *A′A″* is parallel to line *B′B″*, then line *A A″* is parallel to line *BB″*. Girard Desargues (1593–1662), the French architect-mathematician, was one of the first to study conic sections as projections of circles.

The property enunciated above is a special case of his beautiful theorem concerning perspective triangles to which we shall often refer. The example of an affine plane given in Section IV.11 shows that not every affine plane has the first Desargues property. Since this property is essential in order that the binary relation for vectors we are establishing be an equivalence relation, we restrict our attention from now on to those planes that, in addition to satisfying Postulates 1, 2, and 3, Section IV.1, have the first Desargues property. In these planes the equivalence relation for three non-null vectors with pairwise distinct carriers is transitive. The ordinary euclidean plane has the first Desargues property.

V.I. Completion of the Equivalence

Definition for Vectors

The definition of the desired relation is now completed by defining it for distinct vectors with the same carrier. The criterion is embodied in the following rule.

RULE 4. *If* $\overrightarrow{AB}$, $\overrightarrow{EF}$ *are distinct vectors with the same carrier,* $\overrightarrow{AB} = \overrightarrow{EF}$ *if and only if a vector* $\overrightarrow{CD}$ *exists, with carrier distinct from that of* $\overrightarrow{AB}$, *such that (under Rule 3)* $\overrightarrow{AB} = \overrightarrow{CD}$ *and* $\overrightarrow{CD} = \overrightarrow{EF}$.

Clearly, we wish the equivalence of the vectors $\overrightarrow{AB}$, $\overrightarrow{EF}$, with the same carrier, to be *independent* of the choice of the auxiliary vector $\overrightarrow{CD}$, so Rule 4 needs to be justified by showing that this is indeed the case.

Let $\overrightarrow{C'D'}$ be another choice of a vector, with carrier distinct from that of $\overrightarrow{AB}$, such that $\overrightarrow{AB} = \overrightarrow{C'D'}$ and $\overrightarrow{C'D'} = \overrightarrow{EG}$. Suppose $\overrightarrow{CD}$ and $\overrightarrow{C'D'}$ have different carriers (see Figure 17).

Since the carriers of vectors $\overrightarrow{AB}$, $\overrightarrow{CD}$, $\overrightarrow{C'D'}$ are pairwise distinct, and the plane has the first Desargues property, $\overrightarrow{AB} = \overrightarrow{C'D'}$, $\overrightarrow{AB} = \overrightarrow{CD}$ imply $\overrightarrow{CD} = \overrightarrow{C'D'}$. This, together with $\overrightarrow{CD} = \overrightarrow{EF}$, yields (for the same reason) $\overrightarrow{C'D'} = \overrightarrow{EF}$, and, consequently, line *D'F* is parallel to line *C'E*. But $\overrightarrow{C'D'} = \overrightarrow{EG}$ implies line *D'G* is parallel to line *C'E*. Hence line *D'F* is identical to line *D'G*, so *F* = *G*.

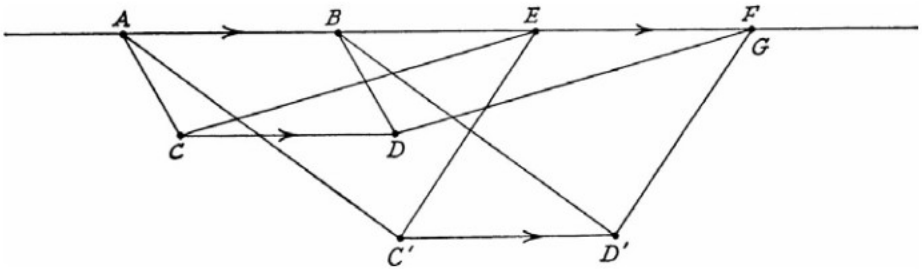

Figure 17

Thus, if $\overrightarrow{AB} = \overrightarrow{EF}$ follows from Rule 4, by use of a vector $\overrightarrow{CD}$ whose carrier is distinct from that of $\overrightarrow{AB}$, $\overrightarrow{AB} = \overrightarrow{EF}$ follows also, by use of *any* vector $\overrightarrow{C'D'}$ whose carrier is distinct from that of $\overrightarrow{CD}$ and such that $\overrightarrow{AB} = \overrightarrow{C'D'}$, $\overrightarrow{EF} = \overrightarrow{C'D'}$. How would the reader proceed in the event a vector $\overrightarrow{C'D'}$ has the same carrier as $\overrightarrow{CD}$?

● EXERCISES

1. Show that the binary relation defined by Rules 1–4 in the set of vectors of plane Π, with the first Desargues property is an equivalence relation (that is, is reflexive, symmetric, and transitive).

2. If $\overrightarrow{AA'} = \overrightarrow{BB'}$, $\overrightarrow{A'A''} = \overrightarrow{B'B''}$ (no two vectors having the same carriers), prove $\overrightarrow{AA''} = \overrightarrow{BB''}$. How is this property related to the first Desargues property?

3. Prove $\overrightarrow{AB} = \overrightarrow{AC}$ if and only if $B = C$.

V.2. Addition of Vectors

If $\overrightarrow{AB}$ is any vector and P is any point, there is exactly one point Q such that $\overrightarrow{AB} = \overrightarrow{PQ}$. There is at most one such point Q, since if $\overrightarrow{AB} = \overrightarrow{PQ_1}$ and $\overrightarrow{AB} = \overrightarrow{PQ_2}$, then $\overrightarrow{PQ_1} = \overrightarrow{PQ_2}$, by transitivity of vector equivalence, and $Q_1 = Q_2$ (Exercise 3, Section V.1) If $\overrightarrow{AB}$ is a null vector, $Q = P$ is the desired point (Rule 1, Section IV.10). If $\overrightarrow{AB}$ is not a null vector, suppose, first, P is not on the carrier of $\overrightarrow{AB}$. The line on P, parallel to line AB, intersects the line on B, parallel to line AP, in the desired point Q ($\overrightarrow{AB} = \overrightarrow{PQ}$, by Rule 3, Section IV.10). Finally, if P is on the line AB, let $\overrightarrow{CD}$ be any vector such that $\overrightarrow{AB} = \overrightarrow{CD}$ and line AB is distinct from line CD. The line on D, parallel to line CP, meets line AB in the desired point Q ($\overrightarrow{AB} = \overrightarrow{PQ}$, by Rule 4, Section V.1).

DEFINITION (VECTOR ADDITION). *Let* $\overrightarrow{AB}$, $\overrightarrow{CD}$ *be any two vectors. If* $B = C$, *then* $\overrightarrow{AB} + \overrightarrow{CD} = \overrightarrow{AD}$. *If* $B \neq C$, *and* Q *denotes the unique point such that* $\overrightarrow{BQ} = \overrightarrow{CD}$, *then* $\overrightarrow{AB} + \overrightarrow{CD} =$
$\overrightarrow{AB} + \overrightarrow{CD} = \overrightarrow{AQ}$.

Remark 1. If $\overrightarrow{CD} = \overrightarrow{C'D'}$, $\overrightarrow{AB} + \overrightarrow{CD} = \overrightarrow{AB} + \overrightarrow{C'D'}$. For, by definition of vector addition, $\overrightarrow{AB} + \overrightarrow{CD} = \overrightarrow{AQ} = \overrightarrow{AB} + \overrightarrow{BQ}$, where $\overrightarrow{BQ} = \overrightarrow{CD}$. Then $\overrightarrow{BQ} = \overrightarrow{C'D'}$, and $\overrightarrow{AB} + \overrightarrow{C'D'} = \overrightarrow{AB} + \overrightarrow{BQ} = \overrightarrow{AQ}$.

Remark 2. If $\overrightarrow{CD} = \overrightarrow{C'D'}$, $\overrightarrow{CD} + \overrightarrow{AB} = \overrightarrow{C'D'} + \overrightarrow{AB}$. For $\overrightarrow{CD} + \overrightarrow{AB} = \overrightarrow{CD} + \overrightarrow{DQ} = \overrightarrow{CQ}$, where $\overrightarrow{DQ} = \overrightarrow{AB}$ and $\overrightarrow{C'D'} + \overrightarrow{AB} = \overrightarrow{C'D'} + \overrightarrow{D'Q'} = \overrightarrow{C'Q'}$, where $\overrightarrow{D'Q'} = \overrightarrow{AB}$. Hence $\overrightarrow{DQ} =$

$\overrightarrow{D'Q'}$, which, together with $\overrightarrow{CD} = \overrightarrow{C'D'}$, gives $\overrightarrow{CQ} = \overrightarrow{C'Q'}$. This is justified by Exercise 2, Section V.1, if the carriers of $\overrightarrow{CD}$, $\overrightarrow{C'D'}$, $\overrightarrow{DQ}$, $\overrightarrow{D'Q'}$ are pairwise distinct. Let the reader check the other possibility.

Remark 3. If $\overrightarrow{AB} = \overrightarrow{A'B'}$ and $\overrightarrow{CD} = \overrightarrow{C'D'}$, $\overrightarrow{AB} + \overrightarrow{CD} = \overrightarrow{A'B'} + \overrightarrow{C'D'}$. For, by Remark 2, $\overrightarrow{AB} + \overrightarrow{CD} = \overrightarrow{A'B'} + \overrightarrow{CD}$, and, by Remark 1, $\overrightarrow{A'B'} + \overrightarrow{CD} = \overrightarrow{A'B'} + \overrightarrow{C'D'}$. Transitivity of vector equivalence gives $\overrightarrow{AB} + \overrightarrow{CD} = \overrightarrow{A'B'} + \overrightarrow{C'D'}$.

THEOREM V.2.1. *Vector addition is associative.*

Proof. If $\overrightarrow{AB}$, $\overrightarrow{CD}$, $\overrightarrow{EF}$ are any three vectors, consider the unique vectors $\overrightarrow{BP}$, $\overrightarrow{PQ}$ such that $\overrightarrow{BP} = \overrightarrow{CD}$ and $\overrightarrow{PQ} = \overrightarrow{EF}$. Then

$$\begin{aligned}(\overrightarrow{AB} + \overrightarrow{CD}) + \overrightarrow{EF} &= (\overrightarrow{AB} + \overrightarrow{BP}) + \overrightarrow{PQ} \qquad \text{(Remark 3)}\\ &= \overrightarrow{AP} + \overrightarrow{PQ} \qquad \text{(definition of vector addition)}\\ &= \overrightarrow{AQ} \qquad \text{(definition of vector addition)},\end{aligned}$$

$$\begin{aligned}\overrightarrow{AB} + (\overrightarrow{CD} + \overrightarrow{EF}) &= \overrightarrow{AB} + (\overrightarrow{BP} + \overrightarrow{PQ})\\ &= \overrightarrow{AB} + \overrightarrow{BQ}\\ &= \overrightarrow{AQ},\end{aligned}$$

and, consequently, $(\overrightarrow{AB} + \overrightarrow{CD}) + \overrightarrow{EF} = \overrightarrow{AB} + (\overrightarrow{CD} + \overrightarrow{EF})$.

THEOREM V.2.2. *Vector addition is commutative.*

Proof. Let $\overrightarrow{AB}$, $\overrightarrow{CD}$ be any two vectors, and let $\overrightarrow{BQ} = \overrightarrow{CD}$. Then $\overrightarrow{AB} + \overrightarrow{CD} = \overrightarrow{AQ}$. Suppose $\overrightarrow{AB}$, $\overrightarrow{BQ}$ have distinct carriers, and let the line on *A*, parallel to line *BQ*, meet the line on *Q*, parallel to line *AB*, at *P*. Then $\overrightarrow{CD} = \overrightarrow{BQ} = \overrightarrow{AP}$, and $\overrightarrow{AB} = \overrightarrow{PQ}$ yields $\overrightarrow{CD} + \overrightarrow{AB} = \overrightarrow{AP} + \overrightarrow{PQ} = \overrightarrow{AQ}$.

If, on the other hand, $\overrightarrow{AB}$, $\overrightarrow{BQ}$ have the same carrier, let *S* be a point of Π not on line *AB* (Postulate 3, Section IV.1). Then

$$\begin{aligned}
\overrightarrow{CD} + \overrightarrow{AB} &= \overrightarrow{BQ} + \overrightarrow{AB} = (\overrightarrow{BS} + \overrightarrow{SQ}) + \overrightarrow{AB} \\
&= \overrightarrow{BS} + (\overrightarrow{SQ} + \overrightarrow{AB}) \quad \text{(Theorem V.2.1)} \\
&= \overrightarrow{BS} + (\overrightarrow{AB} + \overrightarrow{SQ}) \quad \text{(since } \overrightarrow{AB}, \overrightarrow{SQ} \text{ have different} \\
&\qquad\qquad\qquad\qquad\qquad \text{carriers)} \\
&= (\overrightarrow{BS} + \overrightarrow{AB}) + \overrightarrow{SQ} \\
&= (\overrightarrow{AB} + \overrightarrow{BS}) + \overrightarrow{SQ} = \overrightarrow{AS} + \overrightarrow{SQ} = \overrightarrow{AQ},
\end{aligned}$$

and the proof is complete.

These two theorems have important consequences in regard to the algebraic structure of the ternary ring [Γ, *T*]. A one-to-one correspondence between the set of vectors $\overrightarrow{OX}$ and the points *X* of the unit line is obtained by associating with each such vector its terminal point *X* (the origin *O* is associated with the null vector $\overrightarrow{OO}$). This one-to-one correspondence, together with the one-to-one correspondence *γ* between the points of the unit line and the elements of the coordinate set Γ (see Section IV.3) establishes a one-to-one correspondence between the vectors $\overrightarrow{OX}$, *X* ∈ line *OI*, and the elements of Γ, in which $\overrightarrow{OA}$ corresponds to *a*, where $a = \gamma(A) \in \Gamma$.

If *A*(*a*, *a*), *B*(*b*, *b*) ∈ line *OI*, and *C* = *A* + *B* (see Figure 11), $\overrightarrow{OA} = \overrightarrow{UP} = \overrightarrow{BC}$, so $\overrightarrow{OA} + \overrightarrow{OB} = \overrightarrow{BC} + \overrightarrow{OB} = \overrightarrow{OB} + \overrightarrow{BC} = \overrightarrow{OC}$. Hence if *A*, *B* ∈ line *OI* that correspond, respectively, to vectors $\overrightarrow{OA}$, $\overrightarrow{OB}$, their sum *A* + *B* corresponds to the vector sum $\overrightarrow{OA} + \overrightarrow{OB}$, and, consequently, if *a*, *b* ∈ Γ that correspond, respectively, to points A, B (and hence to vectors $\overrightarrow{OA}$, $\overrightarrow{OB}$), their sum $a + b$ corresponds to $C = A + B$, and hence to $\overrightarrow{OC} = \overrightarrow{OA} + \overrightarrow{OB}$. Thus, the vector that corresponds to the sum of a and b is the sum of the vector corresponding to a and the vector corresponding to b. We conclude that this correspondence between vectors $\overrightarrow{OX}$, $X \in$ line OI, and elements x of Γ is an *isomorphism with respect to addition*. Since vector addition is associative and commutative, it follows that *addition in* $[\Gamma, T]$ *is associative and commutative also*. Suppose $a, b \in \Gamma$ and $a \sim \overrightarrow{OA}$, $b \sim \overrightarrow{OB}$ in the correspondence defined above (where the symbol ~ is read "corresponds to"). Then $a + b \sim \overrightarrow{OA} + \overrightarrow{OB}$, and $b + a \sim \overrightarrow{OB} + \overrightarrow{OA}$, and, since $\overrightarrow{OA} + \overrightarrow{OB}$ and $\overrightarrow{OB} + \overrightarrow{OA}$ are the *same* vector $\overrightarrow{OC}$, and the correspondence is one-to-one, $a + b = b + a$. In a similar manner addition in $[\Gamma, T]$ is shown to be associative.

We have proved that with respect to ordered addition (Remark 2, Section IV.8) $[\Gamma, T]$ is a loop. Imposing the first Desargues property on plane Π results in associativity of addition in $[\Gamma, T]$, hence $[\Gamma, +]$ is a *group* (a loop with associativity of the operation). Since addition is, moreover, commutative, the group $[\Gamma, +]$ is an *abelian* (that is, commutative) group.

We have now established the following important result.

THEOREM V.2.3. *If a rudimentary affine plane* Π *has the first Desargues property, every planar ternary ring* $[\Gamma, T]$ *defined over* Π *is an abelian group with respect to addition.*

V.3. Linearity of the Ternary Operator

Without assuming the affine plane Π to have the first Desargues property, we have seen that certain classes of lines of Π are represented by equations having the same forms as in ordinary analytic geometry. Thus lines in the parallel class of the y-line have equations $x = a$, $a \in \Gamma$; those in the parallel class of the x-line have equations $y = b$, $b \in \Gamma$; those in the parallel class of the unit line have equations $y = x + c$, $c \in \Gamma$; and those lines on O with slope m, $m \in \Gamma$, have equations $y = xm$ (where the dot indicating multiplication has been omitted). Now it will be established that, as a consequence of assuming the first Desargues property valid in II, each line of Π with slope m and y-intercept b has an equation $y = xm + b$, as in ordinary analytic geometry.

Consider the line with equation $y = T(x, m, b)$, where $m \neq 0, 1$ and $b \neq 0$ (Figure 18).

The two triples A^*, A', A'' and B^*, B', B'' of Figure 18 are such that: (1) the six points are pairwise distinct, (2) lines A^*B^*, $A'B'$, $A''B''$ are pairwise mutually parallel, and (3) line A^*A' is parallel to line B^*B', and line A^*A'' is parallel to line B^*B''. It follows from the first Desargues property that line $A'A''$ is parallel to line $B'B''$, and hence line $B'B''$ is in the parallel class of the x-line. Consequently, points B', B' have the same ordinates, so $T(a, m, b) = am + b$, $a \neq 0$. By Section IV.6, $T(0, m, b) = b = T(a, 0, b)$; by Section IV.8, $T(a, 1, b) = a + b$; and by Section IV.9, $T(a, m, 0) = am$. Hence for every triple a, m, $b \in \Gamma$, $T(a, m, b) = am + b$, and each line with slope m and y-intercept b has equation $y = T(x, m, b) = xm + b$. Thus $T(x, m, b)$ is linear.

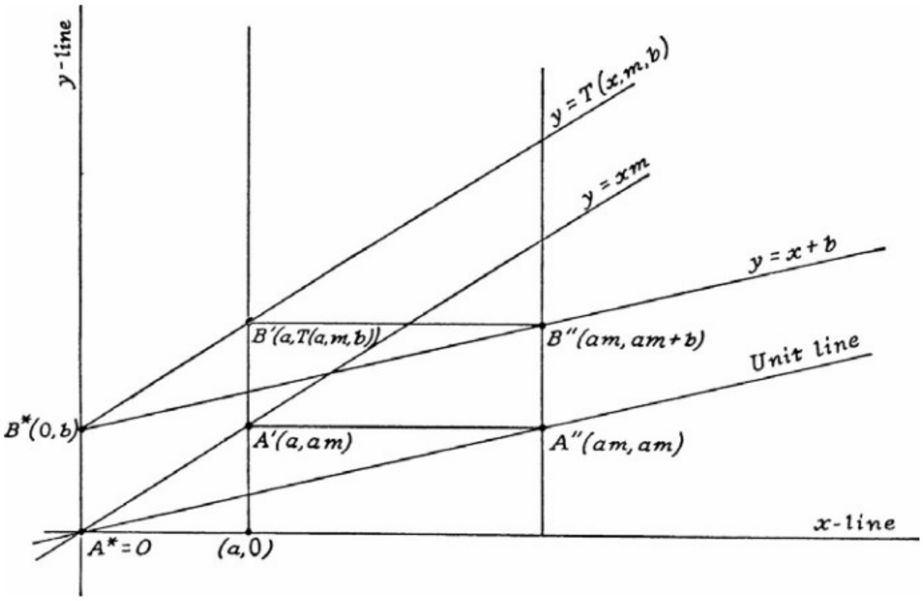

Figure 18

Since $x \cdot y = T(x, y, 0)$, $t + z = T(t, 1, z)$ $(x, y, z, t \in \Gamma)$, it follows that $T(x, y, z)=xy + z= T(xy, 1, z) = T[T(x, y, 0), 1, z]$.

We recall that a coordinate system was established in the affine plane Π by selecting an arbitrary point O of Π for the origin and by choosing three pairwise distinct lines on O and designating them the x-line, the y-line, and the unit line. On the unit line any point distinct from O was chosen and labeled I, and an arbitrary abstract set Γ was selected (subject to the sole requirement that there is a one-to-one correspondence γ between the points of the line OI and the elements of Γ), and $\gamma(O)$, $\gamma(I)$ were labeled 0, 1, respectively. Then a procedure was defined that established a one-to-one correspondence between the points of Π and the elements of the set of all ordered pairs of elements of Γ. The ordered pair of elements of Γ corresponding to a point P of Π are the coordinates of P. A ternary operation $T(a, m, b)$ was defined in Γ, and the system $[\Gamma, T]$ was called a *planar ternary ring*.

Now if a different point O' of Π were chosen for the origin, and three lines on O' selected as the x'-line, y'-line, and unit line (with point I' selected on it), the same set Γ could serve as the coordinate set, since there exists a one-to-one correspondence between the elements of Γ and the points of the new unit line [each line of Π contains the same number (finite or transfinite) of points]. But the ternary operation T', defined by the new lines and new origin, would, in general, be quite different from the ternary operation T defined by the original coordinate system (though the *domain* of the two operators is the same set Γ), so a different planar ternary ring $[\Gamma, T']$ would result. If the first Desargues property is assumed for Π, both operators T, T' are linear; that is $T(x, y, z) = xy + z$, $T'(x, y, z) = [x \odot y] \oplus z$, where the addition $\oplus$ and the multiplication $\odot$ are, in general, different from the addition $+$ and multiplication $\cdot$ defined by using the original coordinate system. We have established the following result.

THEOREM V.3.1. *If the first Desargues property is valid in the affine plane* Π, *every* (*planar*) *ternary ring defined in* Π *is linear*.

Is the converse of this theorem valid; that is, if every (planar) ternary ring defined in the affine plane Π is linear, does it follow that the first Desargues property is valid in Π? The answer is affirmative, as we shall now show.

THEOREM V.3.2. *If every* (*planar*) *ternary ring defined in an affine plane* Π *is linear,* Π *has the first Desargues property*.

Proof. Let A^*, A', A'' and B^* B', B'' be any two triples of points of Π (each two points distinct) such that lines A^*B^*, $A'B'$, $A''B''$ are pairwise mutually parallel and lines A^*A', $A'A''$ are parallel, respectively, to lines B^*B', $B'B''$. We wish to prove that line A^*A'' is parallel to line B^*B''.

We introduce in Π a coordinate system in the following manner. Select A' as the origin, line $A'B'$ as the y-line, the line on A' parallel to line A^*A'' as the x-line, and line $A'A''$ as the unit line (Figure 19).

Then line $A'A^*$ has equation $y = xm$, and line $B'B^*$ has equation $y = T(x, m, b)$ for some element b of Γ (since it is parallel to line $A'A^*$). Since line $B'B''$ is parallel to the unit line, it has equation $y = x + b$. Point A^* has coordinates (a, am) for some element a of Γ, so point A'' has coordinates (am, am), and the coordinates of B^* and B'' are $(a, T(a, m, b))$ and $(am, am + b)$, respectively. But since every ternary ring defined in Π is linear, $T(a, m, b) = am + b$, and, consequently, points B^* and B'' have the same ordinates. It follows that line B^*B'' is in the parallel class of the x-line, and since line A^*A'' is also in that parallel class, and is distinct from line B^*B'', it follows that line A^*A'' is parallel to line B^*B''.

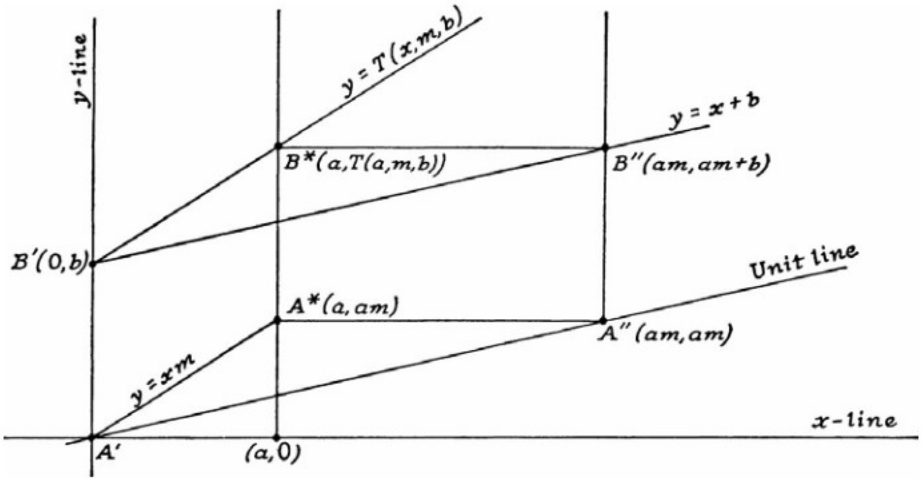

Figure 19

Combining the last two theorems yields the following important result.

THEOREM V.3.3. *The first Desargues property is valid in an affine plane Π if and only if every (planar) ternary ring defined in Π is linear.*

The (geometric) first Desargues property has, then, the algebraic counterpart or *equivalent* that every ternary ring of Π is

Coordinates in an Affine Plane with Desargues and Pappus Properties →

Affine Plane (incidence geometry)

Satisfy the following axioms:

- Any two distinct points lie on a unique line.
- Each line has at least two points.
- Given any line and any point not on that line, there is a unique line which contains the point and does not meet the given line. (Playfair's axiom)
- There exist three non-collinear points (points not on a single line)

In an affine plane, two lines are called parallel if they are equal or disjoint. (disjoint set)

Using this definition, Playfair's axiom above can be replaced by:

- Given a point and a line, there is a unique line which contains the point and is parallel to the line.

CHAPTER 3

Desarguesian Affine Planes

The Greek geometers introduced "geometric algebra" by adding and multiplying lengths of segments in the Euclidean plane. Descartes formalized geometric algebra when he represented the synthetic Euclidean plane as the real coordinate plane. In particular, the points on the x- and y-axes are in one-one correspondence with the real numbers; these points can be added and multiplied geometrically. Addition is done by parallel displacement, while multiplication uses proportional segments. In this chapter we will define and investigate the properties of addition and multiplication in affine planes.

3.1 THE FUNDAMENTAL THEOREM

For a well-defined addition to satisfy the associative and commutative laws, and for a well-defined multiplication to satisfy the associative law, Desargues' Theorem (Theorems 13 and 14 of Chapter 1) is needed. For multiplication to be commutative, Pappus' Theorem (Theorem 12 of Chapter 1) is needed. The statements of the theorems of Desargues and Pappus are meaningful in an arbitrary affine plane because they only involve parallelism. The proofs of these results, as given in Chapter 1, however, rely on concepts (e.g., congruence and similar triangles) relevant to Euclidean geometry but meaningless in arbitrary affine planes.

Thus this chapter concerns affine planes in which Desargues' Theorem is true. Its aim is to define addition and multiplication of points on a given line, relative to fixed units O and I, and to prove the following theorem.

■ **THEOREM 1. The fundamental theorem of synthetic affine planes.** Relative to two fixed points, O and I, any line in a Desarguesian affine plane is a *division ring* in that its addition and multiplication satisfy the following properties:

Addition	**Multiplication**
Associative	Associative
O is the identity	I is the identity
All elements have inverses	All nonzero elements have inverses
Commutative	

Multiplication distributes over addition

A division ring in which multiplication is commutative is a *field*, as defined in Chapter 1.

3.2 ADDITION ON LINES

An addition can be defined on the points of any line through any fixed point O, called the *origin*, and is defined *relative to this* O. In Chapter 4 the effect of selecting different origins will be investigated, and comparisons of sums of points relative to distinct origins will be made.

Definition of addition. In any affine plane $(\mathscr{P}, \mathscr{L})$ select and fix a line $\ell \in \mathscr{L}$, and a point $O \in \ell$. (See Fig. 3.1.) For points A and C in ℓ, to add A and C (relative to O):

1. Select B not in ℓ.
2. Let m be the line through B and parallel to ℓ.
3. Let k be the line through A parallel or equal to $\ell(O, B)$.
4. Let $D = m \cap k$.
5. Let n be the line through D parallel or equal to $\ell(B, C)$.
6. $A + C$ is defined to be $n \cap \ell$.

It will be shown in Section 3.4 that the addition of points on ℓ is independent of the choice of the fixed point B.

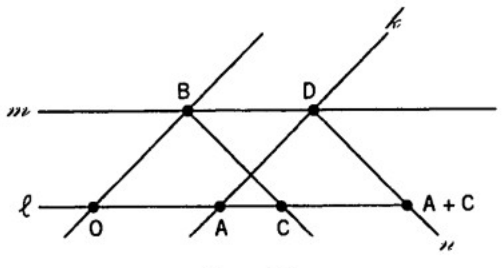

Figure 3.1

If A happens to be the special point O, then line k, as defined in step 3 is $\ell(\mathrm{O}, \mathrm{B})$. The point D defined in step 4 always exists. Otherwise, m and k would be parallel, giving two lines (ℓ and k) through A and parallel to m, whereby $\ell = k$. But ℓ and k are distinct, for k is parallel or equal to $\ell(\mathrm{O}, \mathrm{B})$, and ℓ is neither parallel nor equal to $\ell(\mathrm{O}, \mathrm{B})$. Similarly n is not parallel to ℓ. Thus A + C as defined in step 6 exists.

Parallelograms

Parallelograms, familiar in Euclidean geometry, can also be defined in a general affine plane. A *parallelogram* is an ordered quadruple (A, B, C, D) of points such that $\ell(\mathrm{A}, \mathrm{B}) \| \ell(\mathrm{C}, \mathrm{D})$ and $\ell(\mathrm{B}, \mathrm{C}) \| \ell(\mathrm{A}, \mathrm{D})$. The lines $\ell(\mathrm{A}, \mathrm{C})$ and $\ell(\mathrm{B}, \mathrm{D})$ are called its *diagonals*. Two parallelograms arise in the preceding definition of addition of points, namely (O, A, D, B) and (C, A + C, D, B) which share the common vertices D and B. The definition of addition given here does, in fact, generalize addition on the (real) number line. In that case the *length* of the segment OA is added to the length of OC by moving OA by *parallel displacement*, first to BD and then to C(A + C).

■ **THEOREM 2.** O + C = C for any C in ℓ.

Proof: In the definition above A = O. Therefore, since $k = \ell(\mathrm{O}, \mathrm{B})$ and B = D, we have $n = \ell(\mathrm{B}, \mathrm{C})$ and O + C = C. ■

■ **THEOREM 3.** A + O = A for any A in ℓ.

Proof: Here $\ell(\mathrm{B}, \mathrm{C}) = \ell(\mathrm{B}, \mathrm{O})$, so $n = k$. Since $\mathrm{A} \in k$, $k \cap \ell = \mathrm{A}$, and A + O = A. ■

Either Theorem 2 or 3 implies the following result.

Corollary. O + O = O.

Clearly the fixed origin O acts as a "zero" or additive identity. However, in order that addition satisfy various other familiar properties such as commutativity and associativity, we need to assume *as an axiom* that Desargues' Theorem holds. This is the subject of the next section.

EXERCISES

1. Let $(\mathcal{P}, \mathcal{L})$ be the affine plane of order 3 defined in Example 7 of Chapter 2. On line {GHI} set G = O, and add H + I, using B as the point B was used in the definition of addition. Now compute H + I using whatever point you please for B.

2. Let $(\mathscr{P}, \mathscr{L})$ be the affine plane of order 3 as in Exercise 1. Make an addition table for {AEI}, setting A = O.

+	O	E	I
O			
E			
I			

3. Suppose that A, B, and C are noncollinear points in an affine plane $(\mathscr{P}, \mathscr{L})$. Prove that there is a unique point D in $\mathscr{P}$ such that (A, B, C, D) is a parallelogram.
4. Let $(\mathscr{P}, \mathscr{L})$ be the real Euclidean plane described in Example 1 of Chapter 2. Prove that $((a, b), (c, d), (e, f), (g, h))$ is a parallelogram if and only if $(a + e, b + f) = (c + g, d + h)$.
5. Make an addition table for the line {OAJH} in the plane of order 4, given in Example 8 of Chapter 2.

3.3 DESARGUES' THEOREM

In 1902 F. R. Moulton gave a simple example of an affine plane $(\mathscr{P}, \mathscr{L})$ called the *Moulton Plane*, in which Desargues' Theorem fails to hold. In this plane $\mathscr{P}$ is the set of ordered pairs of real numbers (i.e., the points of the real coordinate plane). $\mathscr{L}$ consists of all Euclidean horizontal lines, vertical lines, and lines with negative slope, together with all "broken"

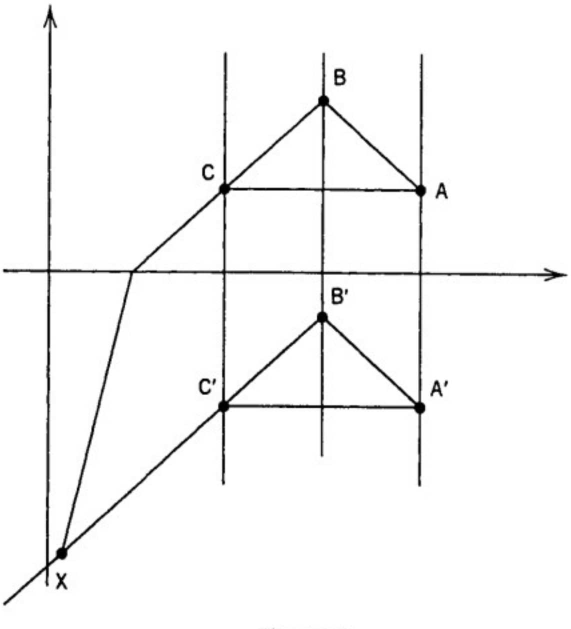

Figure 3.2

Euclidean lines that have positive slope m above the x-axis and slope $2m$ below the axis. It is an exercise in analytic geometry to show that any two points of the Moulton plane lie on one and only one (Moulton) line by finding its equation if it is a Euclidean line, or the point of intersection of the line with the x-axis if it is a broken line. Horizontal lines are parallel, vertical lines are parallel, and lines of the same negative slope are parallel. Broken lines whose slopes agree both above and below the x-axis are parallel as well, so it is apparent that the parallel axiom holds in the Moulton plane. Axiom $A3$ clearly holds. The easiest way to see that the Moulton plane does not satisfy Desargues' Theorem is to look at the example illustrated in Fig. 3.2 where the hypotheses of Desargues' Theorem are satisfied, but $\ell(\mathrm{B},\mathrm{C}) \cap \ell(\mathrm{B}',\mathrm{C}') = \mathrm{X}$.

Thanks to Moulton's example and others, it is clear that if Desargues' Theorem is to be used in affine plane geometry, it must be assumed as an additional axiom. Thus we make the following definition

Definition. A *Desarguesian affine* plane is an affine plane in which the following axiom holds (see Fig. 3.3):

$A4$. Desargues' Theorem.

(I) Suppose that $\ell(\mathrm{A},\mathrm{A}') \| \ell(\mathrm{B},\mathrm{B}') \| \ell(\mathrm{C},\mathrm{C}')$. If $\ell(\mathrm{A},\mathrm{B}) \| \ell(\mathrm{A}',\mathrm{B}')$, and $\ell(\mathrm{A},\mathrm{C}) \| \ell(\mathrm{A}',\mathrm{C}')$, then $\ell(\mathrm{B},\mathrm{C}) \| \ell(\mathrm{B}',\mathrm{C}')$.

(II) Suppose $\ell(\mathrm{A},\mathrm{A}') \cap \ell(\mathrm{B},\mathrm{B}') \cap \ell(\mathrm{C},\mathrm{C}') = \mathrm{P}$. If $\ell(\mathrm{A},\mathrm{B}) \| \ell(\mathrm{A}',\mathrm{B}')$ and $\ell(\mathrm{A},\mathrm{C}) \| \ell(\mathrm{A}',\mathrm{C}')$, then $\ell(\mathrm{B},\mathrm{C}) \| \ell(\mathrm{B}',\mathrm{C}')$.

The rest of this chapter treats Desarguesian planes, while in Chapter 5 we will give some examples of finite non-Desarguesian planes.

Desargues' Theorem is named for the French mathematician and architect Girard Desargues (1593–1662), who first proved it. A contemporary and friend of Descartes, he also designed part of the current city hall in Lyon, France. As an affine axiom, Desargues' Theorem differs from

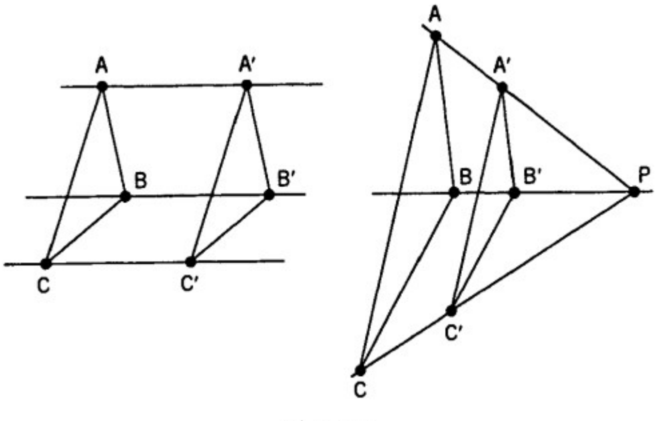

Figure 3.3

the first three in several ways. Clearly its statement is more complicated than the statements of the first three axioms, and in fact has two parts. Additionally it is equivalent to its own converse, which will be shown in Section 3.5. In Chapter 1 Desargues' Theorem was proved synthetically in the Euclidean plane; the following theorem shows that it holds in the coordinate real and rational planes.

■ **THEOREM 4.** The real and rational coordinate planes are Desarguesian.

Proof of (I): First note that A, A′, B, for example are vectors (a_1, a_2), (a'_1, a'_2), (b_1, b_2). (See Fig. 3.4): Since (A, C, C′, A′) is a parallelogram, C′ = C − A + A′. Since (A, B, B′, A′) is a parallelogram, B′ = B − A + A′. Thus C′ = C − B + B′, so (C, B, B′, C′) is a parallelogram, with $\ell(B, C) \| \ell(B', C')$.

Proof of (II): If P = (0, 0), then for some nonzero number m, A′ = mA, B′ = mB, and C′ = mC. (See Fig. 3.4). Thus B′ − C′ = m(B − C), so $\ell(B, C) \| \ell(B', C')$. If P = (p_1, p_2), then subtracting the vector P from each of the other six vectors translates the configuration to one in which the point of intersection of the three lines is the origin. Thus $\ell(B - P, C - P) \| \ell(B' - P, C' - P)$. Adding back the vector P, we have $\ell(B, C) \| \ell(B', C')$. ■

The two statements of Desargues' Theorem for affine planes reduce to just one statement for projective planes. If in an affine plane $(\mathscr{P}, \mathscr{L})$ we have $\ell(A, A') \| \ell(B, B') \| \ell(C, C')$ or $\ell(A, A') \cap \ell(B, B') \cap \ell(C, C') = P$, after adjoining a line at infinity to form the projective plane $(\mathscr{P}', \mathscr{L}')$ the three lines meet at a point, possibly a point at infinity. Thus Axiom $P4$,

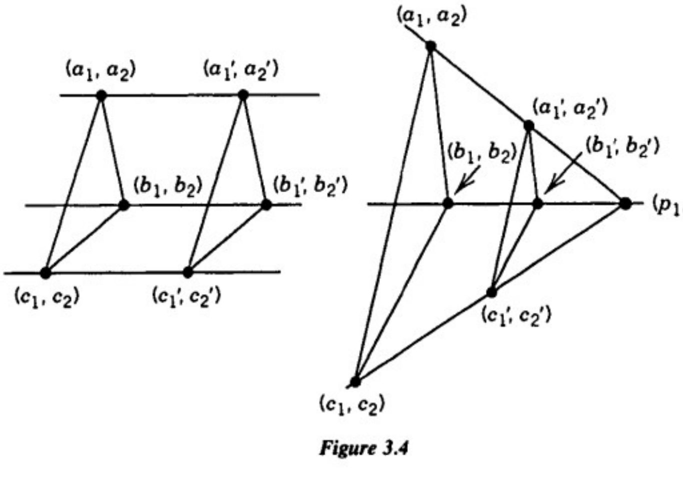

Figure 3.4

which follows, is the statement of Desargues' Theorem for projective planes.

Definition. A projective plane is said to be *Desarguesian* if it satisfies the following axiom (see Fig. 3.5):

> *P*4. Suppose that $\ell(A, A') \cap \ell(B, B') \cap \ell(C, C') = P$. Let $C'' = \ell(A, B) \cap \ell(A', B')$, $B'' = \ell(A, C) \cap \ell(A', C')$, and $A'' = \ell(B, C) \cap \ell(B', C')$. Then A'', B'', and C'' are collinear.

Taking $\ell(A'', B'')$ as the line at infinity, gives Desargues' Theorem in the resulting affine plane, and the two affine statements of Desargues' Theorem correspond to the cases where P either is, or is not, on $\ell(A'', B'')$. Thus, the statement of Desargues' Theorem for the projective plane is an

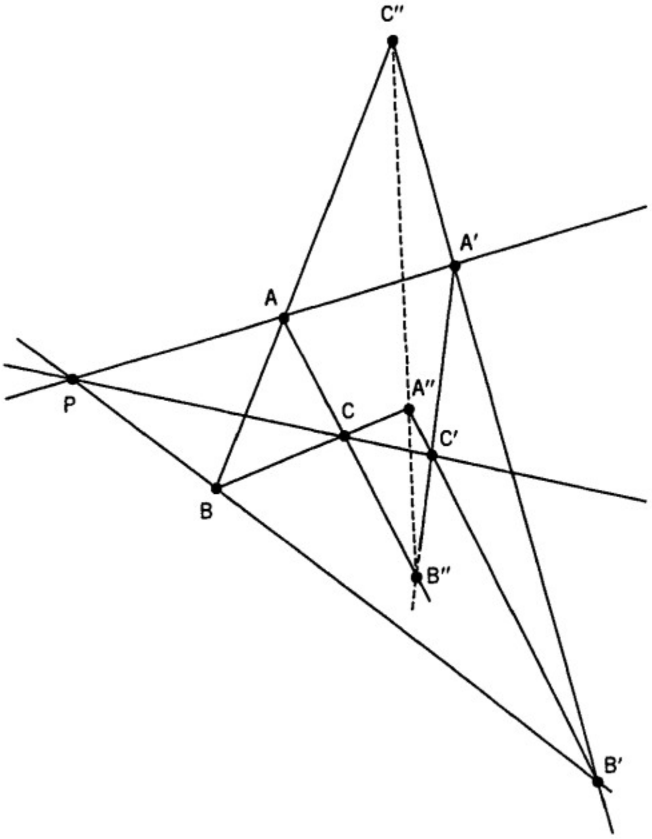

Figure 3.5

example of a single statement in projective geometry being equivalent to more than one affine statement.

Definition. A *triangle* (A, B, C) in a projective plane is a set of three noncollinear points called *vertices*, and the lines containing them called *sides*. The triangles (A, B, C) and (A′, B′, C′) are called *perspective from a point* if the lines joining their vertices are *concurrent*, namely if $\ell(\mathrm{A}, \mathrm{A}') \cap \ell(\mathrm{B}, \mathrm{B}') \cap \ell(\mathrm{C}, \mathrm{C}') = \mathrm{P}$ for some point; they are *perspective from a line* if their corresponding sides meet in collinear points. Thus Desargues' Theorem for the projective plane can be stated as follows:

> *P*4′. If two triangles are perspective from a point, they are perspective from a line.

Note that "triangle" is a self-dual concept in a projective plane, while "perspective from a point" and "perspective from a line" are dual concepts. Therefore

■ **THEOREM 5.** A projective plane is Desarguesian if and only if it satisfies the converse of Desargues' Theorem.

EXERCISES

1. Find the point where the Moulton line ℓ containing (2, 3) and (−1, −4) crosses the *x*-axis. Find the point where the line containing (3, 3) and parallel to ℓ crosses the *x*-axis.
2. Find an example of Desargues' configuration in the affine plane of order 3 (Example 7 of Chapter 2). Do the same for the affine plane of order 4 (Example 8 of Chapter 2).
3. State the converse of Desargues' Theorem as given in Axiom *P*4, and prove that it holds in any Desarguesian projective plane.

*4. Write Desargues' Theorem for affine planes as a single statement. State its converse.

5. Make sketches of the following configurations:
   a. ℓ and m are parallel lines with X, Y, Z, in ℓ and E, F, G, in m.
   b. Modify the sketch from (a) so that

$$\ell(\mathrm{Y}, \mathrm{E}) \| \ell(\mathrm{Z}, \mathrm{F}) \text{ and } \ell(\mathrm{Y}, \mathrm{G}) \| \ell(\mathrm{X}, \mathrm{F}).$$

6. Make sketches of the following configurations:
   a. (A, B, C, D) is a quadrilateral with no pair of its sides parallel.
   b. In the configuration from (a), insert A′ so that (A′, B, C, D) is a parallelogram.

c. In the configuration from (b) insert B′ so that (A, B′, C, D) is a parallelogram.

d. Similarly insert C′ and D′.

*7. Let $(\mathbb{R}, +, \circ)$ be the real numbers with their usual addition, and let k be a fixed positive real number different from 1. Define $r \circ s = rs$ if either r or s is positive or zero, and $r \circ s = krs$ if r and s are both negative. Let $(\mathscr{P}, \mathscr{L})$ be given by $\mathscr{P} = \{(x, y): x, y \in \mathbb{R}\}$ and $\ell \in \mathscr{L}$ if and only if $\ell = \{(x, y): a \circ x + b \circ y = c\}$ where a and b are not both zero.

a. Show that $(\mathscr{P}, \mathscr{L})$ is an affine plane.

b. For $k = 2$, sketch the line $1 \circ x + (-1) \circ y = 0$.

c. For $k = 1/3$, sketch the line $1 \circ x + (-1) \circ y = 0$.

d. For which value of k is $(\mathscr{P}, \mathscr{L})$ the Moulton Plane?

3.4 PROPERTIES OF ADDITION IN AFFINE PLANES

To define addition of coordinates on an affine line, two distinguished (or "special") points were selected: the origin O on ℓ, and a point B (which will be called an *auxiliary point*) not on ℓ. The effect of changing the O will be considered later; now, using Desargues' Theorem, it can be shown that regardless of the choice of B, the same sum (relative to O) will be obtained for any fixed A and C in ℓ.

■ **THEOREM 6.** The definition of A + C is independent of the choice of B.

Proof: Add A and C, using two auxiliary points B_1 and B_2, obtaining $(A + C)_1$ and $(A + C)_2$, as shown in Fig. 3.6. Note that once B_1 and B_2 are chosen, D_1 and D_2 are determined.)

Case 1. B_1, B_2, and O are collinear. The parallel axiom ensures that D_1, D_2, and A are also collinear, on the line containing A and parallel to $\ell(O, B_1)$. Now use Desargues' Theorem on triangles B_1, B_2, C and D_1,

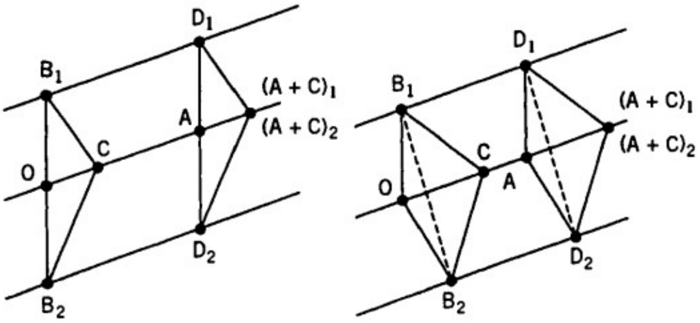

Figure 3.6

D_2, $(A + C)_1$, which gives $\ell(B_2, C) \| \ell(D_2, (A + C)_1)$. But we know that $\ell(B_2, C) \| \ell(D_2, (A + C)_2)$; this implies (by the parallel axiom and the fact that two lines intersect in at most one point) that $(A + C)_1 = (A + C)_2$.

Case 2. $B_2 \notin \ell(O, B_1)$. Desargues' Theorem on triangles B_1, O, B_2 and D_1, A, D_2, gives $\ell(B_1, B_2) \| \ell(D_1, D_2)$. Then using Desargues' Theorem again, this time on triangles B_1, B_2, C and $D_1, D_2, (A + C)_1$, we obtain $\ell(B_2, C) \| \ell(D_2, (A + C)_1)$. As in Case 1, this leads to the conclusion that $(A + C)_1 = (A + C)_2$. ■

Observe the use of the phrase "use Desargues' Theorem on triangles . . ." in the proof above. This is followed by two *ordered* triples of points, representing *corresponding* vertices. In the example above, the listing is B_1, B_2, C and $D_1, D_2, (A + C)_1$, where $\ell(B_1, D_1)$, $\ell(B_2, D_2)$, and $\ell(C, (A + C)_1)$ are parallel lines, while $\ell(B_1, B_2) \| \ell(D_1, D_2)$ and $\ell(B_1, C) \| \ell(D_1, (A + C)_1)$. It becomes much easier to use Desargues' Theorem if the six points involved are listed in the order given here.

In the sequel the phrase, "add A + C using B (and D)" will also be used. This is almost self-explanatory. By putting "(and D)" in parentheses, one emphasizes the fact that choosing an *auxiliary* point B determines which point will play the role of D (the second auxiliary point) in the definition of addition.

Pursuing, as far as possible, the aim of imitating Descartes' introduction of *arithmetic* into geometry, it can now be shown that each point on ℓ has an *additive inverse* on ℓ.

■ **THEOREM 7.** For each point $A \in \ell$, there is a point $(-A) \in \ell$ such that $A + (-A) = (-A) + A = O$.

Proof: Select $B \notin \ell$, and let D be the point such that $\ell(B, D) \| \ell$ and $\ell(O, B) \| \ell(A, D)$ as in the definition of addition. Now let $(-A)$ be the point of intersection of ℓ with the line containing B and parallel to $\ell(O, D)$. (Check that this point exists!) Adding $A + (-A)$ using B (and D), we get $A + (-A) = O$. Adding $(-A) + A$ using D (and B), $(-A) + A = O$ as well. See Fig. 3.7 where this proof is illustrated. ■

The proof that addition of points on a line is *associative* uses the fact that one has complete freedom in choosing "auxiliary" points for addition.

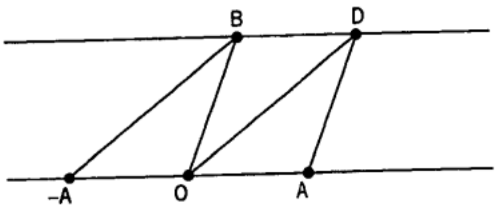

Figure 3.7

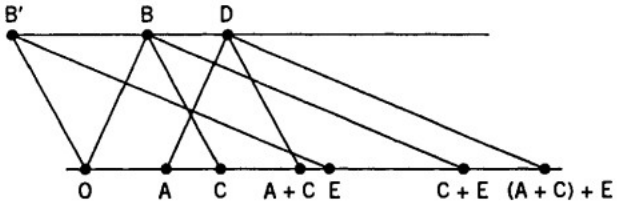

Figure 3.8

■ **THEOREM 8.** Given A, C, and E on ℓ, $(A + C) + E = A + (C + E)$.

Proof: First add $(A + C)$ using B (and D). Then add $(A + C) + E$ using B′ (chosen on $\ell(B, D)$ so that $\ell(O, B')\|\ell(B, C)$). This will force D to be the second auxiliary point, and we obtain $\ell(B', E)\|\ell(D, (A + C) + E)$). (see Fig. 3.8)

Now add $(C + E)$ using B′ (and B), and finally add $A + (C + E)$ using B (and D). This gives $\ell(B, (C + E))\|\ell(D, A + (C + E))$. Since $\ell(B', E)\|\ell(B, C + E)$, the parallel axiom implies that the points $(A + C) + E$ and $A + (C + E)$ are the same. ■

The last main theorem on addition states that addition is *commutative*. For this the *converse* of Desargues' Theorem for affine planes is needed. This, together with a proof that Desargues' Theorem (I) is implied by Desargues' Theorem (II) is the subject of the next section.

EXERCISES

1. Construct an addition table for the line {AEI} in the affine plane of order 3 (Example 7 in Chapter 2) with A = O. Use this table to find the inverse of the point E. Now find this inverse geometrically as in Theorem 7, and observe that they are the same.

   Exercises 2–4 refer to the affine plane of order 4 whose points and lines are repeated below. $\mathcal{P} = \{A, B, \dots, P\}$, and the lines are grouped into pencils:

{OIDF}	{HBCD}	{HFKP}	{OAJH}	{HEIM}
{ECPA}	{EFGJ}	{BEOL}	{GIPB}	{BFAN}
{KMJB}	{IAKL}	{JNCI}	{FCML}	{CGKO}
{GHLN}	{MNOP}	{AGDM}	{EDKN}	{DJLP}

2. a. Find the line containing K and parallel to {BEOL}. Whree does this line intersect {MNOP}?
   b. On {MNOP} add M + N, using B as auxiliary point. What is the second auxiliary point?

3. Complete the addition table for {OIDF}. What is the inverse of D?

+	O	I	D	F
O				
I				
D				
F				

4. Find a parallelogram in the plane. What can you say about is diagonals?
5. Suppose that A, B, and C are noncollinear points in a Desarguesian affine plane $(\mathscr{P}, \mathscr{L})$. Let O be the unique point such that (A, B, C, O) is a parallelogram, and let D be the unique point such that (A, C, B, D) is a parallelogram. Relative to O, show that A + A = D.
6. Suppose that $(\mathscr{P}, \mathscr{L})$ is a Desarguesian affine plane in which the diagonals of every parallelogram are parallel. Suppose that A is any point in $\mathscr{P}$. Prove that relative to any O, A + A = O.
7. Find five orthogonal partitions of the numbers {1, . . . , 16}.
8. Find three orthogonal Latin squares of order 4.

3.5 THE CONVERSE OF DESARGUES' THEOREM

As was stated above, Desargues' Theorem is equivalent to its own converse in the affine as well as the projective plane. By this is meant that the converse of Desargues' Theorem can be proved using Axioms *A*1, *A*2, *A*3, and *A*4, but also by assuming *A*1, *A*2, *A*3, and the converse of Desargues' Theorem, Desargues' Theorem can be proved. In fact more can be done. We will first use *A*1, *A*2, *A*3, and Desargues' Theorem (II) to prove the converse. Then we will use *A*1, *A*2, *A*3, and the converse to prove Desargues' Theorem. This will imply that, instead of assuming Desargues' Theorem, it would have been enough to assume only Desargues' Theorem (II).

■ **THEOREM 9. The converse of Desargues' Theorem for affine planes.** Let A, B, C and A′, B′, C′ be two triples of noncollinear points in a Desarguesian affine plane. Suppose that

$$\ell(A, B) \| \ell(A', B'),\ \ell(A, C) \| \ell(A', C'),\ \text{and}\ \ell(B, C) \| \ell(B', C').$$

Then either $\ell(A, A') \| \ell(B, B') \| \ell(C, C')$ or $\ell(A, A') \cap \ell(B, B') \cap \ell(C, C') = P$ for some P.

Proof (using A1, A2, A3, and Desargues' Theorem (II); see Fig. 3.9): Assume that $\ell(A, B) \| \ell(A', B')$; $\ell(A, C) \| \ell(A', C')$; $\ell(B, C) \| \ell(B', C')$. If it

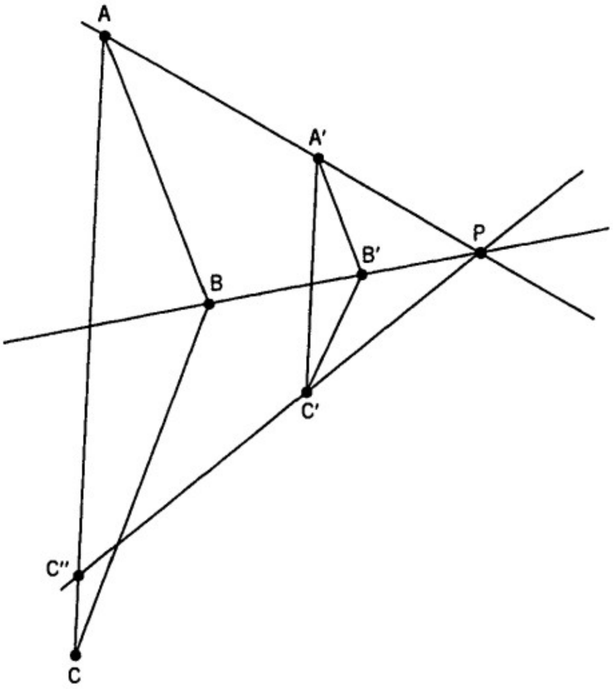

Figure 3.9

is not the case that the lines $\ell(A, A')$, $\ell(B, B')$, and $\ell(C, C')$ are all parallel, two of them must meet. Suppose that $\ell(A, A') \cap \ell(B, B') = P$. Let $\ell(C', P) \cap \ell(A, C) = C''$. Use Desargues' Theorem (II) on A, B, C'' and A', B', C' to obtain $\ell(B, C'') \| \ell(B', C')$. But $\ell(B, C)$ is the unique line through B and parallel to $\ell(B', C')$. Thus $\ell(B, C) = \ell(B, C'')$. This line intersects $\ell(A, C)$ in at most one point; hence $C = C''$, and $P \in \ell(C, C')$.

■

■ **THEOREM 10.** Desargues' Theorem is true in any affine plane in which its converse holds.

Proof: (I) Suppose that A, B, C and A′, B′, C′ are triples of noncollinear points. Suppose that $\ell(A, A') \| \ell(B, B') \| \ell(C, C')$, and let $\ell(A, B) \| \ell(A', B')$ with $\ell(A, C) \| \ell(A', C')$. It must be shown that $\ell(B, C) \| \ell(B', C')$.

Suppose not. Then let C'' be the point on $\ell(A, C)$ such that $\ell(B, C'') \| \ell(B', C')$. If $C \neq C''$, then $\ell(C'', C') \cap \ell(B, B') = P$ for some point P (they cannot be parallel since $\ell(C, C')$ is the unique line containing C′

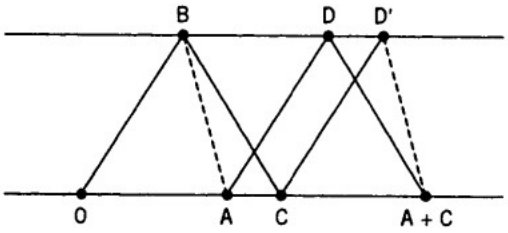

Figure 3.10

parallel to $\ell(B, B')$). Use the converse of Desargues' Theorem on A, B, C'' and A', B', C' to get $\ell(A, A')$, $\ell(B, B')$ and $\ell(C'', C')$ all parallel or all meeting at one point. But the first two are assumed parallel, and the latter two intersect at P, a contradiction.

(II) Let A, B, C and A', B', C' be triples of noncollinear points. Suppose $\ell(A, A') \cap \ell(B, B') \cap \ell(C, C') = P$, and let $\ell(A, B) \| \ell(A', B')$ with $\ell(A, C) \| \ell(A', C')$. It must be shown that $\ell(B, C) \| \ell(B', C')$.

Suppose not. Then let C'' be the point on $\ell(A, C)$ such that $\ell(B, C'') \| \ell(B', C')$. If $C \neq C''$, then P is not contained in $\ell(C'', C')$. Use the converse of Desargues' Theorem on A, B, C'' and A', B', C' to get $\ell(A, A')$, $\ell(B, B')$, and $\ell(C'', C')$ all parallel or all meeting at one point. But the first two are assumed to meet at P, which is not in the third line, a contradiction. ■

Corollary. In any affine space in which Desargues' Theorem (II) holds, Desargues' Theorem holds as well.

■ **THEOREM 11.** Addition of points on a line in any Desarguesian affine plane is commutative.

Proof: Compute $A + C$ using any point B (and D). Now find $C + A$ using the same point B (and D'). Since $\ell(B, A) \| \ell(D', C + A)$, $C + A$ is the same point as $A + C$ if $\ell(B, A) \| \ell(D', A + C)$. (See Fig. 3.10)

First use the converse of Desargues' Theorem on $A, D, A + C$, and D', C, B to show that the lines $\ell(A, D')$, $\ell(D, C)$, and $\ell(A + C, B)$ are all parallel or meet at a single point. Now use Desargues' Theorem on A, D, B, and $D', C, A + C$ to obtain $\ell(A, B) \| \ell(D', A + C)$, which completes the proof. ■

EXERCISES

1. Suppose that ℓ and m are parallel lines in a Desarguesian affine plane $(\mathscr{P}, \mathscr{L})$. Suppose that P, Q, and R are distinct points on ℓ, with S, T, and U distinct points on m as shown in Fig. 3.11. Assume that $\ell(P, S) \| \ell(R, U)$ and $\ell(P, T) \| \ell(Q, U)$. Prove that $\ell(Q, S) \| \ell(R, T)$.

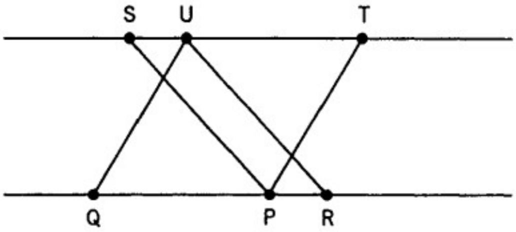

Figure 3.11

2. The statement in Exercise 1 is a theorem in Desarguesian affine planes. State the corresponding theorem for Desarguesian projective planes.
3. Let (A, B, C, D) be a quadrilateral in a Desarguesian affine plane, none of whose sides are parallel. Define A′ to be the unique point such that (A′, B, C, D) is a parallelogram, and B′ the unique point such that (A, B′, C, D) is a parallelogram as shown in Fig. 3.12. Prove that $\ell(A, A') \| \ell(B, B')$.

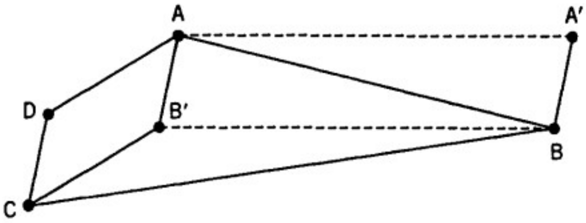

Figure 3.12

4. Let $(\mathscr{P}, \mathscr{L})$ be a Desarguesian affine plane containing the distinct points A, B, C, D, E, F, G. Assume that $\ell(A, D) \| \ell(B, G) \| \ell(E, F)$; $\ell(A, F) \| \ell(D, E)$;

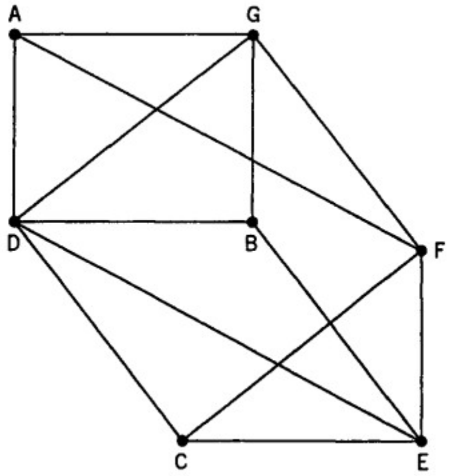

Figure 3.13

$\ell(A, G) \| \ell(D, B) \| \ell(C, E)$; $\ell(D, C) \| \ell(B, E)$ where all lines listed above are distinct. (See Fig. 3.13.) Prove:

a. $\ell(D, C) \| \ell(G, F)$.

b. $\ell(D, G) \| \ell(C, F)$.

3.6 MULTIPLICATION ON LINES OF AN AFFINE PLANE

In the preceding sections it was shown that addition is associative and commutative, O acts as an identity for addition, and every point has an additive inverse. These properties are discussed in Appendix A, together with an appropriate concept of *multiplication*, which can now be introduced for points on a line in an affine plane. Starting with a line ℓ, through a fixed origin O, as above, a fixed point I, *different* from O is chosen (recall that Axiom $A3$ guarantees at least two points on each line). Having these points, multiplication can be defined with respect to the selected O and I.

Definition of multiplication. Again $(\mathscr{P}, \mathscr{L})$ is a Desarguesian affine plane, with ℓ a line and O and I distinguished points of ℓ. (See Fig. 3.14) For points A and C in ℓ, to multiply A and C (relative to O and I):

1. Select B not in ℓ.
2. Let m be the line containing A, and parallel or equal to $\ell(I, B)$.
3. Let $D = m \cap \ell(O, B)$.
4. Let k be the line containing D and parallel or equal to $\ell(B, C)$.
5. AC is defined to be $k \cap \ell$.

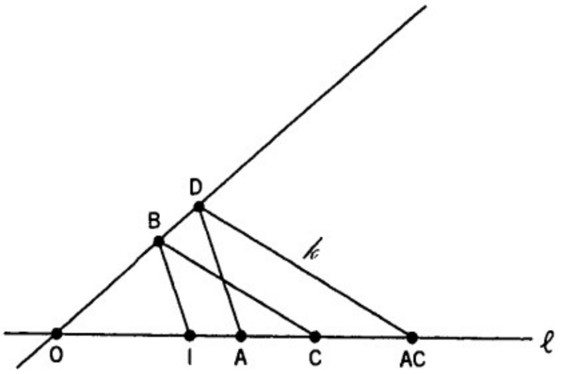

Figure 3.14

It will be shown in Theorem 15 that the multiplication of points on ℓ does not depend on the choice of the fixed point B.

Following the pattern established for addition, it is first shown that the suggestively named "I" acts as a multiplicative identity. Existence of nonzero inverses and associativity will follow as well; however multiplication is *not* in general commutative.

■ **THEOREM 12.** For any A in ℓ, AI = IA = A.

Proof: Select B (and D) as described above. Since $\ell(B, I) \| \ell(D, A)$, it follows that AI = A. In computing IA, note that line m described in step 2 is equal to $\ell(I, B)$, whence D = B and $k = \ell(B, A)$. Thus IA ($= \ell \cap k$) = A. ■

■ **THEOREM 13.** AO = OA = O for any A in ℓ.

Proof: In computing AO, the line k in step 4 is equal to $\ell(B, O)$, whence AO = O. In computing OA, the auxiliary point D is O, thus OA = O. ■

■ **THEOREM 14.** If A ≠ O, there is a point (A^{-1}) in ℓ such that $A(A^{-1}) = (A^{-1})A = I$.

Proof: Select B and D so that $\ell(I, B) \| \ell(A, D)$ with D on $\ell(O, B)$. (See Fig. 3.15.) Let n be the line containing B and parallel to $\ell(D, I)$, and let $n \cap \ell = (A^{-1})$. Multiplying $A(A^{-1})$ using B and D gives I, and multiplying $(A^{-1})A$ using D and B also yields I. ■

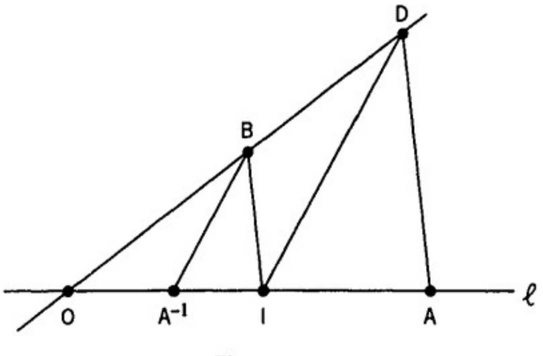

Figure 3.15

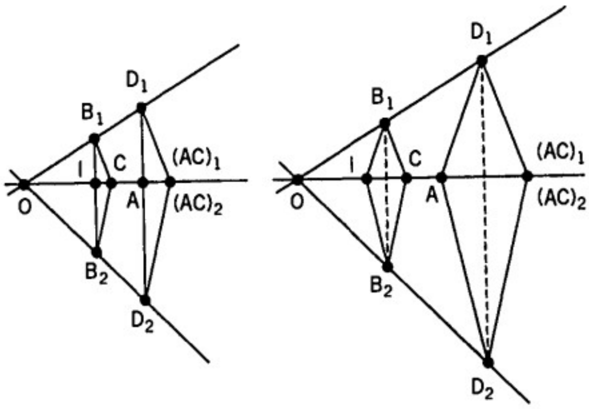

Figure 3.16

In Theorem 6 Desargues' Theorem (I) was used to prove that the sum of two points on a line (relative to a fixed origin O) does not depend on the choice of the auxiliary points. An analogous result (this time depending on Desargues' Theorem (II)) holds for multiplication. Observe also that as was the case with addition, the first auxiliary point determines the second one uniquely.

■ **THEOREM 15.** The definition of AC is independent of the choice of B above.

Proof: Obtain the product $(AC)_1$ by using B_1 (and D_1); then obtain $(AC)_2$ using B_2 (and D_2) as in Fig. 3.16.

CASE 1. I, B_1, and B_2 are collinear. Use Desargues' Theorem on B_1, B_2, C and D_1, D_2, $(AC)_1$ to obtain $\ell(B_2, C) \| \ell(D_2, (AC)_1)$, which forces $(AC)_1 = (AC)_2$.

CASE 2. The proof of Case 2 is left as an exercise. ■

As was the case with addition, Theorem 15 can be used to show that multiplication of points on a line is associative.

■ **THEOREM 16.** For A, C, and E on ℓ, $(AC)E = A(CE)$.

Proof: (See Fig. 3.17, and compare this with the proof that addition is associative.) First multiply AC using B (and D). Now multiply (AC)E using B' (and D), where $\ell(I, B') \| \ell(AC, D)$. Multiply CE using B' (and B), and finally multiply A(CE) using B (and D) to obtain $A(CE) = (AC)E$. ■

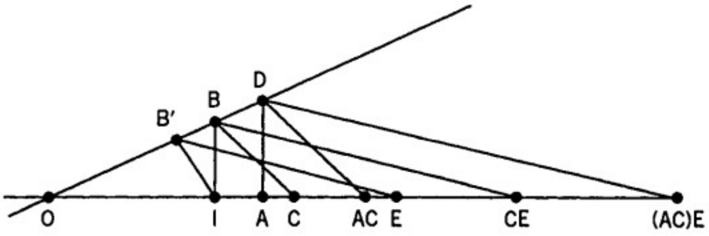

Figure 3.17

EXERCISES

1. In the affine plane of order 3 given in Example 7 of Chapter 2, fix ℓ as {CFI}, and let C = O. Make a multiplication table for the line (which is now {OIF}).
2. In the affine plane of order 4 given with the exercises of Section 3.4, p. 57, make a multiplication table for the line {OIDF}.
   a. What is the multiplicative inverse of D? of F?
   b. Compute (DD)F and D(DF) from the table, and check that they are the same.
   c. Compute D(I + F) and DI + DF from the table and check that they are the same.
3. Prove Case 2 of Theorem 15.
4. Let O, I, and A be distinct collinear points in a Desarguesian affine plane $(\mathscr{P}, \mathscr{L})$. Define the point 2I to be I + I and 2A to be the point A + A, the addition done relative to O. Prove geometrically that (2I)A = A + A assuming that the points O, I, 2I, A, and 2A are all distinct. [*Hint:* Compute I + I using B (and D) as auxiliary points as shown in Fig. 3.18. (2I)A is computed using B (and D′). Compute A + A using B and E.]

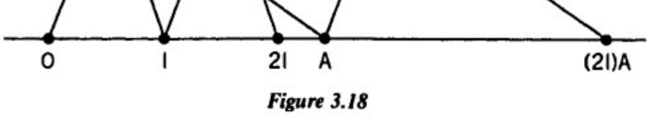

Figure 3.18

3.7 PAPPUS' THEOREM AND FURTHER PROPERTIES

Multiplication in a Desarguesian affine plane is not necessarily commutative. To present an example of a plane with noncommutative multiplication, some algebraic results are necessary, so the example is deferred until Chapter 4. However, the geometric counterpart of commutativity of multiplication is *Pappus' Theorem*, which was stated as a *Euclidean* theorem in Chapter 1, Theorem 12.

■ **PAPPUS' THEOREM.** Let $\ell \cap m = O$, with P, Q, and R in ℓ; S, T, U in m; $\ell(P, T) \| \ell(Q, U)$, and $\ell(Q, S) \| \ell(R, T)$. Then $\ell(P, S) \| \ell(R, U)$.

■ **THEOREM 17.** Pappus' Theorem is true in a Desarguesian affine plane if and only if multiplication on the points of its lines is commutative.

Proof: Choosing I in ℓ so that $\ell(I, S) \| \ell(P, T)$, then PQ = R (multiplied using S (and T)). If Pappus' Theorem is true, then QP = R as well (multiplied using S (and U)). (See Fig. 3.19) Conversely, if Pappus' Theorem fails, then, relative to O and I, PQ = R but QP ≠ R, so multiplication is not commutative. ■

Pappus and Desargues

In all the examples of Desarguesian affine planes presented so far, Pappus' Theorem holds. In fact algebraic methods can be used to show that Pappus' Theorem is true in any *finite* Desarguesian affine plane, but there are (infinite) Desarguesian affine planes in which Pappus' Theorem fails. On the other hand, it has been shown that Pappus' Theorem implies that of Desargues (Hessenberg 1905).

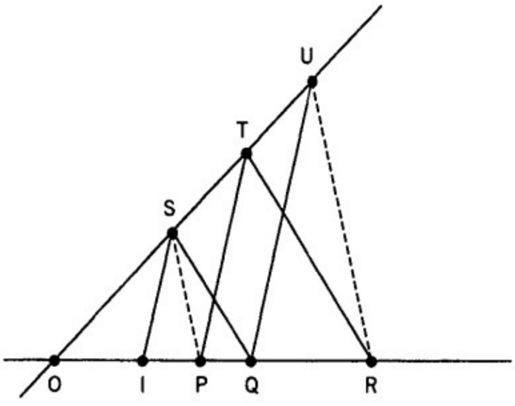

Figure 3.19

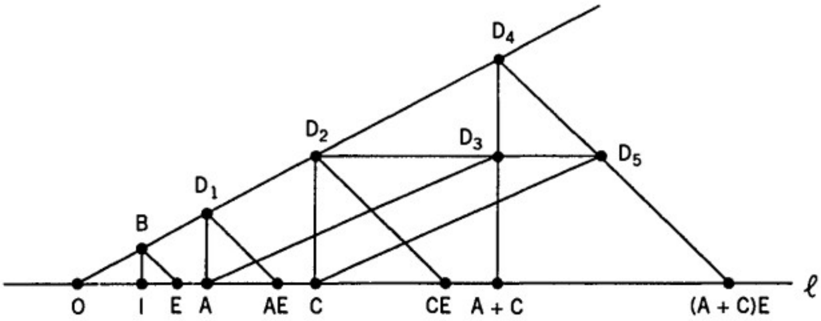

Figure 3.20

The Distributive Laws

Besides their individual properties, addition and multiplication are related by the *distributive laws*. Because multiplication is not necessarily commutative, two distributive laws are needed. Furthermore, after laws $(A + C)E = AE + CE$ and $E(I + C) = E + EC$ are proved *geometrically*, an algebraic proof shows that, for an arbitrary A, $E(A + C) = EA + EC$.

■ **THEOREM 18.** For A, C, and E in ℓ, $(A + C)E = AE + CE$.

Proof: Select $B \notin \ell$. (See Fig. 3.20.)
Compute:

AE using B (and D_1).
CE using B (and D_2).
$A + C$ using D_2 (and D_3).
$(A + C)E$ using B (and D_4).

Let D_5 be in $\ell(D_4, (A + C)E)$, so that $\ell(A, D_3) \| \ell(AE, D_5)$. Use Desargues' Theorem on D_4, D_3, D_5 and D_1, A, AE to get $\ell(D_3, D_5) \| \ell(A, AE)$, which shows that $D_5 \in \ell(D_2, D_3)$. Now add $AE + CE$ using D_2 (and D_5), and note that $\ell(D_2, CE) \| \ell(D_5, AE + CE)$. But this means that $AE + CE = (A + C)E$. ■

■ **THEOREM 19.** For C and E in ℓ, $E(I + C) = E + EC$.

Proof: Select $B \notin \ell$. (See Fig. 3.21.)
Compute:

EC using B (and D).
$I + C$ using B (and D_1).
$E + EC$ using D_1 (and D_2).

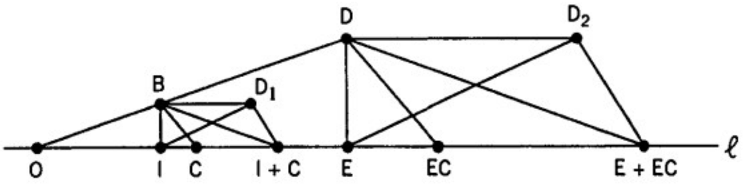

Figure 3.21

Use the converse of Desargues' Theorem on D_1, B, I and D_2, D, E which implies that $O \in \ell(D_1, D_2)$. Now use Desargues' Theorem on D_1, D_2, $E + EC$, and $B, D_1, I + C$, which gives $\ell(D, E + EC) \| \ell(B, I + C)$, whence $E + EC = E(I + C)$. ■

Corollary. For A, C, and E in ℓ, $E(A + C) = EA + EC$.

Proof: If $A = O$, the result is immediate. If $A \neq O$, then

$$\begin{aligned}(E(A + C) - EA - EC)A^{-1} &= E((A + C)A^{-1} - E - ECA^{-1} \\ &= E(I + CA^{-1}) - E - ECA^{-1} \\ &= E + ECA^{-1} - E - ECA^{-1} \\ &= O.\end{aligned}$$

Thus $E(A + C) - EA - EC = O$, and

$$E(A + C) = EA + EC. \qquad ■$$

The fundamental theorem of synthetic affine geometry, stated as Theorem 1 of this chapter and repeated below, has now been proved.

■ **THEOREM 20. The fundamental theorem of synthetic affine geometry.** Relative to fixed coordinates O and I, any line in a Desarguesian affine plane is a *division ring* in that its addition and multiplication are associative, and have identites, every element has an additive inverse, and every nonzero element has a multiplicative inverse. Addition is commutative, and multiplication distributes over addition.

In the next chapter we will prove that for any division ring $\mathbb{D}$, the elements of $\mathbb{D} \times \mathbb{D}$ are the points of a Desarguesian affine plane whose lines satisfy linear equations of the form $xa + yb = c$. Conversely, any Desarguesian affine plane can be so represented over (or *coordinatized by*) a division ring.

This chapter concludes with another example of an affine plane of order 5. It will be shown in Chapter 4 that this plane can be coordinatized by the field $\mathbb{Z}_5$.

□**EXAMPLE 1: An affine plane of order 5.** $\mathscr{P} = \{A, B, C, \ldots, Y\}$, and the lines are

{OIABC}
{DEFGH}
{JKLMN}
{PQRST}
{UVWXY}
{OHMRV}
{IDNSW}
{AEJTX}
{BFKPY}
{CGLQU}

{ODJPU}
{IEKQV}
{AFLRW}
{BGMSX}
{CHNTY}
{OGKTW}
{IHLPX}

{BHJQW}
{AGNPV}
{IFMTU}
{OFNQX}
{IGJRY}
{AHKSU}
{BDLTV}
{CEMPW}

□

EXERCISES

The following exercises pertain to the plane of order 5 given above.

1. Make addition and multiplication tables for {OIABC}.
2. Make addition and multiplication tables for $\mathbb{Z}_5$. Show that {OIABC} is *isomorphic* to $\mathbb{Z}_5$ by finding a bijection from {OIABC} to $\mathbb{Z}_5$ that preserves addition and multiplication. [*Hint:* Map O to 0 and I to 1.]
3. Find a parallelogram in $(\mathscr{P}, \mathscr{L})$ and find the point of intersection of its diagonals.
4. Find an instance of the configurations for Desargues' Theorem in $(\mathscr{P}, \mathscr{L})$.
5. Find an instance of the configuration for Pappus' Theorem in $(\mathscr{P}, \mathscr{L})$.
6. Use $(\mathscr{P}, \mathscr{L})$ to define a projective plane of order 5.

*7. Let $(\mathscr{P}', \mathscr{L}')$ be a projective plane in which Pappus' Theorem holds, and prove Desargues' Theorem as follows: Let $\ell(A, A') \cap \ell(B, B') \cap \ell(C, C') = O$, and let $A'' = \ell(B, C) \cap \ell(B', C')$, $B'' = \ell(A, C) \cap \ell(A', C')$, and $C'' = \ell(A, B) \cap \ell(A', B')$. Define $E = \ell(A, C) \cap \ell(B', C')$, $F = \ell(A, B') \cap \ell(O, C)$, $G = \ell(A, B) \cap \ell(O, E)$, and $H = \ell(A', B') \cap \ell(O, E)$. Prove that A'', B'', and C'' are collinear by using Pappus' Theorem on O, B, B' and A, E, C; then on O, A, A' and B', C', E, and finally, on A, B', F and H, G, E. [*Hint:* In the first use of Pappus' Theorem, since $\ell(B, C) \cap \ell(B', E) = A''$, $\ell(A, B') \cap \ell(O, C) = F$ and $\ell(O, E) \cap \ell(A, B) = G$, we obtain A'', F, and G collinear.]

8. Find six orthogonal partitions of the set $\{1, 2, \ldots, 25\}$.

9. Find four orthogonal Latin squares of order 5.

Theorem 4.12 (Gauss)

There exists a Euclidean construction of a regular n-gon if and only if the number of its sides is equal to

$$n = 2^i F_{m_1} F_{m_2} \dots F_{m_j},$$

where $i \geq 0$, $j \geq 0$, $n \geq 3$ are integers and $F_{m_1}, F_{m_2}, \dots, F_{m_j}$ are distinct Fermat primes.

For a proof based on Galois theory see [199, Chapter 16].

5.2.2 The discretization group

We generalize the above discussion to general K. Consider a ^{K}DMDGP graph $G = (V, E)$ with as few edges as possible, and edge weight function d. The fact that E has minimum cardinality, while G still has a contiguous $(K - 1)$-lateration order, implies that G is just a chain of $(K + 1)$-cliques, with each consecutive pair sharing a K-clique, see Fig. 5.4. In fact, the edges in E are all discretization edges, according to the edge classification introduced at the end of Sect. 4.4.4.

Let X be the set of all realizations of G in $\mathbb{R}^K$ up to rotations and translations. For any $x \in X$ and $v \in V$ with $v > K$, we define the *partial reflection* operator $g_v : \mathbb{R}^{Kn} \to \mathbb{R}^{Kn}$ given by:

$$g_v(x_1, \ldots, x_n) = (x_1, \ldots, x_{v-1}, R_x^v(x_v), \ldots, R_x^v(x_n)), \tag{5.1}$$

where $R_x^v : \mathbb{R}^K \to \mathbb{R}^K$ is a reflection operator that maps each point in $\mathbb{R}^K$ to its reflection with respect to the hyperplane defined by $\{x_{v-1}, \ldots, x_{v-K}\}$.

We remark that for the R_x^v to be reflections in $\mathbb{R}^K$, we need the edge weight function d to be such that the assumption on the rank of A being full holds (Sect. 3.3.6). This assumption will stand for the rest of this chapter.

Obviously, if you apply any reflection operator twice, you reflect points back to their original positions. Since g_v is simply a composition of $v - 1$ identities and $n - v + 1$ reflections, it enjoys the same property: thus, every g_v is idempotent.

Also, for $x \in X$ and $K < u < v$, we have:

$$\begin{aligned}
g_u g_v(x) &= g_u(x_1, \ldots, x_{v-1}, R_x^v(x_v), \ldots, R_x^v(x_n)) \\
&= (x_1 \ldots, x_{u-1}, R^u_{g_v(x)}(x_u), \ldots, R^u_{g_v(x)} R_x^v(x_v), \ldots, R^u_{g_v(x)} R_x^v(x_n)) \\
&= (x_1 \ldots, x_{u-1}, R_x^u(x_u), \ldots, R^v_{g_u(x)} R_x^u(x_v), \ldots, R^v_{g_u(x)} R_x^u(x_n)) \\
&= g_v(x_1, \ldots, x_{u-1}, R_x^u(x_u), \ldots, R_x^u(x_n)) \\
&= g_v g_u(x).
\end{aligned}$$

To infer the third line from the second, we used the fact that $R^u_{g_v(x)} R_x^v(x_w) = R^v_{g_u(x)} R_x^u(x_w)$ for each $w \geq v$. A proof of this is given in [85, Lemma 1]; we only provide here a graphical sketch of the proof in 2D (Fig. 5.5), where, to simplify notation, we let $R_x^v = \rho^y$, where y is the normal to the line through x_{v-1}, x_{v-2}.

Let $\mathscr{G}_D(G) = \langle g_v \mid v > K \rangle$, i.e., the symmetry group generated by the action of all g_v's on the realizations of G, be the *discretization group* of G. Since its elements commute, as shown above, $\mathscr{G}_D$ is an abelian group. Moreover, all of the elements are idempotent. Thus, $\mathscr{G}_D$ is isomorphic to C_2^{n-K}, and the Cartesian product of $n - K$ copies of the cyclic group C_2.

Notice that if $v \in V$ such that $v > K$ and H is the subgraph of G induced by $\{1, \ldots, v\}$, then the discretization group of H is isomorphic to a subgroup of the discretization group of G: this follows

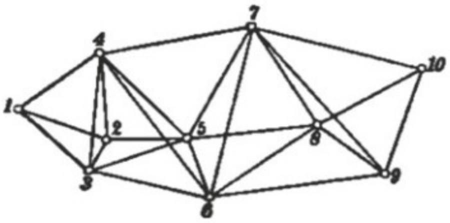

Fig. 5.4 A chain of 4-cliques in $\mathbb{R}^3$ [58].

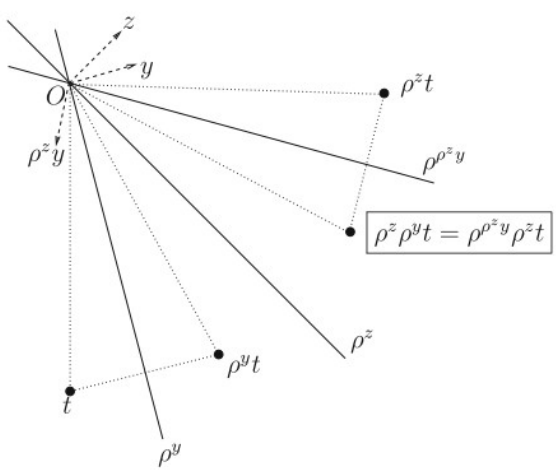

Fig. 5.5 Reflecting through ρ^y first and ρ^z second is equivalent to reflecting through ρ^z first and (the reflection of ρ^y through ρ^z) second.

by mapping $g_u \in \mathscr{G}_D(H)$ to $\bar{g}_u \in \mathscr{G}_D(G)$ (for each $u \leq v$) such that for $\bar{x}$ a realization of G and $x = (\bar{x}_1, \ldots, \bar{x}_v)$ the induced realization of H,

$$\bar{g}_u(\bar{x}) = (g_u(x), R_x^u(x_{v+1}), \ldots, R_x^u(x_n)).$$

The point of this remark is to emphasize that we can apply partial reflections in $\mathscr{G}_D(H)$ to realizations of G.

The most interesting feature of the discretization group is that its action on X is transitive: given a single realization $x^1 \in X$, for every realization $x \in X$ there is $g \in \mathscr{G}_D(G)$ such that $g(x^1) = x$. In other words, $\mathscr{G}_D(G)x^1 = X$. This can be shown by induction on n.

The induction starts because when $n = K + 1$ we have $X = \{x^1, x^2\}$, where x^2 is a reflection of x^1 with respect to $\{x_1, \ldots, x_K\}$ (see Sect. 3.3.4): so $g_{K+1}(x^2) = x^1$ and vice versa.

Now let $H = G[\{1, \ldots, n-1\}]$, $X_H = \mathsf{RealizeDMDGP}(H, d, K)$, and assume that the action of $\mathscr{G}_D(H)$ on X_H is transitive. Pick any two realizations x^1, x^2 of G in X, and consider the partial realizations consisting of their first $n-1$ vectors: let $x^1 = (\bar{x}^1, y)$ and $x^2 = (\bar{x}^2, z)$, where $\bar{x}^1, \bar{x}^2 \in \mathbb{R}^{K(n-1)}$ and $y, z \in \mathbb{R}^K$. Note that RealizeDMDGP computes X by extending partial realizations in X_H using Next, so $\bar{x}^1, \bar{x}^2$ must be in X_H by definition of Next.

By the induction hypothesis, since $\bar{x}^1, \bar{x}^2 \in X_H$, and $\mathscr{G}_D(H)$ is assumed to be transitive, there is $\bar{g} \in \mathscr{G}_D(H)$ such that $\bar{g}(\bar{x}^2) = \bar{x}^1$. Since every hyperplane W, given e.g. as K points in $\mathbb{R}^K$, splits $\mathbb{R}^K$ into two (open) half-spaces, which we can label as positive and negative, we can assign $+, -$ labels to both y and z, according to which side of the reflecting hyperplane W they are on (this labelling is known as an *orientation*). Since a partial reflection g_v will swap the orientation of every realization vector from the v-th onwards, either $\bar{g}$ or $g_n\bar{g}$ maps x^2 to x^1 and vice versa, which concludes the proof.

Limited to graphs with no pruning edges, this suggests an alternative implementation of RealizeDMDGP: whenever $S = \mathsf{Next}_d^K(W)$ is computed (see Alg. 5), arbitrarily dismiss one of the two elements, but record g_v at each level. At level n, when a realization x is found, simply compute X by applying all possible compositions of the group elements $g_{K+1}, \ldots, g_n$ to x. In this setting, x can be found in polytime, since there is no branching, but it still takes exponential time to list all possible subsets of the generators of $\mathscr{G}_D(G)$, see Fig. 5.6.

Lastly, remark that, since $\mathscr{G}_D(G)x = X$ for all $x \in X$, then $\mathscr{G}_D(G)X = \{gx \mid g \in \mathscr{G}_D(G) \wedge x \in X\} = X$: so X is *invariant* with respect to $\mathscr{G}_D(G)$, i.e., X does not change, as a set, under the action of the discretization group.

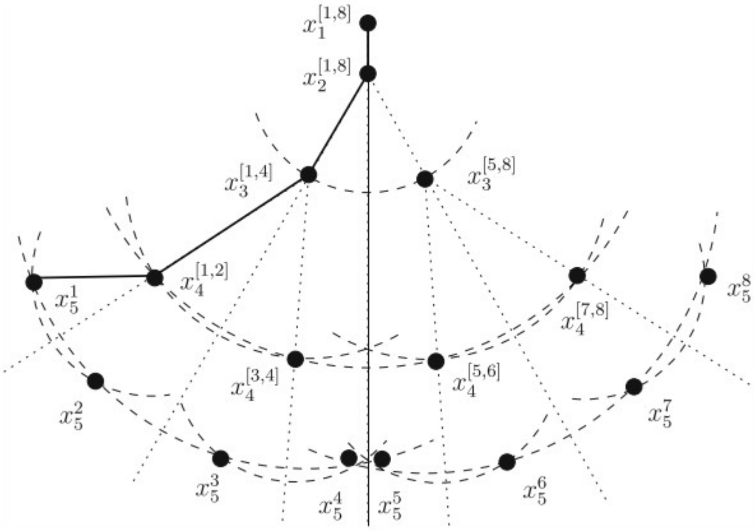

Fig. 5.6 Action of the discretization group $\mathscr{G}_D(G) = \langle g_3, g_4, g_5 \rangle$ on a realization $x^1 = (x_1^1, \ldots, x_5^1)$ is transitive and commutative: we have $g_5(x^1) = x^2, g_4(x^1) = x^4, g_5 g_4(x^1) = g_4 g_5(x^1) = x^3, g_3(x^1) = x^8, g_5 g_3(x^1) = g_3 g_5(x^1) = x^7, g_4 g_3(x^1) = g_3 g_4(x^1) = x^5, g_5 g_4 g_3(x^1) = g_5 g_3 g_4(x^1) = g_4 g_5 g_3(x^1) = g_4 g_3 g_5(x^1) = g_3 g_5 g_4(x^1) = g_3 g_4 g_5(x^1) = x^6$. The notation $x_j^{[i,\ell]}$ indicates that the neighboring dot represents the position of the (equal) point vectors $x_j^i, x_j^{i+1}, \ldots, x_j^{\ell} \in \mathbb{R}^K$, for $j \in \{1, \ldots, 5\}$ and $x^i \in X$ for all $i \leq 8$.

5.2.3 The pruning group

The results of Sect. 5.2.2 rely on G being a chain of $(K+1)$-cliques. But our motivation for studying $^{\mathsf{K}}$DMDGP graphs is that they provide a good model for protein backbones. The issue is that protein graphs have more edges besides those necessary for the existence of their contiguous trilateration order: in other words, their pruning edge set is nonempty. These edges, and their associated distance values, give RealizeDMDGP the information that is necessary in order to prune realizations that are not consistent with the measured distances; therefore, it would be unwise to disregard them. Below, we study how partial reflection symmetries behave in the presence of pruning edges.

Let $G = (V, E)$ be a weighted $^{\mathsf{K}}$DMDGP graph and d an edge weight function. We partition E into discretization edges E_D and pruning edges E_P. The graph $G[E_D]$ induced by the discretization edges is a minimal $^{\mathsf{K}}$DMDGP graph, and hence, by the results in Sect. 5.2.2, its realization set $\bar{X}$ is invariant with respect to its discretization group. We define $\mathscr{G}_D(G) = \mathscr{G}_D(G[E_D])$.

Figure 5.7 shows the partial planar realizations computed by RealizeDMDGP in the first five BP tree levels of an instance where $K = 2$. The positions of vertices at level j arise as the intersection of two circles (dashed arcs) centered at vertex levels $j-1$ and $j-2$, with respective radii $d_{j-1,j}, d_{j-2,j}$. The partial reflection symmetry at each level is defined across the dotted lines through the circle centers at the preceding two levels. The solid concentric circles at levels $1, \ldots, 5$ are all centered at $x_1^{[1,8]}$, and their radii are the distance values on pruning edges which are compatible with the given discretization edges. The crucial observation is the symmetric placement of the points x_j^i on the solid circles, for $i \in \{1, \ldots, 8\}$ and $j \in \{3, 4, 5\}$. More precisely, pairs like $x_4^{[1,2]}, x_4^{[7,8]}$ or $x_4^{[3,4]}, x_4^{[5,6]}$, which are reflections along the line defined by x_1, x_2, are at the same distance from $x_1^{[1,8]}$. So, if $X \neq \varnothing$ and we had a pruning edge $\{1, 4\}$, the distance d_{14} would either prune $x_4^{[1,2]}, x_4^{[7,8]}$ or $x_4^{[3,4]}, x_4^{[5,6]}$; it could

CHAPTER 3

Gravity As Curvature

We now turn to the description of curvature.

3.1. Einstein Identified Gravity with the Curvature of Space-Time

Albert Einstein identified gravity with the curvature of space-time: A massive object distorts, or curves, space-time; and other objects respond gravitationally by following (locally) shortest paths in that curved space, paths that deserve to be called straight. Misner, Thorne, and Wheeler, in their book "Gravitation" [**97**], compare the path followed by an object acting under the influence of gravity to a straight cut in the surface of an apple where this cut, near the stem of the apple, dips toward the stem as if that stem were a source of gravitational force.

Two problems must be solved in application of Einstein's ideas: (1) We usually recognize the curvature of an object by observing how it curves in some larger space (= extrinsic curvature). Since we live *within* space-time, how can we recognize and describe its curvature from within space-time itself (= intrinsic curvature)? (2) How do we recognize and describe the paths in a curved object that are locally shortest, hence deserve to be called *straight* (= geodesic)?

Gauss showed us how these problems can be solved for 2-dimensional surfaces. Riemann generalized Gaussian curvature to higher dimensions by considering the Gaussian curvature of each 2-dimensional slice in higher dimensional space.

In this introduction to curvature, we will restrict ourselves, as Gauss did, to 2-dimensional surfaces that reside in 3-dimensional Euclidean space. But we will not follow Gauss's path. For both questions, we will first approximate the surface by a polyhedral surface where it is easy to answer both questions: How flat is a polyhedral surface? How straight is an edge path in a polyhedral surface? The corresponding concepts in smooth surfaces will then follow by a limiting process.

CHAPTER 4

Curvature by Polyhedral Approximation

4.1. Approximating Smooth Surfaces by Polyhedra

Gauss described a smooth surface in $\mathbb{R}^3$ locally as the image of a map $S : \mathbb{R}^2 \to \mathbb{R}^3 : (x, y) \mapsto (x, y, z)$, where z is a many-times differentiable function of x and y. It is an easy matter to triangulate such a surface.

Key Idea 4.1. *Every smooth surface S in $\mathbb{R}^3$ can be closely approximated locally by polyhedral surfaces S''.*

We restrict our attention to piecewise smooth disks in the surface S.

Definition 4.2. A disk D in a smooth surface S is called *piecewise smooth* if there are finitely many points p_0, p_1, …, $p_n = p_0$ in the boundary ∂D of D that divide ∂D into arcs p_0p_1, p_1p_2, …, $p_{n-1}p_n$ each of which is smooth and such that there is a well-defined angle of turning in ∂D at each of the points p_1, p_2, …, p_n.

Theorem 4.3. *If $D \subset \mathbb{R}^2$ is a disk that is mapped homeomorphically by $S : \mathbb{R}^2 \to \mathbb{R}^3$ to a piecewise smooth disk $S(D) \subset S$, then $S(D)$ can be closely approximated by polyhedral disks $D' \subset \mathbb{R}^3$.*

Proof. Choose points q_0, q_1, …, $q_m = q_0$ in cyclic order on ∂D that divide ∂D into tiny arcs. Since D is piecewise smooth, the points q_i will be the vertices of a polygonal simple closed curve J in $\mathbb{R}^2$ that closely approximates ∂D. The curve J bounds a disk $D' \subset \mathbb{R}^2$ that approximates D. The disk D' can be triangulated with very small triangles T_j. If A, B, and C are the vertices of T_j, then S maps them to vertices $A' = S(A)$, $B' = S(B)$, and $C' = S(C)$. The vertices A', B', and C' are the vertices of a triangle $T'_j \subset \mathbb{R}^3$. The triangles T'_j are the triangles of a polyhedral disk D' that closely approximates $S(D)$. ☐

4.2. The Curvature of a Polyhedral Disk

In this chapter we define the curvature of a polyhedral disk in $\mathbb{R}^3$. We shall see that curvature is the average obstruction to flattening that disk into the plane locally without distorting lengths or areas.

4.3. How Flat Is a Disk?

We consider a polyhedral disk D, not assumed to be flat, triangulated by finitely many Euclidean triangles. Combinatorially, we can picture the disk as lying in the flat plane as in Figure 1, but to do this we may have to change angles and side lengths of the individual triangles.

If we fix our intention on one of the interior vertices v of our disk, then the triangles containing that vertex form a polyhedral cone with that vertex as tip of the cone. This polyhedral cone is called the *star* of the vertex v in D and is denoted

Capítulo 10

Teorema de Pappus, Pascal y Brianchon

Usaremos los resultados anteriores para demostrar los teoremas de Pappus, Pascal y Brianchon. Demostraremos los siguientes resultados debidos a Carnot.

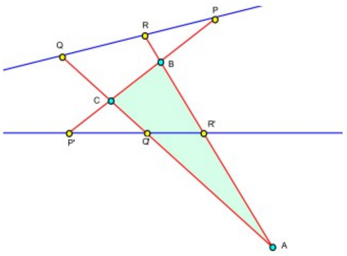
Teorema 10.1 (Carnot para rectas) *Si la recta l intersecta los lados BC, CA y AB del triángulo $\triangle ABC$ en los puntos P, Q y R (pero no uno de los vértices) y la recta l' intersecta los lados BC, CA y AB en los puntos P', Q' y R' (pero no uno de los vértices), entonces*

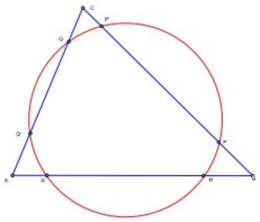
$$\frac{AR}{RB}\frac{BP}{PC}\frac{CQ}{QA}\frac{AR'}{R'B}\frac{BP'}{P'C}\frac{CQ'}{Q'A} = 1$$

Demostración: Usando el teorema de Menelao con las rectas l y l'.

$$\begin{aligned}\frac{AR}{RB}\frac{BP}{PC}\frac{CQ}{QA} &= -1 \\ \frac{AR'}{R'B}\frac{BP'}{P'C}\frac{CQ'}{Q'A} &= -1\end{aligned}$$

que multiplicadas nos dan la igualdad de Carnot. ■





Teorema 10.2 (Carnot) *Si un círculo intersecta los lados BC, CA y AB del triángulo $\triangle ABC$ en los puntos P, P'; Q, Q'; R, R'; respectivamente (pero no uno de los vértices), entonces*

$$\frac{AR}{RB}\frac{BP}{PC}\frac{CQ}{QA}\frac{AR'}{R'B}\frac{BP'}{P'C}\frac{CQ'}{Q'A}=1$$

Demostración: Las potencias de los puntos A, B y C respecto al círculo son:

$$\begin{aligned} AR\cdot AR' &= AQ\cdot AQ' \\ BP\cdot BP' &= BR\cdot BR' \\ CQ\cdot CQ' &= CP\cdot CP' \end{aligned}$$

que multiplicadas nos dan la igualdad de Carnot ■

Los teoremas anteriores se generalizan al caso de una cónica, recordando que un círculo y dos rectas son casos especiales de secciones planas de un cono. Este resultado se puede demostrar usando el corolario 3.75, pag. 114.

Teorema 10.3 (Carnot) *Si una cónica intersecta los lados BC, CA y AB del triángulo $\triangle ABC$ en los puntos P, P'; Q, Q'; R, R'; respectivamente (pero no uno de los vértices), entonces*

$$\frac{AR}{RB}\frac{BP}{PC}\frac{CQ}{QA}\frac{AR'}{R'B}\frac{BP'}{P'C}\frac{CQ'}{Q'A}=1$$

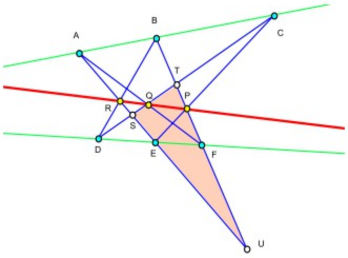
Usando los teoremas de Carnot podemos demostrar ahora los siguientes importantes teoremas. La demostración es la misma para ambos teoremas.

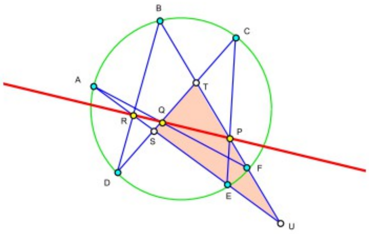
Teorema 10.4 (Pappus) *Si A, B, C son puntos de una recta y D, E y F son puntos de otra recta, entonces los puntos $R = AE\cap BD$, $P = BF\cap CE$ y $Q = AE\cap BD$ están alineados.*

Teorema 10.5 (Pascal) *Si A, B, C, D, E y F son puntos en un círculo (o una cónica), entonces los puntos $R = AE\cap BD$, $P = BF\cap CE$ y $Q = AE\cap BD$ están alineados.*

Demostración: Si $S = AE\cap DC$, $T = BF\cap CD$ y $U = AE\cap BF$ y usamos el teorema de Menelao en el triángulo $\triangle STU$ con las rectas AF, BD y CE obtenemos

$$\begin{aligned} \frac{SQ}{QT}\frac{TF}{FU}\frac{UA}{AS} &= -1 \\ \frac{SD}{DT}\frac{TB}{BU}\frac{UR}{RS} &= -1 \\ \frac{SC}{CT}\frac{TP}{PU}\frac{UE}{ES} &= -1 \end{aligned}$$





y del teorema de Carnot con el triángulo $\triangle STU$

$$\frac{SC}{CT}\frac{TB}{BU}\frac{UA}{AS}\frac{SD}{DT}\frac{TF}{FU}\frac{UE}{ES}=1$$

si multiplicamos las tres primeras igualdades y el resultado lo dividimos entre la última obtenemos

$$\frac{SQ}{QT}\frac{TP}{PU}\frac{UR}{RS}=-1$$

y usando el inverso del teorema de Menelao obtenemos el resultado. ■

Con la notación de los teoremas anteriores denotaremos por $\left\{\begin{smallmatrix} ABC \\ DEF \end{smallmatrix}\right\}$ la recta de Pappus o Pascal respectivamente.

Problemas

Problema 1 *Usar el problema 18, pág. 128,demostrar el teorema de Pappus. (Ayuda: Usar los triángulos de lados AE, BF y CD; y BD, CE y AR).*

Problema 2 **Dado un triángulo ΔABC y un punto P; sean X_a, X_b, P_a y P_b las proyecciones de P en las rectas AP, BP, AC y BC respectivamente. Entonces las rectas X_aP_a, X_bP_b y AB son concurrentes.*

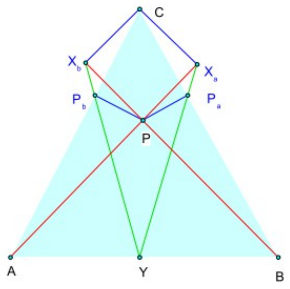


Figura 10-1

Problema 1 **Si A, B, C, D y E son puntos en un círculo $\mathcal{C}$ y F es otro punto tales que los puntos $R = AE \cap BD$, $P = BF \cap CE$ y $Q = AE \cap BD$ están alineados. Entonces $F \in \mathcal{C}$. (Este es un inverso parcial del teorema de Pascal)*

Problema 2 **Dados un triángulo ΔABC, un punto P y una recta p que pasa por P; sean $X_a = p \cap a$, $X_b = p \cap b$, $X_c = p \cap c$, Y_A, Y_B y Y_C las otras intersecciones de AP, BP y CP con el circuncírculo $\mathcal{C}$ del triángulo. Entonces X_aY_A, X_bY_B y X_cY_C son concurrentes.*

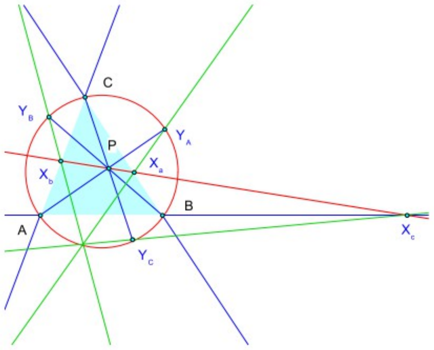

Figura 10-2

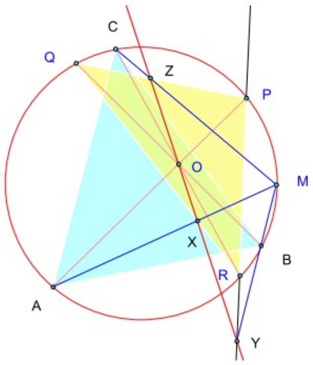

Figura 10-3

Problema 3 *Dados dos triángulos* ΔABC *y* ΔPQR *en perspectiva desde un punto* O *e inscritos en un círculo* $\mathcal{C}$. *Entonces para todo punto* $M \in \mathcal{C}$ *los puntos* O, $X = AM \cap p$, $Y = BM \cap q$ *y* $Z = CM \cap r$ *están alineados.*

Problema 4 **Dado un triángulo* ΔABC *y dos puntos* P *y* Q *conjugados isogonales con triángulos pedales* $\Delta P_aP_bP_c$ *y* $\Delta Q_aQ_bQ_c$ *respectivamente. Entonces los puntos* $X = P_bQ_c \cap P_cQ_b$, $Y = P_cQ_a \cap P_aQ_c$ *y* $Z = P_aQ_b \cap P_bQ_a$ *están en la recta* PQ.

Rectas de Pappus*

Entre las rectas Pappus hay varias relaciones geométricas, como lo muestra el siguiente teoremas.

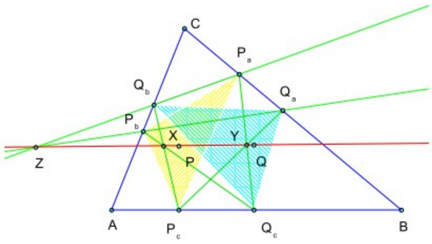

Figura 10-4

Teorema 10.6 (Steiner) *Si A, B, C son puntos de una recta y D, E y F son puntos de otra recta, entonces las rectas $\left\{ {ABC \atop DEF} \right\}$, $\left\{ {ABC \atop EFD} \right\}$ y $\left\{ {ABC \atop FDE} \right\}$ son concurrentes en un punto S^*; también las rectas $\left\{ {ABC \atop EDF} \right\}$, $\left\{ {ABC \atop FED} \right\}$ y $\left\{ {ABC \atop DFE} \right\}$ son concurrentes en un punto S.*

Demostración: Si definimos los triángulos:

- Triángulo $\triangle_1 = \triangle P_1P_2P_3$ de lados AE, CD y BF.
- Triángulo $\triangle_2 = \triangle Q_1Q_2Q_3$ de lados BD, AF y CE.
- Triángulo $\triangle_3 = \triangle R_1R_2R_3$ de lados CF, BE y AD.

Tenemos los siguientes resultados:

Los puntos P_1, Q_1 y R_1 (resp. P_2, Q_2 y R_2; resp. P_3, Q_3 y R_3) definen las rectas de Pappus $c_1 = \left\{ {ABC \atop EDF} \right\}$, $c_2 = \left\{ {ABC \atop FED} \right\}$ y $c_3 = \left\{ {ABC \atop DFE} \right\}$. Los lados correspondientes de los triángulos $\triangle_1$ y $\triangle_2$ se cortan el las rectas de Pappus $x_1 = \left\{ {ABC \atop DEF} \right\}$. Por lo tanto $\triangle_1$ y $\triangle_2$ están en perspectiva y por lo tanto las rectas $\left\{ {ABC \atop DEF} \right\}$, $\left\{ {ABC \atop EFD} \right\}$ y $\left\{ {ABC \atop FDE} \right\}$ son concurrentes, esto es que los triángulos $\triangle_1$, $\triangle_2$ y $\triangle_3$ tienen un centro común de perspectiva.

Análogamente lados correspondientes de los triángulos $\triangle_2$ y $\triangle_3$ (resp. $\triangle_3$ y $\triangle_1$) se cortan el las rectas de Pappus $x_2 = \left\{ {ABC \atop EFD} \right\}$ y $x_3 = \left\{ {ABC \atop FDE} \right\}$. El problema 4, pág. 92 nos dice que los ejes de perspectiva son concurrentes, esto es que las rectas $\left\{ {ABC \atop EDF} \right\}$, $\left\{ {ABC \atop FED} \right\}$ y $\left\{ {ABC \atop DFE} \right\}$ son concurrentes en un punto S. ■

Definición 10.7 *Si A, B, C son puntos de una recta y D, E y F son puntos de otra recta, entonces los puntos S^* y S donde se intersectan las rectas $\left\{ {ABC \atop DEF} \right\}$, $\left\{ {ABC \atop EFD} \right\}$ y $\left\{ {ABC \atop FDE} \right\}$; y $\left\{ {ABC \atop EDF} \right\}$, $\left\{ {ABC \atop FED} \right\}$ y $\left\{ {ABC \atop DFE} \right\}$ respectivamente, se llaman los puntos de Steiner.*

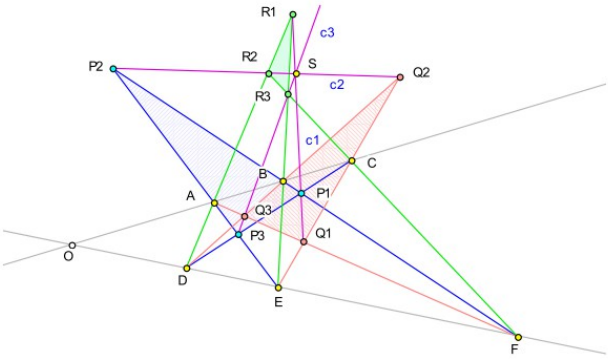

Figura 10-5

Rectas de Pascal*

Corolario 10.8 (Pascal) *Si A, B, C, D, E y F son puntos en una cónica entonces los puntos $R = AE \cap BD$, $P = BF \cap CE$ y $Q = AE \cap BD$ están alineados.*

Definición 10.9 *Si A, B, C, D, E y F son puntos en un cónica, entonces la recta que une los puntos $R = AE \cap BD$, $P = BF \cap CE$ y $Q = AE \cap BD$ se llama la recta de Pascal de los puntos dados. Usaremos la notación: $\left\{\begin{smallmatrix}ABC\\DEF\end{smallmatrix}\right\}$ para esta recta.*

El enunciado clasico de estos teoremas es el siguiente: Dado un exágono $ABCDEF$ inscrito en un cónica, entonces los lados opuestos del exágono se intersectan en tres puntos alineados. Sin embargo como los resultados más interesantes usan distintos ordenes en los puntos dados la notación anterior es más adecuada. Hay que notar que si $p = \left\{\begin{smallmatrix}P_1P_2P_3\\Q_1Q_2Q_3\end{smallmatrix}\right\}$ etonces: $p = \left\{\begin{smallmatrix}P_{i_1}P_{i_2}P_{i_3}\\Q_{i_1}Q_{i_2}Q_{i_3}\end{smallmatrix}\right\}$ y $p = \left\{\begin{smallmatrix}Q_{i_1}Q_{i_2}Q_{i_3}\\P_{i_1}P_{i_2}P_{i_3}\end{smallmatrix}\right\}$ para toda permutación $(i_1i_2i_3)$ de (123). Por lo tanto hay 6 rectas de Pappus asociadas a seis puntos en dos rectas. Análogamente hay $60 = \frac{6!}{3!\cdot 2}$ rectas de Pascal asociadas a seis puntos de una cónica.

Entre estas rectas hay varias relaciones geométricas, como lo muestran los siguientes teoremas.

Claramente la misma demostración que la del teorema 10.6; pag. 239, nos da el siguiente teorema.

Teorema 10.10 (Steiner) *Si A, B, C, D, E y F son puntos en una cónica entonces las rectas $\left\{\begin{smallmatrix}ABC\\DEF\end{smallmatrix}\right\}$, $\left\{\begin{smallmatrix}ABC\\EFD\end{smallmatrix}\right\}$ y $\left\{\begin{smallmatrix}ABC\\FDE\end{smallmatrix}\right\}$ son concurrentes en un punto S; también las rectas $\left\{\begin{smallmatrix}ABC\\EDF\end{smallmatrix}\right\}$, $\left\{\begin{smallmatrix}ABC\\FED\end{smallmatrix}\right\}$ y $\left\{\begin{smallmatrix}ABC\\DFE\end{smallmatrix}\right\}$ son concurrentes en un punto S^*.* ■

Podemos enunciar el teorema de la siguiente forma: Dados A, B, C, D, E y F son puntos en una cónica, entonces para cada partición de los puntos dados en subconjuntos de tres puntos P_1, P_2 y P_3; Q_1, Q_2 y Q_3, entonces las rectas $\left\{\begin{smallmatrix}P_1P_2P_3\\Q_1Q_2Q_3\end{smallmatrix}\right\}$, $\left\{\begin{smallmatrix}P_1P_2P_3\\Q_2Q_3Q_1\end{smallmatrix}\right\}$ y $\left\{\begin{smallmatrix}P_1P_2P_3\\Q_3Q_1Q_2\end{smallmatrix}\right\}$ son concurrentes en un punto S; también las rectas $\left\{\begin{smallmatrix}P_1P_2P_3\\Q_1Q_3Q_2\end{smallmatrix}\right\}$, $\left\{\begin{smallmatrix}P_1P_2P_3\\Q_3Q_2Q_1\end{smallmatrix}\right\}$ y $\left\{\begin{smallmatrix}P_1P_2P_3\\Q_2Q_2Q_3\end{smallmatrix}\right\}$ son concurrentes en un punto

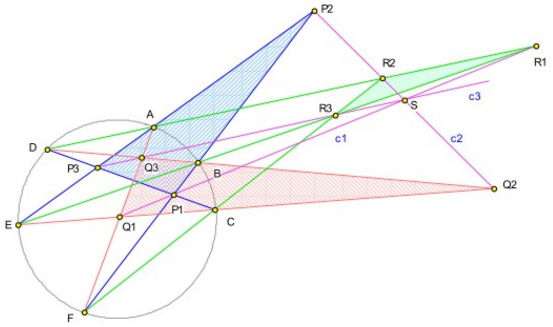

Figura 10-6

S^*. Si suponemos que P_1, P_2 y P_3 y Q_1, Q_2 y Q_3 están en el mismo orden lexicográfico se usará la notación $S = S_{P_1P_2P_3}$ y $S^* = S^*_{P_1P_2P_3}$. Los puntos S y S^* se llaman los puntos de Steiner de $P_1P_2P_3$. Tenemos que $S = S_{Q_1Q_2Q_3}$ y $S^* = S^*_{Q_1Q_2Q_3}$. Por lo tanto podemos suponer que $P_1 = A$ y que $P_1P_2P_3$ está ordenado lexicográfico.

Dados A, B, C, D, E y F puntos en una cónica entonces definimos los siguientes elementos:

A) Los puntos A, B, C, D, E y F los llamaremos los puntos P.

B) Las 15 rectas AB,..., EF las llamamos las rectas C.

C) Cada una de las rectas C, por ejemplo AB, es cortada por las otras en A, B y otros 6 puntos, que llamaremos puntos c. Hay $45 = \frac{6\cdot 15}{2}$ puntos c. Estos puntos son los puntos $AE \cap BD$,..., $CD \cap EF$.

D) Por cada punto c, $AE \cap BD$ por ejemplo, pasan 4 rectas de Pascal $\left\{\begin{smallmatrix}ABC\\DEF\end{smallmatrix}\right\}$, $\left\{\begin{smallmatrix}ABF\\DEC\end{smallmatrix}\right\}$, $\left\{\begin{smallmatrix}ADC\\BEF\end{smallmatrix}\right\}$ y $\left\{\begin{smallmatrix}ADF\\BEC\end{smallmatrix}\right\}$. Por lo tanto hay $60 = \frac{45\cdot 4}{3}$ rectas de Pascal.

E) A los puntos de Steiner los llamaremos puntos g. En cada recta de Pascal hay un solo punto de Steiner. Por lo tanto hay $20 = \frac{60}{3}$ puntos g. Para cada tercia de puntos, ABC por ejemplo, hay dos puntos de Steiner que llamaremos conjugados; los denotaremos por S_{ABC} y S^*_{ABC}.

Los siguientes teoremas nos permitiran definir más elementos asociados a seis puntos de una cónica.

Teorema 10.11 (Kirkman) *Si A, B, C, D, E y F son puntos en una cónica, entonces las rectas de Pascal $\left\{\begin{smallmatrix}ABF\\DEC\end{smallmatrix}\right\}$, $\left\{\begin{smallmatrix}ADC\\FBE\end{smallmatrix}\right\}$ y $\left\{\begin{smallmatrix}EBC\\AFD\end{smallmatrix}\right\}$ son concurrentes.*

Demostración: Sean los triángulos:

- Triángulo $\triangle_1 = \triangle P_1P_2P_3$ de lados AE, BD y CF.
- Triángulo $\triangle_2 = \triangle Q_1Q_2Q_3$ de lados las rectas de Pascal $\left\{\begin{smallmatrix}CFA\\EBD\end{smallmatrix}\right\}$, $\left\{\begin{smallmatrix}CFD\\EBA\end{smallmatrix}\right\}$ y $\left\{\begin{smallmatrix}EFA\\CBD\end{smallmatrix}\right\}$.

Estos triángulos tienen las siguientes propiedades:

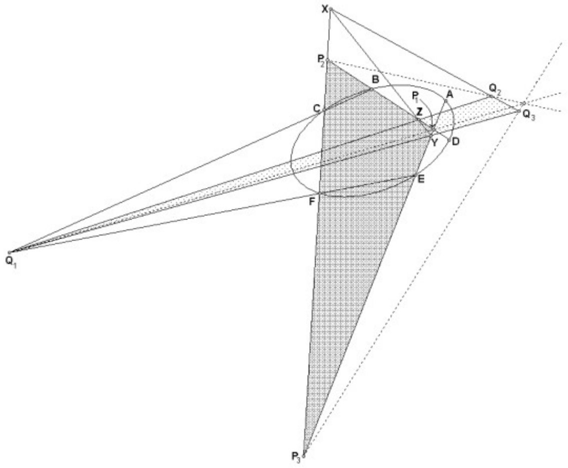

Figura 10-7

Los vértices de $\triangle_1$ son $BD \cap CF$, $CF \cap AE$ y $AE \cap BD$; Los vértices de $\triangle_2$ son $AC \cap DE$, $AB \cap DF$ y $BC \cap EF$. Por lo tanto los vértices correspondientes de los triángulos están en en las rectas de Pascal $\left\{\begin{smallmatrix}EBC\\AFD\end{smallmatrix}\right\}$, $\left\{\begin{smallmatrix}ADC\\FBE\end{smallmatrix}\right\}$ y $\left\{\begin{smallmatrix}ABF\\DEC\end{smallmatrix}\right\}$.

Las intersecciones de los lados correspondientes de los triángulos $\triangle_1$ y $\triangle_2$ son $AE \cap CD$, $BD \cap AF$ y $CF \cap BE$ que definen la recta de Pascal $\left\{\begin{smallmatrix}ABC\\DFE\end{smallmatrix}\right\}$, lo que implica que los triángulos $\triangle_1$, $\triangle_2$ están en perspectiva. Por lo tanto las rectas de Pascal $\left\{\begin{smallmatrix}EBC\\AFD\end{smallmatrix}\right\}$, $\left\{\begin{smallmatrix}ADC\\FBE\end{smallmatrix}\right\}$ y $\left\{\begin{smallmatrix}ABF\\DEC\end{smallmatrix}\right\}$ son concurrentes. ■

Nota: Llamaremos al punto $\left[\begin{smallmatrix}ABC\\DEF\end{smallmatrix}\right] = \left\{\begin{smallmatrix}ABF\\DEC\end{smallmatrix}\right\} \cap \left\{\begin{smallmatrix}ADC\\FBE\end{smallmatrix}\right\} \cap \left\{\begin{smallmatrix}EBC\\AFD\end{smallmatrix}\right\}$ un punto de Kirkman. En general el punto de Kirkman $\left[\begin{smallmatrix}P_1P_2P_3\\Q_1Q_2Q_3\end{smallmatrix}\right]$ es la intersección $\left\{\begin{smallmatrix}P_1P_2Q_3\\Q_1Q_2P_3\end{smallmatrix}\right\} \cap \left\{\begin{smallmatrix}P_1Q_1P_3\\Q_3P_2Q_2\end{smallmatrix}\right\} \cap \left\{\begin{smallmatrix}Q_2P_2P_3\\P_1Q_3Q_1\end{smallmatrix}\right\}$.

Teorema 10.12 *Si A, B, C, D, E y F son puntos en una cónica, entonces el punto de Steiner S_{ABC} y los puntos de Kirkman $\left[\begin{smallmatrix}ABC\\DEF\end{smallmatrix}\right]$, $\left[\begin{smallmatrix}ABC\\EFD\end{smallmatrix}\right]$ y $\left[\begin{smallmatrix}ABC\\FDE\end{smallmatrix}\right]$ están alineados.*

Demostración: Sean los triángulos:

- Triángulo $\triangle_1 = \triangle P_1P_2P_3$ de lados BD, AF y CE.
- Triángulo $\triangle_2 = \triangle Q_1Q_2Q_3$ de lados las rectas de Pascal $\left\{\begin{smallmatrix}ABF\\DEC\end{smallmatrix}\right\}$, $\left\{\begin{smallmatrix}AEC\\DBF\end{smallmatrix}\right\}$ y $\left\{\begin{smallmatrix}DBC\\AEF\end{smallmatrix}\right\}$.
- Triángulo $\triangle_3 = \triangle R_1R_2R_3$ de lados las rectas de Pascal $\left\{\begin{smallmatrix}EBC\\AFD\end{smallmatrix}\right\}$, $\left\{\begin{smallmatrix}ABD\\EFC\end{smallmatrix}\right\}$ y $\left\{\begin{smallmatrix}AFC\\EBD\end{smallmatrix}\right\}$.

Estos triángulos tienen las siguientes propiedades:

Los vértices de $\triangle_1$ son $AF \cap CE$, $BD \cap CE$ y $BD \cap AF$; Los vértices de $\triangle_2$ son $AB \cap DE$, $AC \cap DF$ y $BC \cap EF$; Los vértices de $\triangle_3$ son $BC \cap DF$, $AB \cap EF$ y $AC \cap DE$. Por lo tanto los vértices correspondientes de los triángulos están en en las rectas de Pascal $\left\{\begin{smallmatrix}FEB\\CAD\end{smallmatrix}\right\}$, $\left\{\begin{smallmatrix}EDA\\BCF\end{smallmatrix}\right\}$ y $\left\{\begin{smallmatrix}DFC\\ABE\end{smallmatrix}\right\}$.

Las intersecciones de los lados correspondientes de los triángulos $\triangle_1$ y $\triangle_2$ son $BD \cap AE$, $AF \cap CD$ y $CE \cap BF$ que están en la recta de Pascal $\left\{{ABC \atop DEF}\right\}$, lo que implica que los triángulos $\triangle_1$, $\triangle_2$ y $\triangle_3$ tienen un centro común de perspectiva. Las intersecciones de los lados correspondientes de los triángulos $\triangle_1$ y $\triangle_3$ son $BD \cap CF$, $AF \cap BE$ y $CE \cap AD$ que están en la recta de Pascal $\left\{{ABC \atop EFD}\right\}$. Por lo tanto los ejes de perspectiva de los triángulos $\triangle_1$ y $\triangle_2$ y de los triángulos $\triangle_1$ y $\triangle_3$ se intersectan en el punto de Steiner S_{ABC}.

Por lo tanto el eje de perspectiva de los triángulos $\triangle_2$ y $\triangle_3$ pasa por S_{ACE}, pero este eje esta definido por los puntos de Kirkman $\left[{ABC \atop DEF}\right]$, $\left[{ABC \atop EFD}\right]$ y $\left[{ABC \atop FDE}\right]$. ■

Por lo tanto tenemos las siguientes propiedades asociadas a seis puntos en una cónica

F) Claramente la recta de Pascal $\left\{{P_1P_2P_3 \atop Q_1Q_2Q_3}\right\}$ contiene los puntos de Kirkman siguientes: $\left[{P_1P_2P_3 \atop Q_1Q_2Q_3}\right]$, $\left[{P_3P_1P_2 \atop Q_3Q_1Q_2}\right]$ y $\left[{P_2P_3P_1 \atop Q_2Q_3Q_1}\right]$. Y por lo tanto hay 60 puntos de Kirkman.

G) Los 60 puntos de Kirkman están en 20 rectas una por cada punto de Steiner, las llamamos las rectas G.

Teorema 10.13 *Los puntos de Steiner S^*_{ABC}, S^*_{ABD}, S^*_{AED} y S^*_{AEC} están alineados.*

Demostración: Sean las rectas de Pascal siguientes: $x_1 = \left\{{ABF \atop DEC}\right\}$, $x_2 = \left\{{ACD \atop FEB}\right\}$, $x_3 = \left\{{ADF \atop ECB}\right\}$, $p_1 = \left\{{AEC \atop DFB}\right\}$, $p_2 = \left\{{AED \atop BCF}\right\}$ y $p_3 = \left\{{ADB \atop CEF}\right\}$. Entonces tenemos los puntos de Kirman siguientes:

$$\begin{aligned}
O &= \begin{bmatrix} ABC \\ DEF \end{bmatrix} = x_1 \cap x_2 \cap x_3 \\
P_1 &= \begin{bmatrix} EAF \\ CBD \end{bmatrix} = x_1 \cap p_2 \cap p_3 \\
P_2 &= \begin{bmatrix} FDC \\ EAB \end{bmatrix} = p_1 \cap x_2 \cap p_3 \\
P_3 &= \begin{bmatrix} EDB \\ CFA \end{bmatrix} = p_1 \cap p_2 \cap x_3
\end{aligned}$$

Definimos ahora el triángulo $\triangle Q_1Q_2Q_3$, donde $Q_1 = DF \cap AC$, $Q_2 = ED \cap CB$ y $Q_3 = EF \cap AB$. Entonces $Q_i \in x_i$, $i = 1, 2, 3$, y además los lados del triángulo $\triangle Q_1Q_2Q_3$ son las rectas de Pascal $q_1 = \left\{{AEC \atop FBD}\right\}$, $q_2 = \left\{{AED \atop FBC}\right\}$ y $q_3 = \left\{{ADB \atop FCE}\right\}$.

Por lo tanto tenemos O es el centro de perspectiva de los triángulos $\triangle P_1P_2P_3$ y $\triangle Q_1Q_2Q_3$. Y por lo tanto las interseccións $p_i \cap q_i$, $i = 1, 2, 3$, están alineadas. Pero estas intersecciones son:

$$\begin{aligned}
p_1 \cap q_1 &= \begin{Bmatrix} AEC \\ DFB \end{Bmatrix} \cap \begin{Bmatrix} AEC \\ FBD \end{Bmatrix} = S^*_{AEC} \\
p_2 \cap q_2 &= \begin{Bmatrix} AED \\ BCF \end{Bmatrix} \cap \begin{Bmatrix} AED \\ FBC \end{Bmatrix} = S^*_{AED} \\
p_3 \cap q_3 &= \begin{Bmatrix} ADB \\ CEF \end{Bmatrix} \cap \begin{Bmatrix} ABD \\ FEC \end{Bmatrix} = S^*_{ABD}
\end{aligned}$$

Si intercambiamos los puntos B y E obtenemos que los puntos

$$\begin{aligned} p_1 \cap q_1 &= \left\{ \begin{matrix} ABC \\ DFE \end{matrix} \right\} \cap \left\{ \begin{matrix} ABC \\ FED \end{matrix} \right\} = S^*_{ABC} \\ p_2 \cap q_2 &= \left\{ \begin{matrix} ABD \\ ECF \end{matrix} \right\} \cap \left\{ \begin{matrix} ABD \\ FEC \end{matrix} \right\} = S^*_{ABD} \\ p_3 \cap q_3 &= \left\{ \begin{matrix} ADE \\ CBF \end{matrix} \right\} \cap \left\{ \begin{matrix} AED \\ FBC \end{matrix} \right\} = S^*_{AED} \end{aligned}$$

están alineados. Por lo tanto S^*_{ABC}, S^*_{ABD}, S^*_{AED} y S^*_{AEC} están alineados. ■

Las tercias de puntos ABC, ABD, ADE y ACE que definen los puntos de Steiner en el teorema anterior son las tercias tales que no tiene puntos comunes de la tercia las parejas $\{AF, BE, CD\}$, como hay 15 tercias de parejas distintas y cada una define un recta que contiene a 4 puntos de Steiner.

Más aun si $\{PX, QY, RZ\}$ es una tercia de parejas de puntos, entonces los puntos de Steiner que definen son los que están en las rectas de Pascal $\left\{ {PQR \atop XYZ} \right\}$, $\left\{ {PQZ \atop XYR} \right\}$, $\left\{ {PYR \atop XQZ} \right\}$ y $\left\{ {PYZ \atop XQR} \right\}$. De esta presentación se ve que si PQR y XYZ están en el mismo orden lexicográfico tenemos el punto S_{PQR} en caso contrario a S^*_{PQR}, igualmente con los otros tres puntos. Se deja como ejercicio demostrar que el número de puntos conjugados S^* es igual a 0, 2 o 4.

Teorema de Brianchon

Demostraremos ahora el teorema de Brianchon, que es el teorema dual al teorema de Pascal. La demostración que dio Brianchon usa la teoría de polos y polares, ver teorema 13.17, pag. 274, sin embargo por mucho tiempo se busco una demostración que usara únicamente herramientas euclideanas. No es hasta 1961 que Smogorzhevskil, ver [38], dio una demostración de este estilo. Usaremos el concepto de centro radical para demostrar el teorema de Brianchon. Para esto necesitamos el siguiente lema.

Lema 10.14 *Si en un círculo se tienen dos tangentes* t_A *y* t_B *en los puntos* A *y* B *y se dan dos puntos* A' *y* B' *en* t_A *y* t_B *respectivamente tales que* $AA' = BB'$*, entonces existe un círculo tangente a* t_A *y* t_B *en los puntos* A' *y* B'*.*

Demostración: Si $O = t_A \cap t_B$, entonces la homotecia con centro O que lleva A en A', lleva B en B'. Y por lo tanto lleva el círculos en el círculo buscado. ■

Teorema 10.15 (Brianchon) *Si* $ABCDEF$ *es un exágono circunscrito a un círculo* $\mathcal{C}$*, entonces las rectas* AD*,* BE *y* CF *que unen los vértices opuestos son concurrentes.*

Demostración: Sean P, Q, R, S, T y U los puntos de tangencia de los lados AB, BC, CD, DE, EF y FA respectivamente. Tomemos puntos P_B, Q_B, R_D, S_D, U_F y T_F en los lados AB, BC, CD, DE, EF y FA de tal forma que el punto X_Y esta en la tangente el el punto X y del mismo lado que el punto Y, además

$$PP_B = QQ_B = RR_D = SS_D = TT_F = UU_F$$

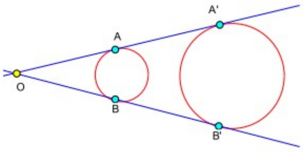

Figura 10-8

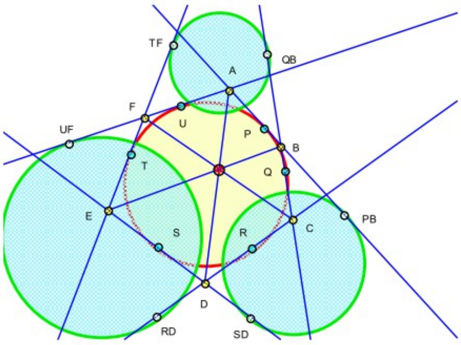

Figura 10-9

por el lema anterior tenemos circulos $\mathcal{C}_1$, $\mathcal{C}_2$ y $\mathcal{C}_3$ tangentes a los lados del exágono en los puntos T_F y Q_B; P_B, S_D; R_D y U_F; respectivamente. Entonces

$$\begin{aligned} BQ_B &= QQ_B - BQ = PP_B - PB = BP_B \\ ET_F &= TT_F + TE = SS_D + SE = ES_D \end{aligned}$$

por lo tanto B y E tienen la misma potencia respecto a los círculos $\mathcal{C}_2$ y $\mathcal{C}_3$ y por lo tanto BE es su eje radical. Análogamente AB y CF son los ejes radical de los círculos $\mathcal{C}_1$ y $\mathcal{C}_2$ y $\mathcal{C}_1$, $\mathcal{C}_3$ respectivamente. Por lo tanto estos tres ejes radicales son concurrentes. ■

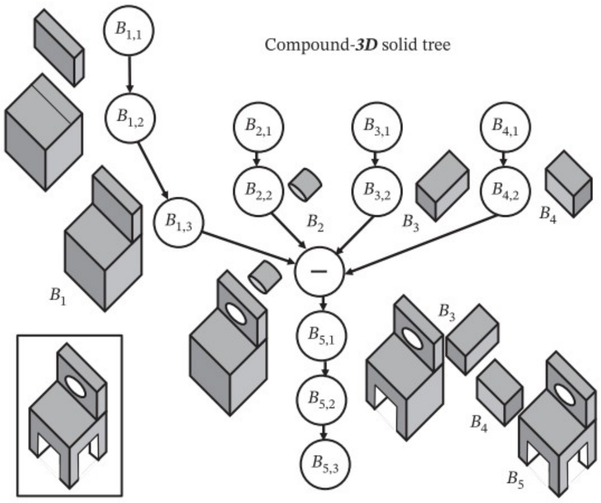

Figure 4.9 Constructing compound ***3D*** solid generated from several developed primitive solids.

operations is utilizing solids $B_{1,1}$ and $B_{1,2}$ to produce a single solid body B_1 through the $B_{1,3}$ *union* process. Similarly solid bodies B_2, B_3, and B_4 are created. Solid B_5 is then generated from solids B_1, B_2, B_3, and B_4 using a *difference Boolean* operation. After the *Boolean* operation, several edges of solid B_5 may be changed to fillet surfaces using a rounding operation (not shown in Figure 4.9). Other procedures are possible to produce a compound solid object. These procedures depend on the proficiency of the user in building ***3D*** models in different software packages. The chair-like object in Figure 4.9 can be produced in fewer steps such as a seat, a back, and four legs. The seat and the back can also be a one free-form surface with a certain thickness.

Trees representing the solid design process are usually displayed on a side screen to enable the user to document and edit the process. A single solid tree is representing the design process of a single solid (Figure 4.8). A compound solid tree is representing the relationships of solid bodies, which are combined using *Boolean* or other operations; see Figure 4.9. Using such trees, a designer can enter undo or redo commands to regenerate a previous solid if it is allowed. To generate or modify a solid, the user gives commands to the geometric modeling module. The *tree processor* stores the operations of all trees in some geometric modeling packages.

4.1.2 Homogeneous Coordinates Versus Cartesian Coordinates

Homogeneous coordinates have been devised to provide means to solve several problems such as solving sets of simultaneous *homogeneous* equations. They are also described or defined as *affine transformation*. Figure 4.10 defines the homogeneous coordinates in the two-dimensional (***2D***) Cartesian space. The homogeneous coordinates introduce an extra coordinate h_H. In that, the *homogeneous* coordinate of a *Cartesian* point of (x, y) is defined as (x, y, h_H) with the extra h_H added to the definition. However, we usually *normalize* the coordinates to have all coordinates lie on the homogenous plane of $(x, y, 1)$. All points (x, y, h_H) in the homogeneous coordinates will map into $(x/h_H, y/h_H, 1)$ as apparent in Figure 4.10. Homogenization operation in R^3 affirms that point (x, y, h_H) is homogenized to the point $(x/h_H, y/h_H, 1)$. In ***3D***, the *normalized homogeneous coordinate* $(x, y, z, 1)$ represents the *Cartesian* point (x, y, z). The homogeneous coordinates of (x, y, z, h_H) represent the *Cartesian* coordinates of $(x/h_H, y/h_H, z/h_H)$. Homogeneous coordinates of $(h_H x, h_H y, h_H z, h_H)$ should represent the *Cartesian* coordinates of

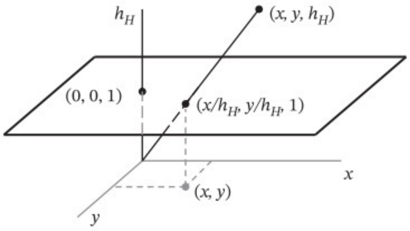

Figure 4.10 Definition of the homogeneous coordinates in the ***2D*** *Cartesian* space.

(x, y, z). In homogeneous coordinates, each (unique) *Cartesian* coordinate represents an unlimited or (∞) numbers of *homogeneous* coordinates, i.e. homogeneous coordinates are redundant. The value of h_H is an arbitrary constant.

4.1.2.1 Point in Space

In *Cartesian* coordinates a point is defined by its Cartesian coordinate values $\boldsymbol{P}_{C1}$ (x_1, y_1, z_1) and can also take the form of a *position vector* from the origin to the point.

$$\boldsymbol{P}_{C1} = [x_1 \ \ y_1 \ \ z_1]^T \tag{4.3}$$

The vectors are usually defined as *column arrays* but may also be defined as *row arrays*.

In *homogeneous* coordinates,

$$\boldsymbol{P}_{H1} = \begin{bmatrix} x_1 & y_1 & z_1 & 1 \end{bmatrix} \tag{4.4}$$

In this text, it was observed that points in homogeneous coordinates are better defined as *rows*. This allows the definition of body geometry by its main characteristic points, vertices, or corners as a set in a column array of these distinctive points. It can also be assumed that one might use $\boldsymbol{P}_1 = \boldsymbol{P}_{H1}$.

In *geometric modeling*, points $\boldsymbol{P}_1, \boldsymbol{P}_2, \ldots, \boldsymbol{P}_n$ may also be referred to as vertices $\boldsymbol{V}_1, \boldsymbol{V}_2, \ldots, \boldsymbol{V}_n$.

4.1.2.2 Vectors

In *Cartesian* coordinates a vector $\boldsymbol{V}_{C1}$ is defined by its coordinate components. It is usually set in a *column* array form.

$$\boldsymbol{V}_{C1} = \begin{bmatrix} \boldsymbol{V}_{1x} & \boldsymbol{V}_{1y} & \boldsymbol{V}_{1z} \end{bmatrix}^T \tag{4.5}$$

In *homogeneous* coordinates, a vector can be defined as the subtraction of two position arrays.

$$\boldsymbol{V}_{H1} = \begin{bmatrix} \boldsymbol{V}_{1x} & \boldsymbol{V}_{1y} & \boldsymbol{V}_{1z} & 0 \end{bmatrix}^T \tag{4.6}$$

It should be noted that the *0* in the fourth location should be carefully handled. The components of the vector are given the names $\boldsymbol{V}_{1x}$, $\boldsymbol{V}_{1y}$, and $\boldsymbol{V}_{1z}$ rather than x_1, y_1, and z_1 for location of point "*1*."

4.1.2.3 Lines

In homogeneous coordinates, a line $\boldsymbol{L}_H$ between two points $\boldsymbol{P}_1$ and $\boldsymbol{P}_2$ is given by

$$\boldsymbol{L}_H = \begin{bmatrix} \boldsymbol{P}_1 \\ \boldsymbol{P}_2 \end{bmatrix} = \begin{bmatrix} x_1 & y_1 & z_1 & 1 \\ x_2 & y_2 & z_2 & 1 \end{bmatrix}, (2 \times j),\ j = 4 \tag{4.7}$$

The number of rows is 2, which is the number of end points $\boldsymbol{P}_1$ and $\boldsymbol{P}_2$ defining the line. The number of the columns *j* is the number of homogeneous coordinates, which is 4. Note that $\boldsymbol{P}_1$ and $\boldsymbol{P}_2$ are used to represent $\boldsymbol{P}_{H1}$ and $\boldsymbol{P}_{H2}$.

4.1.2.4 Body Geometry and Vertices

Define the geometry of the body $\boldsymbol{B}_H$ in homogeneous coordinates by the matrix $[\boldsymbol{P}_B]$ representing the object *vertices* or *points* $\boldsymbol{P}_i$, each of which is a row $(x_i, y_i, z_i, 1)$ in this matrix. The body $\boldsymbol{B}_H$ can then have the following definition:

$$\boldsymbol{B}_H = \begin{bmatrix} \boldsymbol{P}_1 \\ \boldsymbol{P}_2 \\ \cdots \\ \boldsymbol{P}_n \end{bmatrix} = \begin{bmatrix} x_1 & y_1 & z_1 & 1 \\ x_2 & y_2 & z_2 & 1 \\ \cdots & \cdots & \cdots & \cdots \\ x_n & y_n & z_n & 1 \end{bmatrix}, (i \times j), \quad i = n, \quad j = 4 \tag{4.8}$$

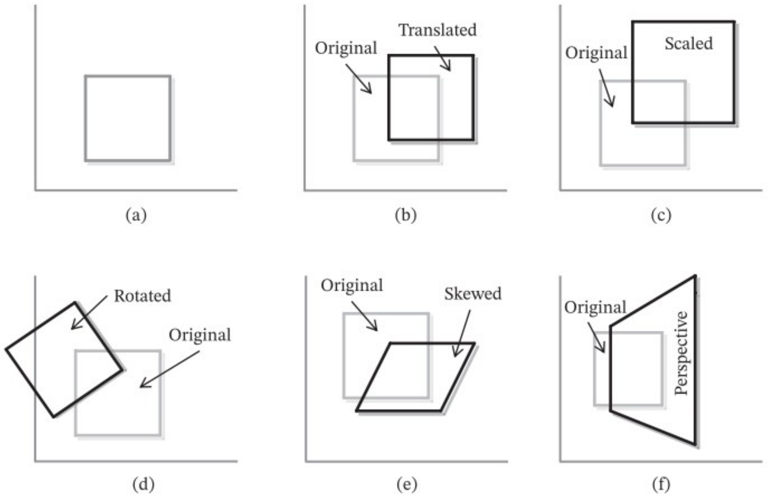
Note that $\boldsymbol{P}_1, \ldots, \boldsymbol{P}_n$ are used to represent $\boldsymbol{P}_{H1}, \ldots, \boldsymbol{P}_{Hn}$.

4.1.3 Body Transformation

The body $\boldsymbol{B}_H$ can be transformed in the homogeneous space by *translation, rotation, scaling, zooming, skewing*, or *perspective viewing*. A simple original ***2D*** shape of a body in a plane is shown in Figure 4.11a, and each of its particular transformation is indicated as in Figure 4.11b for translation, in Figure 4.11c for scaling, in Figure 4.11d for rotation, in Figure 4.11e for skewing, and in Figure 4.11f for perspective. The transformed body matrix $\boldsymbol{B}_H{}'$ is obtained collectively or by any one of the transformations in any other order by the following matrix multiplication:

$$\begin{aligned} \boldsymbol{B}_H{}' &= \boldsymbol{B}_H \ \ [\boldsymbol{T}_{xyz}][\boldsymbol{R}_{xyz}][\boldsymbol{S}_H][\boldsymbol{Z}_H][\boldsymbol{K}_H] \ldots [\boldsymbol{P}_H] \\ &= \boldsymbol{B}_H[\boldsymbol{T}_{xyz}\, \boldsymbol{R}_{xyz}\, \boldsymbol{S}_H\, \boldsymbol{Z}_H\, \boldsymbol{K}_H \ldots \boldsymbol{P}_H] \\ &= \boldsymbol{B}_H \ \ \boldsymbol{T}_{\mathrm{GH}} \end{aligned} \tag{4.9}$$

where $\boldsymbol{T}_{\mathrm{xyz}}$ is the translation matrix; $\boldsymbol{R}_{xyz}$ is the rotation matrix about x, y, or z; $\boldsymbol{S}_H$ is the scaling matrix; $\boldsymbol{Z}_H$ is the zooming matrix; $\boldsymbol{K}_H$ is the skewing matrix; $\boldsymbol{P}_H$ is the perspective matrix; and $\boldsymbol{T}_{\mathrm{GH}}$ is the general total homogeneous



(a) (b) (c)

(d) (e) (f)

Figure 4.11 A simple original shape of a body (a) in a plane and each of its transformation is indicated in (b) translation, (c) scaling, (d) rotation, (e) skewing, and (f) perspective.

transformation matrix. The order of multiplication is important in defining the intended "motion" or transformation of the body in space from its original position to its final intended location and defined shape. Note that matrix multiplication is *associative*, but not *commutative*. The matrices will be defined later on, but their final multiplication form represents the general transformation matrix, which is post-multiplied by the body matrix $\boldsymbol{B}_H$ to get the shape of the transformed body matrix $\boldsymbol{B}_H{}'$. The general homogeneous transformation matrix $\boldsymbol{T}_{\mathrm{GH}}$ can then have the following form:

$$\boldsymbol{T}_{\mathrm{GH}} = [\boldsymbol{T}_{\mathrm{GH}}] = \begin{bmatrix} a & k & n & h \\ d & b & p & g \\ e & m & c & f \\ t & u & v & z \end{bmatrix} \tag{4.10}$$

The components of the matrix are representing different transformations. Components a, b, and c are the *scaling* amounts in x, y, and z, respectively. The components t, u, and v are the *translation* amounts in x, y, and z, respectively. The components h, g, and f are the *perspective* amounts in x, y, and z, respectively. The components d, e, k, m, n, and p are the *skewing* amounts in x, y, and z. The component z is the *inverse zooming* amount in all x, y, and z. Each of the respective transformation matrixes is defined separately as follows:

4.1.3.1 Translation

The *translation matrix* can have the form

$$\boldsymbol{T}_{xyx} = \begin{bmatrix} 1 & & & \\ & 1 & & \\ & & 1 & \\ t_x & t_y & t_z & 1 \end{bmatrix} \tag{4.11}$$

The components t_x, t_y, and t_z are the translation amounts in x, y, and z, respectively. All empty locations in the $\boldsymbol{T}_T$ matrix are zeros.

4.1.3.2 Rotation

The *rotation matrix* about z, which can be checked with that defined in mechanics subject, has the following form:

$$\boldsymbol{R}_z = \begin{bmatrix} \cos(\theta_z) & \sin(\theta_z) & 0 & 0 \\ -\sin(\theta_z) & \cos(\theta_z) & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \tag{4.12}$$

where θ_z is the rotation angle about z.

The *rotation matrix* about y has the form

$$\boldsymbol{R}_y = \begin{bmatrix} \cos(\theta_y) & 0 & -\sin(\theta_y) & 0 \\ 0 & 1 & 0 & 0 \\ \sin(\theta_y) & 0 & \cos(\theta_y) & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \tag{4.13}$$

where θ_y is the rotation angle about y.

The *rotation matrix* about x has the form

$$\boldsymbol{R}_x = \begin{bmatrix} 0 & 0 & 0 & 0 \\ 0 & \cos(\theta_x) & \sin(\theta_x) & 0 \\ 0 & -\sin(\theta_x) & \cos(\theta_x) & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \tag{4.14}$$

where θ_x is the rotation angle about x.

4.1.3.3 Scaling

The *scaling matrix* is given by the following form:

$$\boldsymbol{S}_H = \begin{bmatrix} S_x & 0 & 0 & 0 \\ 0 & S_y & 0 & 0 \\ 0 & 0 & S_z & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \tag{4.15}$$

The components S_x, S_y, S_z are the scales in x, y, and z, respectively.

4.1.3.4 Zooming

The *zooming matrix* is given by the following form:

$$\boldsymbol{Z}_H = \begin{bmatrix} 1 & & & \\ & 1 & & \\ & & 1 & \\ & & & 1/z_f \end{bmatrix} \tag{4.16}$$

where z_f is the zooming factor and all empty locations are zeros.

4.1.3.5 Skewing

The *skewing matrix* is given by the following form:

$$\boldsymbol{K}_H = \begin{bmatrix} 1 & k & n & \\ d & 1 & p & \\ e & m & 1 & \\ & & & 1 \end{bmatrix} \tag{4.17}$$

where d, e, k, m, n, and p are the skewing amounts in x, y, and z, where all empty locations in the matrix $\boldsymbol{K}_H$ are zeros.

4.1.3.6 Perspective

The *perspective matrix* is defined on the condition that the eye of the observer is on the z-coordinate axis and at a distance of f_z from the body.

$$\boldsymbol{P}_H = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & -1/f_z \\ 0 & 0 & 0 & 1 \end{bmatrix} \tag{4.18}$$

where f_z is the distance from the eye to the projection plane when the *eye* is on the z-axis as previously required by this procedure. Usually the projection plane is set to be the x–y plane (or z plane). The distance f_z may be called the *focal distance* along the z-axis. This is usually performed after rotating the body and the eye to set the looking *eye* on the z direction at a f_z distance off the body location.

4.1.3.7 Orthographic Projection

After all transformations and considering the z-axis to be normal to the plane of the screen (the +ve behind the screen), the simplest method of projection is to ignore the z-coordinate of every point in space. This would render the ***3D*** points (x, y, z) to be only ***2D*** points (x, y).

4.1.3.8 Body Transformation Systems

Note that since matrix multiplication is *associative*, but not *commutative*, the order of multiplication is important.

If the body matrix $\boldsymbol{B_C}$ representing the object vertices or points each of which as a ***column*** vector $[x_i \quad y_i \quad z_i \quad 1]^T$ in this matrix, the transformed body matrix $\boldsymbol{B}_C{}'$ is obtained by any one of the transformations or collectively in any other proper order by

$$\begin{aligned} \boldsymbol{B}_C' &= [\boldsymbol{T}^T_{xyz}][\boldsymbol{R}^T_{xyz}][\boldsymbol{S}^T_H][\boldsymbol{Z}^T_H][\boldsymbol{K}^T_H]\cdots[\boldsymbol{P}^T_H]\ \boldsymbol{B}_C \\ &= \boldsymbol{T}^T_{\mathrm{GH}}\ \boldsymbol{B}_C \end{aligned} \tag{4.19}$$

This process is used by many computer graphics texts and by most *OpenGL* systems. For the computer programming, however, it is usually easier to represent and save a body n points or vertices in an $(n \times 4)$ matrix instead of the $(4 \times n)$ matrix. Several graphics texts are also using the formulation procedure adopted herein rather than the usual *OpenGL* Systems. Note that using the transpose will cause the multiplication to be in a *post-multiplication* rather a *pre-multiplication* way. In providing *OpenGL* systems with vertices, this is not an issue since the order of the internal calculations is not observed or be concerned with.

Example 4.1 A line is defined by its two ***3D*** end points $\boldsymbol{P}_1$ (1, 0, 0) and $\boldsymbol{P}_2$ (2, 2, 0) in *Cartesian* coordinates. It is required to translate the line 2 units in the x direction and 1 unit in the y direction simultaneously. After translation, it is required to rotate the line by −10° about the z-axis.

Solution

The line $\boldsymbol{L}$ can be identified in *homogeneous* coordinate by applying Eq. (4.7) such that

$$\boldsymbol{L} = \boldsymbol{L}_H = \begin{bmatrix} \boldsymbol{P}_1 \\ \boldsymbol{P}_2 \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 & 1 \\ 2 & 2 & 0 & 1 \end{bmatrix} \tag{a}$$

To translate in x and y by 2 and 1, respectively, the transformation matrix for translation is

$$\boldsymbol{T}_{xyz} = \begin{bmatrix} 1 & & & \\ & 1 & & \\ & & 1 & \\ t_x & t_y & t_z & 1 \end{bmatrix} = \begin{bmatrix} 1 & & & \\ & 1 & & \\ & & 1 & \\ 2 & 1 & 0 & 1 \end{bmatrix} \tag{b}$$

Considering the line to be our ***3D*** body, the new translated line $\boldsymbol{L}_1$ is obtained by applying Eq. (4.9) to get the following:

$$\boldsymbol{L}_1 = \boldsymbol{L}_H\ \boldsymbol{T}_{xyz} = \begin{bmatrix} 1 & 0 & 0 & 1 \\ 2 & 2 & 0 & 1 \end{bmatrix} \begin{bmatrix} 1 & & & \\ & 1 & & \\ & & 1 & \\ 2 & 1 & 0 & 1 \end{bmatrix} = \begin{bmatrix} 3 & 1 & 0 & 1 \\ 4 & 3 & 0 & 1 \end{bmatrix} \tag{c}$$

The solution is simply the multiplication of the two matrices. Figure 4.12 shows the original line $\boldsymbol{L}$ and the translated line $\boldsymbol{L}_1$.

The following rotation is −10° about the z-axis with the rotation matrix defined by Eq. (4.11):

$$\boldsymbol{R}_z = \begin{bmatrix} \cos(\theta_z) & \sin(\theta_z) & 0 & 0 \\ -\sin(\theta_z) & \cos(\theta_z) & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} = \begin{bmatrix} \cos(-10) & \sin(-10) & 0 & 0 \\ -\sin(-10) & \cos(-10) & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} = \begin{bmatrix} 0.9848 & -0.1736 & 0 & 0 \\ -(-0.1736) & 0.9848 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \tag{d}$$

$$\boldsymbol{L}_2 = \boldsymbol{L}_1\ \boldsymbol{R}_z = \begin{bmatrix} 3 & 1 & 0 & 1 \\ 4 & 3 & 0 & 1 \end{bmatrix} \begin{bmatrix} 0.985 & -0.174 & 0 & 0 \\ 0.174 & 0.985 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} = \begin{bmatrix} 3.129 & 0.463 & 0 & 1 \\ 4.462 & 2.259 & 0 & 1 \end{bmatrix} \tag{e}$$

Figure 4.12 shows the original line $\boldsymbol{L}$, the translated line $\boldsymbol{L}_1$, and the rotated line $\boldsymbol{L}_2$.

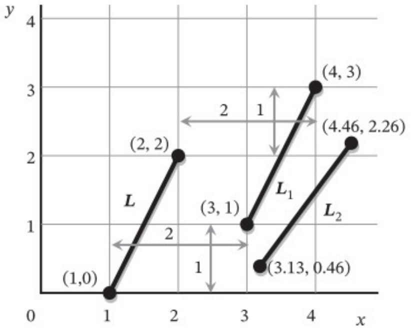


Figure 4.12 A line $\boldsymbol{L}$ defined by its two end points $\boldsymbol{P}_1$ and $\boldsymbol{P}_2$ in *Cartesian* coordinates. It is translated to line $\boldsymbol{L}_1$ by *2* units in the x direction and *1* unit in the y direction. It is then rotated to line $\boldsymbol{L}_2$ by −10°.

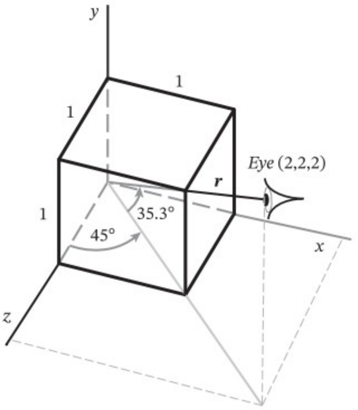

Figure 4.13 A unit cube body attached to the origin of the coordinate system *xyz*. The observer eye is located at the position (2, 2, 2) and is looking along the cube diagonal toward the origin.

Example 4.2 A unit cube body has its bottom corner attached to the origin of the coordinate system *xyz* as shown in Figure 4.13. The observer eye is located at the position (2, 2, 2) and is looking along the cube diagonal toward the origin. It is required to find the projection of the cube on the normal plane to the line of sight and passing by the origin. Does this projection produce the perceived ***perspective*** of the cube by the observer?

Solution

The body matrix $\boldsymbol{B}_H$ is defined by the following:

$$\boldsymbol{B}_H = \begin{bmatrix} 0 & 0 & 0 & 1 \\ 1 & 0 & 0 & 1 \\ 1 & 1 & 0 & 1 \\ 0 & 1 & 0 & 1 \\ 0 & 0 & 1 & 1 \\ 1 & 0 & 1 & 1 \\ 1 & 1 & 1 & 1 \\ 0 & 1 & 1 & 1 \end{bmatrix} = \begin{bmatrix} 0 & 1 & 1 & 0 & 0 & 1 & 1 & 0 \\ 0 & 0 & 1 & 1 & 0 & 0 & 1 & 1 \\ 0 & 0 & 0 & 0 & 1 & 1 & 1 & 1 \\ 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \end{bmatrix}^T \tag{a}$$

Note that the cube corners, vertices, or points $\boldsymbol{P}_i$ are considered as row vectors. The *eye (2, 2, 2)*, or in general location vector $\boldsymbol{r}$ *(a_E, b_E, c_E)*, makes the following angles to transform the *eye* to be located on the z-axis in preparation for applying the perspective transformation. The radial distance r_{eye} from the origin to the eye is then

$$r_{\text{eye}} = (a_E{}^2 + b_E{}^2 + c_E{}^2)^{1/2} \quad \text{Or} \quad r_{2,2,2} = (12)^{1/2} = 3.46 = f_z \tag{b}$$

The angle θ_y between the projected $\boldsymbol{r}$ vector on the x–z plane and the y–z plane is

$$\theta_y = \tan^{-1} a_E/c_E = \tan^{-1} 1 = 45^\circ \tag{c}$$

Then the *eye* and the body should be rotated in the opposite direction, i.e. rotated by $-\theta_y$ so that the *eye* would be located in the y–z plane. Therefore, the rotation should be $\theta_y = -45^\circ$.

The angle between the *eye* – while on the y–z plane after θ_y rotation – and the x–z plane is given by

$$\beta_x = -\sin^{-1}\left(b_E/(a_E{}^2 + b_E{}^2 + c_E{}^2)^{1/2}\right) = -\sin^{-1}(2/3.46) = -35.3^\circ \tag{d}$$

Here, the *eye* and the body should be rotated in the opposite direction, i.e. by $-\beta_x$ so that the eye would be located on the z-axis. Therefore, the rotation should be $\beta_x = 35.3^\circ$.

For the rotation matrices, one calculates $\cos\theta_y = 0.707$, $\sin\theta_y = -0.707$, $\cos\beta_x = 0.816$, and $\sin\beta_x = 0.578$. The rotation matrices are then

$$\boldsymbol{R}_y = \begin{bmatrix} \cos(\theta_y) & 0 & -\sin(\theta_y) & 0 \\ 0 & 1 & 0 & 0 \\ \sin(\theta_y) & 0 & \cos(\theta_y) & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} = \begin{bmatrix} 0.707 & 0 & 0.707 & 0 \\ 0 & 1 & 0 & 0 \\ -0.707 & 0 & 0.707 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \tag{e}$$

$$\boldsymbol{R}_x = \begin{bmatrix} 0 & 0 & 0 & 0 \\ 0 & \cos(\beta_x) & \sin(\beta_x) & 0 \\ 0 & -\sin(\beta_x) & \cos(\beta_x) & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} = \begin{bmatrix} 0 & 0 & 0 & 0 \\ 0 & 0.816 & 0.578 & 0 \\ 0 & -0.578 & 0.816 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \tag{f}$$

The order of rotation is important and should be $\boldsymbol{R}_y$ then $\boldsymbol{R}_x$, i.e.,

$$\boldsymbol{R}_{xyz} = \boldsymbol{R}_y \boldsymbol{R}_x = \begin{bmatrix} 0.707 & 0 & 0.707 & 0 \\ 0 & 1 & 0 & 0 \\ -0.707 & 0 & 0.707 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} 0 & 0 & 0 & 0 \\ 0 & 0.816 & 0.578 & 0 \\ 0 & -0.578 & 0.816 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} = \begin{bmatrix} 0.707 & -0.409 & 0.577 & 0 \\ 0 & 0.816 & 0.578 & 0 \\ -0.707 & -0.409 & 0.577 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \tag{g}$$

Transformation of rotation then *perspective* $\boldsymbol{P}_H$, where $\boldsymbol{P}_H$ is given by

$$\boldsymbol{P}_H = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & -1/3.464 \\ 0 & 0 & 0 & 1 \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & -0.289 \\ 0 & 0 & 0 & 1 \end{bmatrix} \tag{h}$$

The total transformation matrix $\boldsymbol{T}_{\text{GH}}$ is then (after multiplication)

$$\boldsymbol{T}_{\text{GH}} = \boldsymbol{R}_{xyz}\ \boldsymbol{P}_H = \begin{bmatrix} 0.707 & -0.409 & 0.577 & 0 \\ 0 & 0.816 & 0.578 & 0 \\ -0.707 & -0.409 & 0.577 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & -0.289 \\ 0 & 0 & 0 & 1 \end{bmatrix} = \begin{bmatrix} 0.707 & -0.409 & 0.577 & -0.167 \\ 0 & 0.816 & 0.578 & -0.167 \\ -0.707 & -0.409 & 0.577 & -0.167 \\ 0 & 0 & 0 & 1 \end{bmatrix} \tag{i}$$

Note that the first three columns are exactly the same as the total rotation matrix $\boldsymbol{R}_{xyz}$.

The body after total transformation is then given by (after multiplication)

$$\boldsymbol{B}'_H = \boldsymbol{B}_H \;\; \boldsymbol{T}_{\mathrm{GH}} = \begin{bmatrix} 0 & 0 & 0 & 1.0000 \\ 0.7071 & -0.4082 & 0.5774 & 0.8333 \\ 0.7071 & 0.4082 & 1.547 & 0.6667 \\ 0 & 0.8165 & 0.5774 & 0.8333 \\ -0.7071 & -0.4082 & 0.5774 & 0.8333 \\ 0.0000 & -0.8165 & 1.1547 & 0.6667 \\ 0.0000 & 0.0000 & 1.7321 & 0.5000 \\ -0.7071 & 0.4082 & 1.1547 & 0.6667 \end{bmatrix} \tag{j}$$

To project the body, a *homogeneous normalization* is necessary. It means that the fourth column must have the value of one for each point or row. This can be implemented by dividing each component of a row by the fourth column value of that row, which normalizes the fourth component to the value of *1*. Performing the process for all the rows causes the fourth column to a unity. After *homogeneous normalization*, the perspective projection body is then

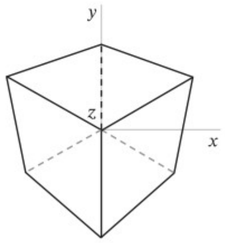
$$\boldsymbol{B}'_H = \begin{bmatrix} 0 & 0 & 0 & 1.0000 \\ 0.8486 & -0.4899 & 0.6929 & 1.0000 \\ 1.0606 & 0.6123 & 1.7320 & 1.0000 \\ 0 & 0.9798 & 0.6929 & 1.0000 \\ -0.8486 & -0.4899 & 0.6929 & 1.0000 \\ 0 & -1.2247 & 1.7320 & 1.0000 \\ 0 & 0 & 3.4642 & 1.0000 \\ -1.0606 & 0.6123 & 1.7320 & 1.0000 \end{bmatrix} \tag{k}$$

The plotting of the body on x–y plane is shown in Figure 4.14. This projection produces the perceived *perspective* of the cube by the observer. If all lines are extended, they will meet at the three *vanishing points* known in regular graphics or drawing subjects.

4.1.4 Stereo Viewing

To produce a stereo view for a body, we need to generate two views of the body, one for each eye of the viewer. The two views are looked at simultaneously by each eye to generate the ***3D*** stereo of the body. The right eye should only see the right body view, and the left eye should only see the left view of the body. This is similar to the ***3D*** movies where one would use eyeglasses with right and left piece of different polarization planes. Usually one piece is of a vertical polarization, and the other is of a horizontal polarization. The movie is produced with two cameras for the right and left eyes and projects both simultaneously through the two polarized planes onto the theater screen. For LCD or LED screens, the process is different so far. It requires that the eyeglasses should synchronize with the projection of the right and left views; see also Section 3.4 about virtual reality (VR).

Figure 4.14 Plotting of the body onto the projection x–y plane. The projection produces the perceived perspective of the cube by the observer.



It should be of interest to note that by comparing Eq. (5.139) to Eq. (5.143), one can get the *inverse* of the *non-square matrix* as follows:

$$\boldsymbol{G}^{-1} = [\boldsymbol{G}^T\boldsymbol{G}]^{-1}\boldsymbol{G}^T \tag{5.144}$$

This is called the ***pseudo inverse*** or *minimum norm inverse*. MATLAB provide a *pseudo inverse function* "`pinv`" to carry such an inverse.

5.5.4.3 Gradient Projection Method

The method of ***GP*** is concerned about moving along the constraint boundary. If we hit the constraints, we may like to move on the constraints by projecting the gradient vector onto the constraints tangent as shown in Figure 5.24. The projected gradient vector consists of the gradient vector itself minus the component u_i normal to the tangent (i.e. parallel to $\nabla\mathbf{g}$). This is translated to the following relation for r constraints *in effect* at the point in question:

$$\nabla f_p = \nabla f - u_1\nabla g_1 - u_2\nabla g_2 \ldots\ \ u_r\nabla g_r \tag{5.145}$$

Note again that only few "r" of the "m" constraints are active. Equation (5.145) can be rewritten as

$$\nabla\boldsymbol{f}_p = \nabla\boldsymbol{f} - \begin{bmatrix}\nabla\mathbf{g}_1 & \nabla\mathbf{g}_2 & \ldots. & \nabla\mathbf{g}_r\end{bmatrix}\begin{bmatrix}u_1\\ u_2\\ \ldots\\ u_r\end{bmatrix} = \nabla\boldsymbol{f} - \boldsymbol{G}_r\boldsymbol{u} \tag{5.146}$$

It should be noted that, generally, $\boldsymbol{G}_r \neq \boldsymbol{G}$. But the rejection vector must be *orthogonal* to the constraints gradient, which requires that

$$\nabla\mathbf{g}_1^T\nabla\boldsymbol{f}_p = \nabla\mathbf{g}_2^T\nabla\boldsymbol{f}_p = \cdots = \nabla\mathbf{g}_r^T\nabla\boldsymbol{f}_p = 0 \tag{5.147}$$

This is rewritten as

$$\boldsymbol{G}_r^T\nabla\boldsymbol{f}_p = \mathbf{0} \tag{5.148}$$

Substituting Eq. (5.148) into Eq. (5.145) by the through multiplication by G_r^T, one obtains the following:

$$\begin{aligned}&\boldsymbol{G}_r^T[\nabla\boldsymbol{f} - \boldsymbol{G}_r\boldsymbol{u}] = \mathbf{0}\\ &\boldsymbol{G}_r^T\nabla\boldsymbol{f} = \boldsymbol{G}_r^T\boldsymbol{G}_r\boldsymbol{u}\end{aligned} \tag{5.149}$$

Or

$$\boldsymbol{u} = [\boldsymbol{G}_r^T\boldsymbol{G}_r]^{-1}\boldsymbol{G}_r^T\nabla\boldsymbol{f} \tag{5.150}$$

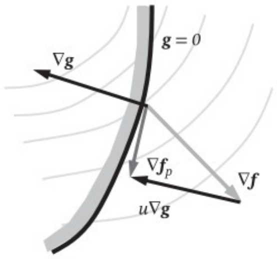


Figure 5.24 Projecting the gradient vector $\nabla\boldsymbol{f}$ onto the constraints tangent to get the gradient projection $\nabla\boldsymbol{f}_p$.

This relation is in a similar form to the *Lagrange multipliers* in Eq. (5.143), but without the negative sign. Substituting Eq. (5.150) into Eq. (5.145) gives the projection vector.

$$\nabla \boldsymbol{f}_p = \nabla \boldsymbol{f} - \boldsymbol{G}_r\,[\boldsymbol{G}_r^T \boldsymbol{G}_r]^{-1} \boldsymbol{G}_r^T \nabla \boldsymbol{f}$$

$$\nabla \boldsymbol{f}_p = \{I - \boldsymbol{G}_r\,[\boldsymbol{G}_r^T \boldsymbol{G}_r]^{-1} \boldsymbol{G}_r^T \nabla \boldsymbol{f}\} \nabla \boldsymbol{f} \tag{5.151}$$

Therefore, for minimization we can proceed in the $-\nabla \boldsymbol{f}_p$ direction. In that situation, what might happen? Three cases are expected to occur; see Figure 5.25 for a hypothetical constraint that has *convex*, *linear*, and *concave* sections:

- At point (a) on the *convex constraint* section, obviously we go into the infeasible region. If we want to continue, we have to step in the $-\nabla \boldsymbol{g}$ direction to converge. Thus, method is not appropriate for convex constraints.
- For *concave constraint* section at point (b), we move into the feasible region, and we can continue in the normal search procedure.
- For *linear constraint* section at (c), we move in just the right direction. The method in most useful and suitable. This is one way of handling constraints in *linear programming*.

5.5.4.4 *Heuristic Gradient Projection Method (HGP)*

As indicated in the previous ***GP*** section and for convex constraints, the search direction should depart the constraint boundary into the infeasible region if these constraints were active. To continue, one must step into the $-\nabla \boldsymbol{g}_i$ to converge. If the component of $-\nabla \boldsymbol{g}_i$ is included in the new combined ***GP*** search direction $-\nabla \boldsymbol{g}_i{}^T \nabla \boldsymbol{f}$, the process should be automatic. Therefore, this method is suitable for convex constraints. For concave constraints, the search direction also steps into the feasible region. To continue, one may need to step into the $\nabla \boldsymbol{g}_i$ to converge. If the component of $\nabla \boldsymbol{g}_i$ is also included in the new combined search direction $\nabla \boldsymbol{g}_i{}^{\boldsymbol{T}} \nabla \boldsymbol{f}$, the process should also be automatic. Figure 5.26 shows the projection of the gradient vector ∇f onto the constraints tangent to get the *heuristic gradient projection* (***HGP***) ∇f_{pH}, which is away from the constraint. In many cases, however, the constraint gradient may be in the same direction as the gradient of the objective function. The search can thus continue in the normal procedure; see, e.g. Abd El Malek (2005) and Metwalli (2012).

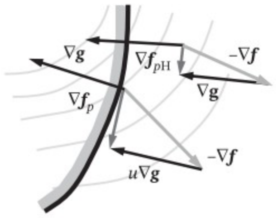

Figure 5.26 Projecting the gradient vector $\nabla \boldsymbol{f}$ onto the constraints tangent to get the heuristic gradient projection $\nabla \boldsymbol{f}_{\mathrm{pH}}$ away from the constraint.

The ***HGP*** method is most suitable to apply for problems that are expected to have a constrained minimum with defined formulation for both objective function and constraints. The optimization of ***3D*** space frames is a problem where the objective function is defined as the total volume and the constraints are restricted to satisfy allowable stress values. The optimization of ***3D*** space frames is then most suitable to demonstrate the ***HGP*** method. The objective function for ***3D*** space frames is the total volume of the n members of circular cross section each of a diameter d_i and a length l_i. The total volume is therefore the objective function defined as

$$f(d) = \sum_{i=1}^{n} \pi {d_i}^2 l_i/4 \tag{5.152}$$

Without any loss of generality, if the ***3D*** frame will not be *topologically optimized* except by removing trivially loaded members, the objective function will take the form

$$f(d) = \sum_{i=1}^{n} a_i {d_i}^2 \tag{5.153}$$

where a_i is a constant that can represent $\pi l_i/4$. In the local coordinates, the stress in each member is evaluated numerically (Abd El Malek et al. 2005). Without key loss of generality, the stress constraints may be initially defined by the following expression:

$$g_i(d) \cong b_i {d_i}^{-3} - c_i \leq 0 \tag{5.154}$$

where b_i is a constant that includes the *stress* constants and c_i is a constant representing the *allowable strength*. It is assumed initially that the coupling between members and its feedback can be automatically accounted for during iterations. If, however, the members were mainly subjected to axial loading, Eq. (5.154) would instead be mainly in (d^{-2}). This is one other alternative, which can be used. Other options have also been used; see, e.g. Senousy et al. (2005), Hanafy and Metwalli (2009), and Abd El-Aziz et al. (2016).

The components of the gradient vectors for the objective function and the constraints are obtained from Eqs. (5.153) and (5.154) as follows:

$$\begin{aligned} \nabla f(d) &= \alpha_i d_i \\ \nabla g_i(d) &= -\beta_i {d_i}^{-4} \end{aligned} \tag{5.155}$$

The components of *projected gradient vector* can be obtained as follows:

$$\nabla {g_i}^T \nabla f = -\gamma_i \, {d_i}^{-3} \tag{5.156}$$

To implement the procedure and considering the *slackness variables* along the ***HGP*** direction, we use the recursive heuristic direction components for constraints and minimize the objective function at the same time such that

$$s_{\mathrm{pi}}(d_i) = \sigma_{i,\mathrm{equiv}} \; (d_{i,\mathrm{new}})^{-3} - S_{i,\mathrm{const}} \; (d_i)^{-3} \tag{5.157}$$

where d_i is the *member diameter*, $d_{i,\mathrm{new}}$ is the *new diameter* of the member, s_{pi} is the component of slackness on the projection vector, $\sigma_{i,\mathrm{equiv}}$ is the *equivalent stress* (e.g. *von Mises*), and $S_{i,\mathrm{const}}$ is the *allowable strength* constraint.

This can be implemented by *recursive* use of the following relation:

$$d_{i,\mathrm{new}}^3 = d_i^3 \frac{\sigma_{i,\mathrm{equiv}}}{S_{i,\mathrm{const}}} \tag{5.158}$$

The relation defined in Eq. (5.158) satisfies the constraint; in addition, it reduces the objective function. Therefore, these steps chase the constraint boundary while reducing the objective function. This is tantamount to the process of ***GP*** method, but does not require following the constraint tangents. This is the reason of applying the name ***HGP*** on this method.

5.5.4.5 Constrained Optimization Sample

This section presents a simple constrained problem to clarify concepts and demonstrate constraint optimization handling.

Example 5.14 Consider the simple objective function defined by

$$\boldsymbol{f} = -(x_1 + x_2) \tag{a}$$

The constraints for this problem are

$$\begin{aligned} \mathbf{g}_1 &= -x_1 \leq 0 \\ \mathbf{g}_2 &= x_1^2 + x_2^2 - 1 \leq 0 \end{aligned} \tag{b}$$

Start at $\boldsymbol{X}_o = (0, -1/2)$, use the first direction of any first-order method (*gradient*) to reach the next point. Check if the point $x_1 = \sqrt{2}/2,\ x_2 = \sqrt{2}/2$ is a constraint optimum.

Solution

Data: $\boldsymbol{X}_0 = (0, -1/2)$ and check *K–T* conditions at (0.707, 0.707). The value of the objective point at $\boldsymbol{X}_0$ is $\boldsymbol{f}_0 = 1/2$.

The plot of the function contours and constraints is given in Figure 5.27 showing the infeasible and feasible regions. The objective function gradient is

$$\nabla f = \begin{bmatrix} \dfrac{\partial f}{\partial x_1} \\ \dfrac{\partial f}{\partial x_2} \end{bmatrix} = \begin{bmatrix} -1 \\ -1 \end{bmatrix} \tag{c}$$

First search direction $\boldsymbol{S}$ of any first-order method is in the negative direction of the gradient, *i.e.* $-\nabla \boldsymbol{f}$. Get the intersection of $\boldsymbol{S}$ line with the constraint such as

$$\begin{aligned} x_2 &= x_1 - 0.5, \\ x_1^2 + (x_1 - 0.5)^2 - 1 &= 0 \end{aligned} \tag{d}$$

which gives a point at $x_1 = 0.9114$ and -0.4114. At $x_1 = 0.9114$, the next point is then $\boldsymbol{X}_1 = (0.9114, 0.4115)$. At $x_1 = -0.4114$, the point is in the infeasible region and thus will be discarded. The required next point $\boldsymbol{X}_1 = (0.9114, 0.4115)$ is then shown in Figure 5.13.

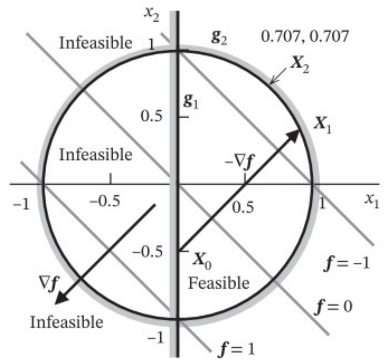

Figure 5.27 The plot of the function contours and constraints of Example 5.14 showing the infeasible and feasible regions.

denote the five families of parallelohedra, namely, parallelepiped, rhombic dodecahedron, hexagonal prism, elongated rhombic dodecahedron, and truncated octahedron, respectively. For each of these five families F_i ($i = 1, \ldots, 5$), choose a polyhedron $P_i \in F_i$ to be a **representative** in any manner. The resulting set $\Sigma = \{P_1, \ldots, P_5\}$ consists of five parallelohedra, and we call it a **representative set of parallelohedra.**

Let $\Sigma = \{P_1, \ldots, P_5\}$ be a representative set. Given any parallelohedron $P \in \Pi$, there exists an affine-stretching transformation $A : \mathbb{R}^3 \longrightarrow \mathbb{R}^3$ such that $A(P) \in \Sigma$. Hence, in order to determine an atom for the set Π, it suffices to find a polyhedron σ and a representative set $\Sigma = \{P_1, \ldots, P_5\}$ such that each parallelohedron $P_i \in \Sigma$ is the union of a finite number of copies of σ. Therefore, in this paper we consider the **representative set** that consists of the cube, the rhombic dodecahedron, the skewed hexagonal prism, the elongated rhombic dodecahedron, and the truncated octahedron.

2. AN ATOM FOR THE SET OF PARALLELOHEDRA

Throughout the paper, we denote the set of all parallelohedra by Π, and we use Σ to denote the **representative set** of parallelohedra that consists of the cube, the rhombic dodecahedron, the skewed hexagonal prism, the elongated rhombic dodecahedron, and the truncated octahedron. In the following theorem, we will show that a special kind of pentahedron, which we call a **pentadron**, is an **atom** for the set Π. A **pentadron** is either one of the pentahedra shown in Figure 2(a), with developments shown in Figure 2(b).

Rotating asymmetrical objects will emit at their rotational frequencies, but only rapidly rotating neutron stars and black holes are likely to be detectable for a long time to come, so their frequencies of interest range from about 10 Hz to 10 kHz. Asymmetrical supernova explosions and the like will probably emit between 100 mHz and 10 Hz.

{90} GW170817: Three Detectors and Two Neutron Stars

We have seen (Chapters 1 and 4) that the first gravitational wave event, **{10}** GW150914, arose from the merger of two black holes. Furthermore, as just considered above, several types of compact object mergers and binary systems may potentially produce observable gravitational waves. All currently known gravitational wave events are reviewed in Chapter 6 and the vast majority of those also arise from black hole mergers. Let us here, therefore, look in more detail at a gravitational wave event which resulted from one of the other types of sources discussed above and which is different in many ways from the black hole mergers.

This event, **{90}** GW170817, originated in the merger of two neutron stars and is of great significance in its own right. It was also only the second event clearly detected by three gravitational wave detectors; the two AdvLIGO instruments and AdvVirgo (Chapters 6 and 8), which enabled a fairly accurate position in the sky to be found for it. This position then enabled **{90}** GW170817 to be identified with a gamma ray burst and radio and optical transient events so that it was the first and, so far, only gravitational wave event to be unequivocally detected via its electromagnetic emissions as well.

Two well-separated detectors enable the position of the source of the gravitational waves to be constrained to lie within an annulus of the sky. However, that annulus still covers a large area of the sky (Figure 5.3), so any attempts to locate other emissions from the event, such as gamma rays, light, neutrinos, etc., are almost certainly doomed to failure; even if black hole mergers led to significant such emissions which, by and large, they do not.

During AdvLIGO's second observing run (O2), however, it was joined on the 1st of August 2017 by the AdvVirgo gravitational wave detector beginning its science operations (Chapter 8). With three detectors, the problem of identifying the source of a gravitational wave event is dramatically changed. By taking the detectors in pairs, we get three position annuli on the sky and, in exactly the same way that navigators use triangulation of three sightings to determine their positions at sea, so the position of the source may be identified to lie within a much smaller area of the sky by triangulation of the position annuli (Figure 5.3).

Location Annulus for Gravitational Wave detectors #3 and #1

Figure 5.3 The narrowing down of the position of a gravitational wave source when three detectors are in use, by triangulation. The huge reduction in the necessary search area is clear to see

The AdvLIGO and AdvVirgo operators were very lucky—within two weeks a black hole merger was detected by all three detectors. **{80}** GW170814—detected on the 14th of August 2017—was around 580 Mpc away and involved black holes with masses of 30.7 $M_{\odot}$ and 25.3 $M_{\odot}$ (Chapter 6). The triangulation from the three detectors limited its position to within about 60 square degrees; ~10% of the smallest possible search area for **{10}** GW150914 and in an area of Eridanus between Horologium and Phoenix. As already mentioned, though, the energy released during black hole mergers goes mostly into the gravitational wave emissions, so even with the small location area to be searched, no electromagnetic or other emissions could be detected. The precise identification of the whereabouts of the source, that is, the galaxy within which it occurred, therefore, still remains unknown.

Just three days later, though; the 17th of August 2017, the next event was very different. **{90}** GW170817 involved two neutron stars merging, not black holes—though they may have formed a black hole after the merger (below). Neutron stars (Chapters 5 and 6), unlike black holes, are not reticent about emitting electromagnetic radiation across the whole spectrum and the resulting fireworks were observed from gamma rays to radio waves, as well, of course, as the gravitational wave event itself.

The three gravitational wave detectors triangulated the search area down to a lenticular zone close to gamma Hydra and covering about 16 square degrees (Figure 5.4). Ironically, AdvVirgo did not appear to have detected the event, but its negative data was still used to narrow the search area for the source—by utilising the area of the sky that was AdvVirgo's blind spot. Later work showed the AdvVirgo had made a detection, but that it was very faint through the source being located within that blind spot (Figure 5.6).

Sixteen square degrees (initially 28 square degrees) is still a large(ish) area of the sky—about 80 times the area of the full Moon—but it is small enough for radio and optical astronomers to search with some hope of successfully finding the source from its electromagnetic emissions. Those searches started within a few hours and had their first result within less than half a day.

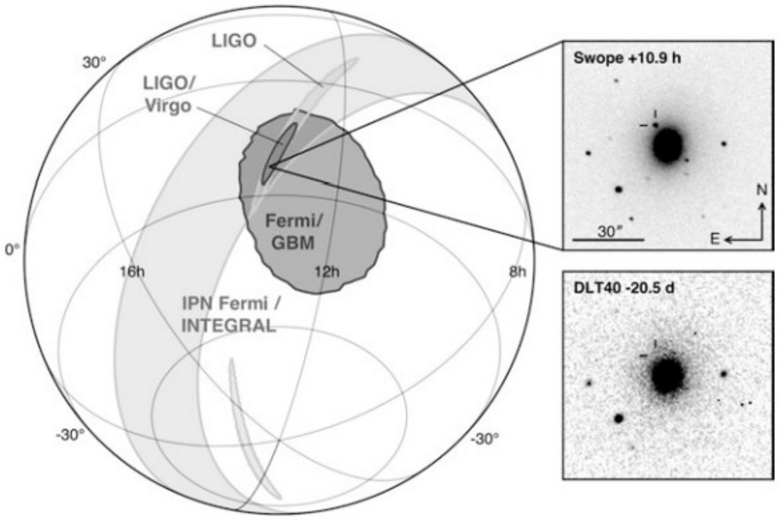

Figure 5.4 Triangulation of the search area for **{90}** GW170817 from the two AdvLIGO detectors and the AdvVirgo detector (indicated as 'LIGO/Virgo'). Two narrow lenticular areas based upon the two AdvLIGO detectors alone (the top one indicated as 'LIGO') are also shown. Plus, the possible source location areas for the gamma ray burst GRB170817A from the Fermi gamma ray Burst Monitor ('Fermi/GBM') and from timing measurements by Fermi and INTEGRAL spacecraft detections processed by the InterPlanetary Network ('IPN Fermi/INTEGRAL') are indicated. An image of the optical transient thought to be identified with both **{90}** GW170817 and GRB170917A in NGC 4993 (shown by the two dashes) obtained 10.9 hours after GRB170817A by the 1 m Swope telescope in Chile is shown at the upper right, while a pre-discovery image of NGC4993 obtained by the 0.4 m PROMPT telescope in Chile (operated by the DLT Supernova Search Collaboration and which also detected the optical counterpart of the **{90}** GW170817 event) is shown at the bottom right for comparison. (Reproduced by courtesy of B. P. Abbott *et al*. 'Multi-messenger Observations of a Binary Neutron Star Merger'. ApJ Lett., L12, **848**, 2017, DOI:https://doi.org/10.3847/2041-8213/aa91c9)

Before then, however, and independently of the gravitational wave detection, two gamma ray space observatories, Fermi and INTEGRAL, had detected a gamma ray burst just 1.74 seconds later than AdvLIGO's and AdvVirgo's receptions of the gravitational wave (Figure 5.5). GRB170817A was registered as occurring at 12:41:06 UTC, and its detection automatically generated an electronic alert to other observatories just 14 seconds later. **{90}** GW170817 occurred at 12:41:04 UTC; being received in the order: AdvVirgo → 22 milli-seconds → Livingston → 3 milli-seconds → Hanford, but the first, low priority, alert did not go out for 26 minutes. The first alert that gave a reasonably precise and accurate search area for the gravitational wave event was sent out just over 12 hours after it had occurred—so the initial searches were actually looking for the source of the gamma ray burst, not the gravitational wave event.

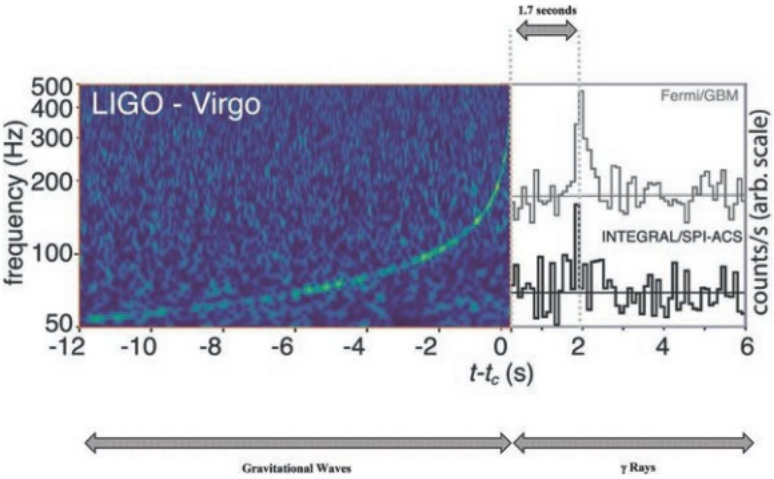

Figure 5.5 The times of reception of the **{90}** GW170817 and GRB170817A signals at AdvLIGO Livingston/Hanford and Fermi/INTEGRAL. (Reproduced by courtesy of B. P. Abbott *et al*. 'Multi-messenger Observations of a Binary Neutron Star Merger'. ApJ Lett., L12, **848**, 2017, https://doi.org/10.3847/2041-8213/aa91c9)

Of course, it could be that the gravitational wave emission, the gamma ray burst and the optical transient were three separate and independent events. However, the luminosity distance to **{90}** GW170817 is 40 Mpc (±10 Mpc) and those to the optical transient and NGC4993 from their cosmological redshifts are both 42.9 Mpc (±3.2 Mpc); so the three distances are essentially the same. Adding the excellent overlap of the search areas (Figure 5.4) to the distance estimates, then a false alarm; that is, just coincidence of three independent events, would occur only about once in 80,000 years. Hence **{90}** GW170817, GRB170817A and the optical transient in NGC4993 are now unanimously taken to have arisen from the same binary neutron star merger.

The distance of **{90}** GW170817 and its associated events of about 43 Mpc is equal to about 140 million light years. That means that although we saw the events in the year 2017, they actually occurred some 140,000,000 years earlier; the look-back time. This would have placed it in the middle of the Mesozoic era, when the first mammals were starting to evolve and dinosaurs were at their peak. For comparison, the look-back time to **{10}** GW150914 is about ten times larger—during the Earth's Proterozoic era—when multicellular life was still struggling to emerge.

The masses of the two neutron stars involved in **{90}** GW170817 were relatively small—the primary probably being between 1.36 and 1.60 $M_{\odot}$ and the secondary between 1.17 and 1.36 $M_{\odot}$, with a total mass close to 2.74 $M_{\odot}$. These lower masses than those of the merging black hole binaries (Chapters 4 and 6) meant that the merger event happened more slowly. The signals for **{90}** GW170817 thus lasted for nearly 30 seconds (Figures 5.5 and 5.6)—compared with the 200 milli-seconds for **{10}** GW150914 (Figure 3.1). The mass lost during the merger and so also the total amount of energy radiated away was about 1% that of **{10}** GW150914, but the distance being only about a tenth that of **{10}** GW150914, meant that the apparent gravitational brightnesses of the two events were similar. **{90}** GW170817, though, radiated much more electromagnetic energy than **{10}** GW150914.

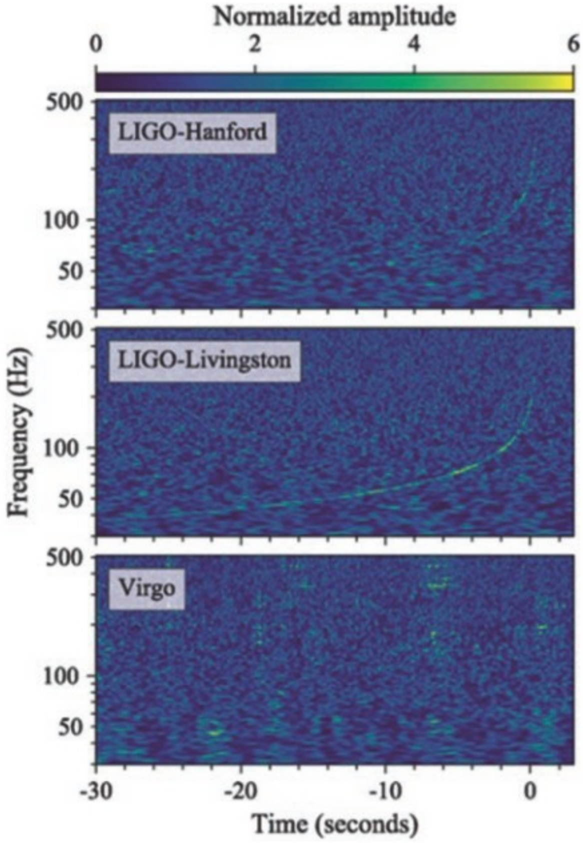

Figure 5.6 {90} GW170817—The three gravitational wave signals for AdvLIGO Hanford, AdvLIGO Livingston and AdvVirgo. Note the absence of a noticeable signal from AdvVirgo, arising from {90} GW170817's source being within AdvVirgo's blind spot. (Reproduced by courtesy of B. P. Abbott *et al*. 'GW170817: Observation of Gravitational Waves from a Binary Neutron Star Inspiral'. Phys. Rev. Lett., 161101-1, **119**, 2017. DOI:https://doi.org/10.1103/PhysRevLett.119.161101)

The merger of the neutron stars resulted in a short gamma ray burst (sGRB—GRB170817A), as already mentioned. Some tens of sGRBs have now been observed and, of those whose distances can be estimated, GRB170817 at about 40 Mpc, is the closest to us so far. The merger of two neutron stars leaves a large amount of debris surrounding the final merged object. The electromagnetic emissions are largely coming from this debris. The energy for those emissions is derived from radioactive decay of elements produced by nucleosynthesis during the merger. For {90} GW170817 about 0.05 $M_\odot$ or about 20,000 Earth masses, of such radioactive elements are estimated to have been synthesised, including about ten Earth masses of platinum and gold—which latter detail is what made the popular-press headlines.

The radioactive elements are built up from lighter nuclei during the merger through their rapid capture of free neutrons (the r-process). In this they resemble 'ordinary' novae, but the total energy emitted in that way is up to a thousand times that of a nova. The processes leading up to the electromagnetic events are hence sometimes given the name of 'Kilonova' (also Macronova).

The merged object in the case of **{90}** GW170817 was initially thought to be a small(ish) black hole, but the possibility of it being a very massive magnetar; a neutron star possessing a very intense magnetic field—(Chapter 5) is now thought to be the more probable. The evidence for this is a five second chirp, descending in frequency from about 1 kHz to 49 Hz, occurring immediately after the initial ascending frequency chirp and observed by the two AdvLIGO detectors. This descending frequency chirp is interpreted as arising from the simple slowing of the rotation or spin down of the merged object as a neutron star rather than the ringdown of a merged black hole as in **{10}** GW150914 (Chapters 4 and 7). More recent observations have, at least partially, re-raised the possibility that the merged object has become a black hole—so that matter is still being debated at the time of writing.

In the months following the outburst, the radio emissions from the electromagnetic transient increased in intensity steadily, but after half a year or so, they started to fade rapidly. Modelling of this behaviour suggests that material ejected during the outburst was initially expanding outwards relatively slowly and cocooning the central remnant. Later a narrow high-speed jet developed that punched its way through the cocoon and is now taking away most of the energy of the outflow. As of the time of writing (Dec 2020), gamma, X-ray and radio emissions are still being received from the debris, though declining in their intensities steadily. The optical emissions, though, are now too faint to detect.

Scientifically, though, the most significant observation to come from **{90}** GW170817 was probably the 1.7 second delay between the gravitational and gamma ray signals. Even if the peak of the gravitational wave emission and that of the gamma ray emission exactly coincided—and they probably did not, the 1.7 second difference in the arrival times after travelling 43 Mpc means that the speeds of gravity and light are almost identical. As we have seen earlier (Chapter 1), the speed of gravity being equal to the speed of light is a fundamental assumption underlying General Relativity. So, this result provides yet more strong evidence for the validity of General Relativity over alternative theories of gravity—some of which would have predicted delays between the two signals measured in years.

If we assume that the gravitational and gamma ray signals were emitted simultaneously, then the delay implies that the speed of gravity lies between about 9×10^{-7} m s^{-1} slower than the speed of light and 2×10^{-7} m s^{-1} faster than the speed of light—for comparison, an oak tree grows in height at a rate of about 2×10^{-8} m s^{-1}. However, of course, it is quite likely that the two signals were not emitted simultaneously—they originate from different physical processes, after all—and so the speeds of gravity and light could well be exactly equal. Confirmation of this equality, based upon the gravitational and gamma ray signal timings, has come independently from the transit times of the gravitational waves alone between the detectors for eight of the 11 O1 and O2 events.

The 1.7 second delay also provides a second confirmation of the probable validity of General Relativity via testing the equivalence principle. The Shapiro effect (Chapter 1) should act on both gravitons, if these are massless (Chapter 3), and photons equally. The magnitudes of those effects depend upon the mass distribution all along the path from their source to the Earth and that is not well known. However, an approximate estimate of that mass distribution plus the 1.7 second delay leads to the result that the Shapiro effect for gravitons differs from that for photons by less than one part in a million—again a striking confirmation of General Relativity. The result also sets an upper limit on the rest mass of the graviton of $\leq\sim 1.4 \times 10^{-58}$ kg; that is, at least 10^{28} gravitons would be required to add up to the mass of one electron—the Chandra spacecraft though has already set a limit on the graviton mass that is a million or more times smaller than this value (Chapter 3).

From the estimated number of neutron star binaries in the Universe and their estimated merger rate, events like **{90}** GW170817 may occur within a spherical volume, 1,000 Mpc in radius and centred on the Earth, at a rate of between 1,000 and 20,000 per year. **{90}** GW170817 was 'only' about 40 Mpc, that is about 400 times the size of the optically visible part of our Milky Galaxy, away. With the levels of sensitivity which AdvLIGO and AdvVirgo achieved during the O2 observing run, it provided a relatively strong signal—probably, it could have been detected out to some 100 Mpc or so.

With the O3 observing run (Chapter 6), sensitivities were improved by about 50–100% over the O2 run. Although the data analysis is still in progress at the time of writing, an additional five binary neutron star merger events were detected with reasonable certainty during run O3, with another four events being possibilities—though none of these events has had associated gamma ray or other non-gravitational transient events detected. The actual discovery rate of neutron star binary mergers was thus about one per month, compared with nearly six mergers per month involving black holes or black hole and neutron stars.

Some Final Questions and Thoughts About Gravitational Wave Sources

> I think the problem, (said the Deep Thought computer—Author's note) to be quite honest with you, is that you've never actually known what the question is. (Douglas Adams. 'Hitchhiker's Guide to the Galaxy'. BBC Radio 4, 1978).

Does the Earth Generate Gravitational Waves?

Yes, of course.

It is a member of a complex multiple system of mutually interacting objects, that is, the Solar System, with the Earth–Moon and Sun–Earth binary systems being the main, but not the only, contributors to the Earth's gravitational emissions. The Earth is also rotating and is asymmetric—Everest and the Marianas trench immediately spring to mind, but the Earth is also squashed along its polar axis; an oblate spheroid, so that its polar diameter is 42 km shorter than its equatorial diameter. On the intermediate size scales, there are very large regions of the Earth that are higher or lower than the average by tens of metres. Much of Europe and the North Atlantic, for example, is raised by around 50 m, whilst most of the Indian ocean floor is lower than average by 80 or more metres.

More significantly, the Earth's mantle is not uniform and large masses move slowly around so that the Earth's pattern of asymmetry changes. N.B.—it is the instantaneous pattern of the Earth's asymmetry combined with its rotation that produces gravitational waves of even remotely possible interest. While the motions of masses of material within the mantle doubtless will also produce gravitational waves, it seems unlikely that they could ever be detectable.

Note that, by the substitution above, if a, b, c are the side lengths of a triangle, the inequality of Example 5.4.3 above gives[14]

$$\sqrt{a+b-c}+\sqrt{b+c-a}+\sqrt{c+a-b} \leq \sqrt{a}+\sqrt{b}+\sqrt{c}.$$

Example 5.4.4 Show that, for $0 \leq x_1, \dots, x_n \in \mathbb{R}$, $2 \leq n \in \mathbb{N}$, we have

$$\sum_{1 \leq i < j \leq n} x_i x_j \cdot \sum_{k=1}^{n} x_k^2 \leq \frac{1}{8} \left(\sum_{k=1}^{n} x_k \right)^4 .$$

Indeed, using the AM-GM inequality as in Example 5.4.1, we calculate

$$\begin{aligned} \left(\sum_{k=1}^{n} x_k \right)^4 &= \left(\sum_{k=1}^{n} x_k^2 + 2 \sum_{1 \leq i < j \leq n} x_i x_j \right)^2 \\ &\geq 4 \left(\sum_{k=1}^{n} x_k^2 \right) \left(2 \sum_{1 \leq i < j \leq n} x_i x_j \right) = 8 \sum_{1 \leq i < j \leq n} x_i x_j \cdot \sum_{k=1}^{n} x_k^2 \end{aligned}$$

The inequality now follows.

We complete this cadre of examples by one that shows how the AM-GM inequality can sometimes be used to solve a system of non-linear equations.

Example 5.4.5 Solve the following system of equations for $x, y, z \in \mathbb{R}$:

$$x + y = 2, \quad xy - z^2 = 1.$$

First, $xy = 1 + z^2 \geq 1$, so that, by the first equality, we obviously have $x, y > 0$. Now, the AM-GM inequality gives $2 = x + y \geq 2\sqrt{xy}$. Hence $xy \leq 1$. Combining this with the previous inequality, we obtain $xy = 1$, and consequently $x = y = 1$. Finally, the second equality gives $z = 0$.

We finish this section by another application of the AM-GM inequality: The **Babylonian Method** on how to approximate the square root of a natural number $a \in \mathbb{N}$ by rational numbers.

We assume that $a \in \mathbb{N}$ is not a perfect square. We let $0 < q_0 \in \mathbb{Q}$ and define the sequence $(q_n)_{n \in \mathbb{N}_0}$ inductively by

$$q_{n+1} = \frac{1}{2} \left(q_n + \frac{a}{q_n} \right), \quad n \geq 0.$$

---

[14] This was a problem in the Asian Pacific Mathematical Competition, 1996.

Remark We will give a geometric interpretation of this formula in Section 8.2. This can be substantially generalized to what is known as **Newton's Method**, and it goes far beyond our rational approximations of the square root of a natural number. This particular case was also known to the ancient Babylonians, and this is why it carries the name "Babylonian Method."

Clearly, $(q_n)_{n \in \mathbb{N}_0}$ is a sequence of rational numbers. We claim that it is decreasing from the **first** term q_1 onward, and $\lim_{n\to\infty} q_n = \sqrt{a}$.

By our initial choice, we have $q_0 > 0$. Assuming $q_n > 0$, $n \in \mathbb{N}_0$, a quick look at the inductive formula above gives $q_{n+1} > 0$. It now follows from Peano's Principle of Induction that $q_n > 0$ for all $n \in \mathbb{N}_0$.
We can actually say more. The AM-GM inequality gives

$$0 < a = q_n \cdot \frac{a}{q_n} < \frac{1}{4}\left(q_n + \frac{a}{q_n}\right)^2 = q_{n+1}^2.$$

Note the sharp inequality in the middle as $q_n \neq a/q_n$ (since otherwise we would have $q_n^2 = a$, and a would be a perfect square). We thus obtain $q_{n+1}^2 > a$ for all $n \in \mathbb{N}_0$.

Rearranging this last inequality, we have

$$q_{n+1} > \frac{1}{2}\left(q_{n+1} + \frac{a}{q_{n+1}}\right) = q_{n+2}, \quad n \in \mathbb{N}_0.$$

We see that the sequence $(q_n)_{n\in\mathbb{N}}$ is strictly decreasing and bounded from below. By (Cauchy) completeness of $\mathbb{R}$, we have $\lim_{n\to\infty} q_n = r \in \mathbb{R}$, and, in addition, we also have $r^2 \geq a$. Letting $n \to \infty$ in the inductive definition of the sequence $(q_n)_{n\in\mathbb{N}}$ above, we obtain

$$r = \frac{1}{2}\left(r + \frac{a}{r}\right).$$

Rearranging, we obtain $r^2 = a$. This finally gives[15] $r = \sqrt{a}$.

To find the rate of convergence, we introduce the **relative error**

$$\delta_n = \frac{q_n}{\sqrt{a}} - 1 > -1, \quad n \in \mathbb{N}_0.$$

Clearly, $\delta_n \neq 0$ since $\sqrt{a}$ is irrational. We rewrite this as $q_n = \sqrt{a}(\delta_n + 1)$, $n \in \mathbb{N}_0$. We now claim that the following inductive relation holds for the relative error:

$$\delta_{n+1} = \frac{\delta_n^2}{2(\delta_n + 1)}, \quad n \in \mathbb{N}_0.$$

---

[15] Note that this can also serve as a definition of $\sqrt{a}$ as the equivalence class of the rational Cauchy sequence $(q_n)_{n\in\mathbb{N}}$.

Note that this implies $\delta_n > 0$ for $n \in \mathbb{N}$. (The initial δ_0 may be negative.) We now calculate

$$\delta_{n+1} = \frac{q_{n+1}}{\sqrt{a}} - 1 = \frac{q_n + a/q_n}{2\sqrt{a}} - 1 = \frac{q_n^2 + a}{2\sqrt{a}q_n} - 1$$
$$= \frac{a(1+\delta_n)^2 + a}{2\sqrt{a}\sqrt{a}(1+\delta_n^2)} - 1 = \frac{(1+\delta_n)^2 + 1}{2(\delta_n + 1)} - 1 = \frac{\delta_n^2}{2(\delta_n + 1)}.$$

The inductive formula for the relative error above follows.

Since $\delta_n > 0$ for $n \in \mathbb{N}$, this implies

$$\delta_{n+1} = \frac{\delta_n}{\delta_n + 1} \cdot \frac{\delta_n}{2} \leq \frac{\delta_n}{2} \quad \text{and} \quad \delta_{n+1} = \frac{1}{\delta_n + 1} \cdot \frac{\delta_n^2}{2} \leq \frac{\delta_n^2}{2}.$$

(The first estimate is better than the second for $\delta_n > 1$, which may happen for some initial values of the indices $n \in \mathbb{N}$.) Putting these together, we obtain

$$0 < \delta_{n+1} \leq \min\left(\frac{\delta_n}{2}, \frac{\delta_n^2}{2}\right), \quad n \in \mathbb{N}.$$

The first estimate implies $\delta_2 \leq \delta_1/2$ ($n = 1$), $\delta_3 \leq \delta_2/2 \leq \delta_1/2^2$ ($n = 2$), $\delta_4 \leq \delta_3/2 \leq \delta_1/2^3$ ($n = 3$), etc. In general, we have $0 < \delta_{n+1} \leq \delta_1/2^n$, $n \in \mathbb{N}$. In particular, we obtain $\lim_{n\to\infty} \delta_n = 0$. The Babylonian approximation method is established.

The following table depicts the first 5 iterates of the Babylonian Method for $\sqrt{2}$ starting with $q_0 = 1$:

n	q_n	δ_n
0	1	$-2.92893218 \cdot 10^{-1}$
1	$\frac{3}{2} = 1.5$	$6.06601778 \cdot 10^{-2}$
2	$\frac{17}{12} = 1.41\overline{6}\ldots$	$1.73460668 \cdot 10^{-3}$
3	$\frac{577}{408} = 1.414\overline{2156862745098039}\ldots$	$1.50182509 \cdot 10^{-6}$
4	$\frac{665857}{470832} \approx 1.41421356237468991062629{6}$	$1.12773761 \cdot 10^{-12}$
5	$\frac{886731088897}{627013566048} \approx 1.414213562373095048802$	$6.35896059 \cdot 10^{-25}$

Exercise

5.4.1. A triangle with side lengths that form three consecutive terms in a geometric sequence exists if and only if the ratio q of the geometric sequence satisfies $1/\tau < q < \tau$, where τ is the golden number.

5.5 Lines and Circles

We now return to our Cartesian distance d and study its invariance properties under some transformations (self-maps) of the plane $\mathbb{R}^2$.

For $W \in \mathbb{R}^2$, we define the **translation** by W as the map $T_W : \mathbb{R}^2 \to \mathbb{R}^2$ given by $T_W(P) = P + W$, $P \in \mathbb{R}^2$. In coordinates, if $W = (u, v) \in \mathbb{R}^2$, then we have

$$T_W(P) = P + W = (x + u, y + v), \quad P = (x, y) \in \mathbb{R}^2.$$

The Cartesian distance d is invariant (unchanged) under translations; that is, for $W \in \mathbb{R}^2$, we have

$$d(T_W(P_0), T_W(P_1)) = d(P_0, P_1), \quad P_0, P_1 \in \mathbb{R}^2.$$

Indeed, this is obvious since, in the definition of the Cartesian distance, we take differences of the respective coordinates of P_0 and P_1, and thus the coordinates u and v of W cancel.

Another type of transformation of the plane $\mathbb{R}^2$ that we will utilize is the (positive) **quarter-turn**. We define the (positive) quarter-turn $S_0 : \mathbb{R}^2 \to \mathbb{R}^2$ about the origin by $S_0(P) = S_0(x, y) = (-y, x)$, $P = (x, y) \in \mathbb{R}^2$. Its square $S_0^2 = S_0 \circ S_0 : \mathbb{R}^2 \to \mathbb{R}^2$ (by composition) is the negative of the identity $-\mathrm{id}_{\mathbb{R}^2}$, the **half-turn** about the origin, given by $S_0^2(x, y) = (-x, -y)$, $P = (x, y) \in \mathbb{R}^2$. The (positive) quarter-turn about any point $O \in \mathbb{R}^2$ is defined by the composition $S_O = T_O \circ S_0 \circ T_{-O}$. Once again, the square S_O^2 is the half-turn about the point O. We call O the **center** of S_O.

Once again, it follows easily that the Cartesian distance d is invariant under a quarter-turn about any center.

These transformations are **affine** in the sense that they map lines to lines preserving the respective affine coordinate functions. (This follows immediately from the strict triangle inequality or by direct computation.) In particular, for $P_0, P_1 \in \mathbb{R}^2$, we have $T_W([P_0, P_1]) = [T_W(P_0), T_W(P_1)]$, $W \in \mathbb{R}^2$, and $S_O([P_0, P_1]) = [S_O(P_0), S_O(P_1)]$, $O \in \mathbb{R}^2$. In addition, these transformations preserve the relation being parallel, that is, they send pencils of parallel lines to pencils of parallel lines.

A translation sends a line to a **parallel** line. Indeed, if a line ℓ is given by the equation $ax - by = c$, $a^2 + b^2 > 0$, then a translation T_W with $W = (u, v) \in \mathbb{R}^2$ sends ℓ into a line with equation $a(x - u) - b(y - v) = c$, that is, $ax - by = c + au - bv$.

A half-turn sends a line to a **parallel** line. Indeed, since translations do the same (by the above), it is enough to show this for the half-turn about the origin, the negative of the identity map. Now, if a line ℓ is given by the equation $ax - by = c$, $a^2 + b^2 > 0$, then the half-turn about the origin sends ℓ to the line with equation $-ax + by = c$, that is, $ax - by = -c$.

Finally note that these transformations preserve ω, and therefore they are **orientation preserving** in the sense that if (P_0, P_1, P_2) is a positively oriented triple, then so are the corresponding transformed triples.

Remark The adjective "positive" for the quarter-turn S_O about a point $O \in \mathbb{R}^2$ is due to the fact that, for any $P \in \mathbb{R}^2$, $P \neq O$, the triple $(O, P, S_O(P))$ is **positively** oriented. Indeed, since translations are orientation preserving, it is enough to show this for the quarter-turn about the origin. Now, if $P = (x, y)$, $x^2 + y^2 > 0$, then we have $\omega((0, 0), (x, y), (-y, x)) = x^2 + y^2 > 0$.

We say that two lines are **perpendicular** if one is obtained from the other by a quarter-turn. As simple computation shows, if a line ℓ is given by the equation $ax - by = c$, $a^2 + b^2 > 0$, then, for $O = (u, v) \in \mathbb{R}^2$, the transformed perpendicular line $S_O(\ell)$ is given by the equation $bx + ay = c + a(v - u) + b(v + u)$.

On the other hand, as noted above, a pencil of parallel lines is given by the equation $ax - by = c$, where the constant $c \in \mathbb{R}$ varies over all real numbers. It follows that the relation of being perpendicular depends only on the pencils of parallel lines that each of the two perpendicular lines is participating in. In other words, if two lines are perpendicular, then so are any two lines in the respective pencils of parallel lines.

Since every pencil of parallel lines contains a unique representative through the origin, and $S_0^2 = -\,\mathrm{id}$, it also follows that the relation being perpendicular is symmetric.

Finally, if two lines ℓ and ℓ' are intersected by another line perpendicular to both, then ℓ and ℓ' are parallel.

Example 5.5.1 (Perpendicular Bisector) Determine the set of points that are **equidistant** from two given distinct points P_0 and P_1 on the plane $\mathbb{R}^2$.

I. Algebraic Solution. Let $P_0 = (x_0, y_0)$ and $P_1 = (x_1, y_1)$, $P_0 \neq P_1$. A variable point $P = (x, y)$ is equidistant from P_0 and P_1 if and only if $d(P, P_0) = d(P, P_1)$. Using the distance formula, after squaring, we calculate

$$\begin{aligned}
(x - x_0)^2 + (y - y_0)^2 &= (x - x_1)^2 + (y - y_1)^2 \\
2(x_0 - x_1)x + 2(y_0 - y_1)y &= x_0^2 - x_1^2 + y_0^2 - y_1^2 \\
2(x_0 - x_1)x + 2(y_0 - y_1)y &= (x_0 - x_1)(x_0 + x_1) + (y_0 - y_1)(y_0 + y_1).
\end{aligned}$$

A final rearrangement and grouping the multiples of $(x_0 - x_1)$ and $(y_0 - y_1)$ give the symmetric form

$$(x_1 - x_0)\left(x - \frac{x_0 + x_1}{2}\right) + (y_1 - y_0)\left(y - \frac{y_0 + y_1}{2}\right) = 0.$$

First, this equation is linear (since $(x_0 - x_1)^2 + (y_0 - y_1)^2 > 0$), and hence it must represent a line. Second, it is also clear (by substituting $x = (x_0 + x_1)/2$ and $y = (y_0 + y_1)/2$) that this line contains the **midpoint** M of the line segment $[P_0, P_1]$ (Example 5.3.2) since

$$M = \left(\frac{x_0 + x_1}{2}, \frac{y_0 + y_1}{2} \right).$$

Finally, as shown above, an equation of the line containing the points $P_0 = (x_0, y_0)$ and $P_1 = (x_1, y_1)$ is given by

$$(y_1 - y_0)x - (x_1 - x_0)y = x_0 y_1 - x_1 y_0.$$

Comparing the equations of these lines, we see that they are perpendicular.

We conclude that the set of points equidistant from two distinct points P_0 and P_1 is the **perpendicular bisector** of the line segment $[P_0, P_1]$ that contains their **midpoint** M. As a byproduct, we also recover the **midpoint formula** for M above (Example 5.3.2 again).

II. Geometric Solution After Euclid.[16] Let P be a point such that $d(P, P_0) = d(P, P_1)$. Then the triangle $\triangle[P, P_0, P_1]$ is isosceles. Thus, by the Theorem on Isosceles Triangles in Euclid's *Elements* (Book I, Proposition 5), the angles at P_0 and P_1 are congruent. Consider the midpoint M of the line segment $[P_0, P_1]$. Then the sub-triangles $\triangle[P, P_0, M]$ and $\triangle[P, P_1, M]$ are congruent.[17] Thus, these sub-triangles must have right angle at M. We obtain that P is on the perpendicular bisector of the line segment $[P_0, P_1]$.

History

In the discussion above we used the **Theorem on Isosceles Triangles**: The angles opposite to the equal sides of an isosceles triangle are equal. It is also called the **pons asinorum**, "bridge of donkeys" in Latin. It is either a somewhat derogatory phrase pointing to and challenging the reader to tackle this first non-trivial proposition in the *Elements* and pass this bridge to get to harder ones, or the isosceles triangle depicts an actual pointed bridge that only a brave and sure-footed donkey can pass.

We now introduce another fundamental concept of Greek geometry, the concept of a circle. Given a point $O \in \mathbb{R}^2$ and a positive real number $0 < r \in \mathbb{R}$, we define the **circle** of radius r and center at O as the set[18]

$$\mathbb{S}_{O,r} = \{P \in \mathbb{R}^2 \mid d(P, O) = r\}.$$

Letting $O = (u, v)$ and $P = (x, y)$, the Cartesian distance formula gives the equation of the circle $\mathbb{S}_{O,r}$ as

$$(x - u)^2 + (y - v)^2 = r^2,$$

---

[16] This geometric solution can be reworded to become a simple consequence of Birkhoff's Postulates of Angle Measure and Similarity. The validity of these postulates in our model will be proved in Section 5.7. Hence, for a change, we give here a proof based on Euclid's *Elements*.

[17] Warning: Congruence of the triangles $\triangle[P, P_0, M]$ and $\triangle[P, P_1, M]$ also follows from the observation that the lengths of the three pairs of sides of these triangles are equal, but in the *Elements*, this occurs after Proposition 5 of Book I.

[18] Compare this with primitive #15 in the *Elements* as stated at the beginning of this chapter.

where we squared both sides to eliminate the square root. If the center of the circle is the origin 0, then we write $\mathbb{S}_r = \mathbb{S}_{0,r}$. Similarly, if the circle has a unit radius ($r = 1$), then we write $\mathbb{S}_O = \mathbb{S}_{O,1}$. Finally, $\mathbb{S}$ denotes the unit radius circle with center at the origin.

As a simple application of the perpendicular bisector and the concept of a circle, consider three distinct points $A, B, C \in \mathbb{R}^2$ on the plane. We ask the following question: Is there any point on the plane which is equidistant from all these three points?

If A, B, C are **collinear**, then the answer is no. Indeed, the set of points equidistant from A and B is the perpendicular bisector of the line segment $[A, B]$, and the set of points equidistant from B and C is the perpendicular bisector of $[B, C]$. These bisectors are distinct and perpendicular to the line that passes through A, B, C. Thus, they are parallel and have no common intersection.

Assume now that A, B, C are **not collinear**. Consider the perpendicular bisectors ℓ_a, ℓ_b, ℓ_c of the line segments $[B, C], [C, A], [A, B]$. By the previous step, each pair of bisectors intersects in a point. We claim that these (three) points are the same. Indeed if O is the common intersection of ℓ_a and ℓ_b, then $d(O, B) = d(O, C)$ and $d(O, C) = d(O, A)$. Therefore, $d(O, A) = d(O, B)$ so that O is equidistant from A and B, and hence it is on the bisector ℓ_c. We obtain that if A, B, C are not collinear, then there is a **unique** point equidistant from all these three points.

This conclusion can be put into a familiar framework if we consider the points A, B, C, the vertices of the triangle $\triangle[A, B, C]$. Since $d(O, A) = d(O, B) = d(O, C) = R$, say, we see that the circle with center O and radius R contains the points A, B, C. This is the unique circle **circumscribed** about the triangle. We call this the **circumcircle** and its radius the **circumradius** R of the triangle.

We now return to the main line and study the possible configurations of a circle and a line. We claim that there are three possibilities; namely, the circle and the line may be disjoint, meet at one point, or meet at two points. When a circle meets a line at exactly one point, we say that the line is **tangent** to the circle. A line is **secant** to a circle if they intersect at exactly two points.[19]

Discarding the case when the circle and the line are disjoint, we assume that the circle $\mathbb{S}_{O,r}$ and the line ℓ intersect at least in one point $P_0 \in \mathbb{S}_{O,r} \cap \ell$. For simplicity, we translate the entire configuration such that the center of the circle is at the origin. The equation of the circle $\mathbb{S}_r$ above reduces to

$$x^2 + y^2 = r^2.$$

We let $P_0 = (x_0, y_0)$, so that $x_0^2 + y_0^2 = r^2$. As usual, we write the equation of the line ℓ through P_0 as

$$ax - by = ax_0 - by_0, \quad a^2 + b^2 > 0.$$

---

[19] The words "tangent" and "secant" are derived from "tangere" and "secare," respectively, which in Latin mean "to touch" and "to cut."

After simplification and factoring, we obtain that any intersection point $P = (x, y) \in \mathbb{S}_r \cap \ell$ satisfies the system of equations

$$(x - x_0)(x + x_0) + (y - y_0)(y + y_0) = 0$$
$$a(x - x_0) = b(y - y_0).$$

Assuming $P \neq P_0$, that is, discarding the solution $x = x_0$ and $y = y_0$, we obtain $b(x + x_0) + a(y + y_0) = 0$. A simple computation now gives

$$x = x_0 - 2b\frac{bx_0 + ay_0}{a^2 + b^2} \quad \text{and} \quad y = y_0 - 2a\frac{bx_0 + ay_0}{a^2 + b^2}.$$

This is a solution different from $x = x_0$ and $y = y_0$ (which has been discarded) if and only if $bx_0 + ay_0 \neq 0$.

Turning the question around, we see that the circle $\mathbb{S}_r$ and the line ℓ have a **unique** intersection point $P_0 = (x_0, y_0)$ if and only if $bx_0 + ay_0 = 0$. By the discussion at the beginning of this section, $bx + ay = 0$ is an equation of a line **perpendicular** to the tangent line ℓ, and the latter has the equation $ax - by = ax_0 - by_0$.

As a final note, we claim that the entire tangent line ℓ with the exception of the point of tangency P_0 lies in the **exterior** of the circle $\mathbb{S}_r$.

Indeed, letting $P_t = (x_0 + tb, y_0 + at)$, $t \in \mathbb{R}$, the equation of the tangent line ℓ in the form $a(x - x_0) = b(y - y_0)$ above clearly shows that $\ell = \{P_t \mid t \in \mathbb{R}\}$. We now calculate the distance as

$$\begin{aligned} d(P_t, P_t)^2 &= (x_0 + tb)^2 + (y_0 + ta)^2 = x_0^2 + y_0^2 + 2t(bx_0 + ay_0) + t^2(a^2 + b^2) \\ &= r^2 + t^2(a^2 + b^2) \geq r^2 \end{aligned}$$

with equality if and only if $t = 0$, that is, at the point of tangency P_0. The claim follows.

Summarizing, we obtain that through any point P_0 of a circle $\mathbb{S}_{O,r}$ (with center O), there is a unique line ℓ that is **tangent** to $\mathbb{S}_{O,r}$, and it is characterized by the property that it is perpendicular to the radial line containing P_0 and the center O of the circle. Any other line through P_0 is a secant to $\mathbb{S}_{O,r}$, that is, it intersects the circle in two distinct points. Finally, the entire tangent line lies in the exterior of the circle $\mathbb{S}_{O,r}$, except the point of tangency P_0.

History

The ancient Greek mathematicians elevated the study of geometric configurations to the discipline of **Geometry**. These include lines, polygons, circles, parabolas, ellipses, hyperbolas, their metric properties and mutual relationships, such as tangents, secants, intersections, etc. As noted previously, the ancient Greeks also created **Geometric Algebra**, which associated algebraic terms with geometric objects, such as length, perimeter, area, etc. **Algebra** as a discipline separate from Geometry (and Arithmetic) was established by Muhammad ibn Mūsā al-Khwārizmī. To a large extent it was an early theory of equations that studied solutions of linear and quadratic equations. This theory had different developments by Diophantus of Alexandria and the Indian mathematician Brahmagupta. Throughout the Middle Ages Arabic scholars raised this discipline to new heights. The modern symbolic representation of variables and constants, introduced by the French mathematician François Viète (Latin Vieta) (1540–1603) and subsequently brought to perfection by Descartes, put algebra on a solid foundation. But it was the introduction and systematic use of coordinate systems that revolutionized mathematics by establishing a bridge between geometry and algebra.

As an application, we introduce the concept of **distance of a point from a line**. Let O be a point and ℓ a line. By definition, the distance of O from ℓ is

$$d(O, \ell) = \inf\{d(O, P) \mid P \in \ell\}.$$

If $O \in \ell$, then $d(O, \ell) = 0$. We may therefore assume that $O \notin \ell$.

We claim that there is a unique circle with center at O and with ℓ as a tangent line to the circle.

Indeed, by what we proved above, this circle is obtained by taking the line ℓ' through O perpendicular to ℓ, and the radius of the circle is the distance of the intersection point $P_0 = \ell \cap \ell'$ from the center O.

Since ℓ is tangent to the circle, all the points on ℓ except P_0 are in the exterior of the circle. Thus, the radius of the circle realizes the infimum above, and therefore it is the distance $d(O, \ell)$.

To obtain an explicit formula, let ℓ be given by the equation $ax - by = c$, $a^2 + b^2 > 0$, and let $O = (u, v) \in \mathbb{R}^2$. The equation of ℓ' through O and perpendicular to ℓ is given by $bx + ay = bu + av$. Putting these two equations together, a short computation gives the intersection point $P_0 = \ell \cap \ell'$ as

$$P_0 = \left(\frac{b(bu + av) + ac}{a^2 + b^2}, \frac{a(bu + av) - bc}{a^2 + b^2} \right).$$

By a short computation, we arrive at the distance of P_0 from $O = (u, v)$ as

$$d(O, \ell) = \frac{|au - bv - c|}{\sqrt{a^2 + b^2}}.$$

Example 5.5.2 (Angular Bisector) Determine the set of points that are **equidistant** from two given distinct lines ℓ_0 and ℓ_1 on the plane $\mathbb{R}^2$.

If ℓ_0 and ℓ_1 are parallel, then the set of points equidistant from both lines is the parallel line midway between ℓ_0 and ℓ_1.

Assume now that ℓ_0 and ℓ_1 intersect in a point C. The intersecting lines ℓ_0 and ℓ_1 split the plane into four angular sectors. Let P be a point such that $d(P, \ell_0) = d(P, \ell_1)$. We may assume that $P \neq C$ (since C is clearly equidistant from both lines with zero distance) and also that P is not on any of these two lines. Thus, P is contained in one of the open angular sectors. Let $P_0 \in \ell_0$ and $P_1 \in \ell_1$ be such that $d(P, P_0) = d(P, \ell_0) = d(P, \ell_1) = d(P, P_1)$. The two **right** triangles $\triangle[P, P_0, C]$ and $\triangle[P, P_1, C]$ are congruent since they have two equal sides, and they also have a

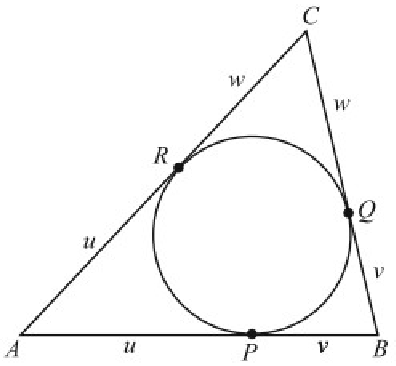

Fig. 5.1 The incircle of a triangle.

common side.[20] Thus their angles at C are equal. We obtain that P is on the bisector of the angular sector that contains P. We conclude that the set of points equidistant from two intersecting lines is the pair of perpendicular angular bisectors.

As an application, consider three lines ℓ_0, ℓ_1, and ℓ_2 that are the extensions of the sides of a (non-degenerate) triangle $\triangle[P_0, P_1, P_2]$. This triangle is the intersection of three angular sectors, one from each vertex (see Figure 5.1). The bisectors corresponding to each angular sector intersect in a point C. This is the unique point equidistant from all the three lines. We obtain that C is the center of the unique **inscribed** circle touching each line at the points where the distance of C and the lines are realized. We call this the **incircle** and its radius the **inradius** of the triangle.

Remark If $\triangle[A, B, C]$ is a (non-degenerate) triangle, then its incircle touches each side of the triangle at a specific point, $P \in [A, B]$, $Q \in [B, C]$, $R \in [C, A]$, say. Clearly, we have $d(A, P) = d(A, R)$, $d(B, P) = d(B, Q)$, and $d(C, Q) = d(C, R)$. Denoting these distances by u, v, and w, we obtain the substitution

$$a = v + w, \quad b = w + u, \quad c = u + v.$$

This gives the geometric interpretation of the substitution at the beginning of the previous section.

We now turn to study **secant** lines. Let $P_0, P_1 \in \mathbb{S}_{O,r}$ be two distinct points on the circle. Once again we translate the entire configuration so that the center of the circle $\mathbb{S}_r$ is at the origin, and thereby it has the equation $x^2 + y^2 = r^2$. By the strict triangle inequality, we have $d(P_0, P_1) \leq d(0, P_0) + d(0, P_1) = 2r$ with equality if and only if $0 \in [P_0, P_1]$.

---

[20] In this example we assume Birkhoff's Postulates of Angle Measure and Similarity and, consequently, the Pythagorean Theorem, whose validity, in our model, will be proved in Section 5.7. This is pedagogically justified since this example is a perfect fit for our present line of argument. Alternatively, one can also refer here to Euclid's *Elements*.

Letting $P_0 = (x_0, y_0)$, $x_0^2 + y_0^2 = r^2$, and $P_1 = (x_1, y_1)$, $x_1^2 + y_1^2 = r^2$, we calculate

$$\begin{aligned} d(P_0, P_1)^2 = (x_0 - x_1)^2 + (y_0 - y_1)^2 &= x_0^2 + y_0^2 + x_1^2 + y_1^2 - 2x_0x_1 - 2y_0y_1 \\ &= 2r^2 - 2(x_0x_1 + y_0y_1). \end{aligned}$$

Now recall the affine coordinate function that parametrizes the line through P_0 and P_1 under which the point $P_t = (1-t)P_0 + tP_1$ corresponds to the parameter $t \in \mathbb{R}$.

Using the result of the previous computation, we have

$$\begin{aligned} d(0, P_t)^2 &= ((1-t)x_0 + tx_1)^2 + ((1-t)y_0 + ty_1)^2 \\ &= (1-t)^2r^2 + t^2r^2 + 2t(1-t)(x_0x_1 - y_0y_1) \\ &= (1-t)^2r^2 + t^2r^2 + t(1-t)(2r^2 - d(P_0, P_1)^2) \\ &= r^2 - t(1-t)d(P_0, P_1)^2. \end{aligned}$$

In particular, we see that, for $t \in [0, 1]$, we have $d(0, P_t) \leq r$ with equality if and only if $t = 0, 1$.

Summarizing, given two distinct points P_0 and P_1 on a circle $\mathbb{S}_{O,r}$, for $t \in [0, 1]$, we have $d(P_t, O) \leq r$ (with equality if and only if $t = 0, 1$), that is, the line segment $[P_0, P_1]$ is contained in the interior of the circle $\mathbb{S}_{O,r}$. Similarly, for $t \notin [0, 1]$, we have $d(P_t, O) > r$.

Exercises

5.5.1. Calculate the length of the hypotenuse of the right triangle $\triangle[A, B, C]$ with right angle at C, where $d(A, C) = d(A, M) = 1$ and M is the midpoint of the hypotenuse $[A, B]$.

5.5.2. Use the pons asinorum to prove **Thales' Theorem**: If A, B, C are distinct points on a circle $\mathbb{S}_{O,r}$ and $O \in [A, B]$ (that is, $[A, B]$ is a diameter), then $\angle ACB$ is a right angle. Generalize this to the case when $[A, B]$ is a chord of the circle, $O \notin [A, B]$; the **Central Angle Theorem**: If C is on the longer circular arc of $\mathbb{S}_{O,r}$ with end-points A, B, then $\mu(\angle AOB) = 2\mu(\angle ACB)$; and if C is on the shorter circular arc of $\mathbb{S}_{O,r}$ with end-points A, B, then $\mu(\angle AOB) = 2(\pi - \mu(\angle BCA))$.

5.5.3. The **power** $\mathfrak{p}_S(P)$ of a point $P \in \mathbb{R}^2$ with respect to a circle $S = \mathbb{S}_{O,r}$ is defined as $\mathfrak{p}_S(P) = d(P, O)^2 - r^2$. (Note that the power is zero for points on the circle, negative for points inside the circle, and positive for points outside the circle.) (a) Prove the **Intersecting Chords Theorem**: Let P be outside S. Show that any line through P that meets S in the points $A, B \in S$;

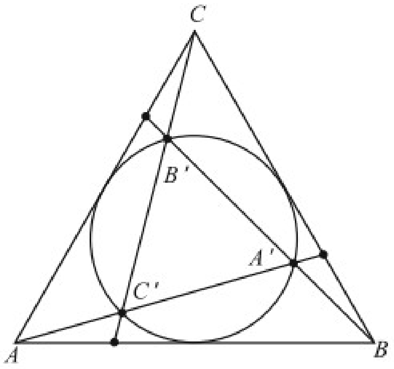

Fig. 5.2 An occurrence of the golden number τ.

we have $\mathfrak{p}_S(P) = d(P, A) \cdot d(P, B)$. (Note that, for a line tangent to S, the point of tangency is $A = B$ so that we have $\mathfrak{p}_S(P) = d(P, A)^2$, and the circle with center at P and radius $d(P, A)$ is orthogonal to S.) (b) Extend (a) to the case when P is inside S. (c) Let $S_1 = \mathbb{S}_{O_1,r_1}$ and $S_2 = \mathbb{S}_{O_2,r_2}$ be two disjoint circles. Show that the set of points in $P \in \mathbb{R}^2$ that have the same power with respect to S_1 and S_2 is a line, the so-called **radical line**. (d) Generalize the radical line to the case of intersecting circles or two circles with one inside the other. (e) Prove **Monge's Theorem**: Given three disjoint circles (with non-parallel radical axes), there is a circle orthogonal to all three.

5.5.4. Let $\triangle[A, B, C]$ be an equilateral triangle and S the incircle. Let $\triangle[A', B', C']$ be an equilateral triangle inscribed in S, that is, $A', B', C' \in S$, such that the line extensions of the sides of this triangle pass through the vertices of $\triangle[A, B, C]$; that is, $A' \in [B, B']$, $B' \in [C, C']$, $C' \in [A, A']$. Show that the ratio $d(A', C')/d(A, C')$ is the golden number τ (see Figure 5.2).

5.5.5. Given a line segment $[A, B]$ on the plane $\mathbb{R}^2$, determine the set of points $C \in \mathbb{R}^2$ such that the non-degenerate triangle $\triangle[A, B, C]$ has obtuse angle at C.

5.5.6. Let A and B be two points on the plane unit distance apart, and $0 < q < 1$, $q \in \mathbb{R}$. Show that the set $\{P \in \mathbb{R}^2 \mid d(P, A) = q \cdot d(P, B)\}$ is a circle, and determine its center and radius (in terms of q).

5.5.7. In a triangle $\triangle[A, B, C]$, let the angular bisector of the (interior) angle at the vertex A intersect the opposite side at the point $D \in [B, C]$. Prove the **Angle Bisector Theorem** $d(A, B)/d(A, C) = d(B, D)/d(C, D)$.

5.5.8. Consider two parallel chords of a circle S with lengths a and b which are d distance apart.[21] Let a third parallel chord of length c be in the midway of the first two. Express c in terms of a, b, d.

---

[21] Generalization of a problem in the American High School Mathematics Examination, 1995.

5.5.9. Three circles of common radius $0 < r \in \mathbb{R}$ are mutually and externally tangent. (a) If they are also internally tangent to a larger circle of radius $0 < R \in \mathbb{R}$, then find R/r. (b) Find the perimeter of the triangle whose sides are tangent to each pair of the three circles.

5.5.10. The vertices of a square of side length 2 are the centers of four circles of radius 1. Find the radius of the smaller circle externally tangent to these four circles whose center is the center of the square.

5.5.11. Two tangents are drawn from a point A to a circle of radius $0 < r \in \mathbb{R}$ and center O. Another tangent to the circle meets the two tangent lines at points B and C such that the triangle $\triangle[A, B, C]$ is disjoint from the circle. Find the perimeter of the triangle in terms of $d(A, O)$ and r.

5.5.12. A circle touches all four sides of an isosceles trapezoid. Find the radius r of the circle in terms of the parallel side lengths (bases) a and c of the trapezoid.

5.6 Arc Length on the Unit Circle

In this section we make a detailed and rigorous study of the **arc length** of circular arcs of a **unit** radius circle $\mathbb{S}_O$ with center $O \in \mathbb{R}^2$. The material presented here is technically demanding, and the readers who have only marginal interest in axiomatic developments may skip it. The results of this section will only be used for the establishment of the Birkhoff angle measure in the next section and for the proof of the Law of Cosines in trigonometry discussed in the last chapter of this book.

Let $P_0, P_1 \in \mathbb{S}_O$ be distinct points. The secant line through P_0 and P_1 divides the circle $\mathbb{S}_O$ into two **circular arcs** with end-points P_0 and P_1. These two circular arcs can be obtained from the equation of the line through the points $P_0 = (x_0, y_0)$ and $P_1 = (x_1, y_1)$ by intersecting the circle $\mathbb{S}_O$ with the two half-planes

$$(y_1 - y_0)x - (x_1 - x_0)y \gtreqless x_0 y_1 - x_1 y_0$$

defined by the equation of the (common boundary) line.

If $d(P_0, P_1) = 2$, then, by the strict triangle inequality, $O \in [P_0, P_1]$, and the two circular arcs are called **semi-circles**.[22] They are congruent via the half-turn about the center O. A line through O and perpendicular to the line extension of $[P_0, P_1]$ splits these two semi-circles into four **quarter-circles**. These quarter-circles are permuted (cyclically) by the quarter-turn S_O.

Assume now that $d(P_0, P_1) < 2$ so that, by the strict triangle inequality, $O \notin [P_0, P_1]$. Unless stated otherwise, we will always denote by $\mathcal{C} \subset \mathbb{S}_O$ the circular arc,[23] which is in the opposite side of the line extension of $[P_0, P_1]$ to the center O.

---

[22] Compare this with definition #18 in the *Elements* at the beginning of this chapter.

[23] As we will see below, $\mathcal{C}$ is the **shorter** (arc length) circular arc with end-points P_0 and P_1.

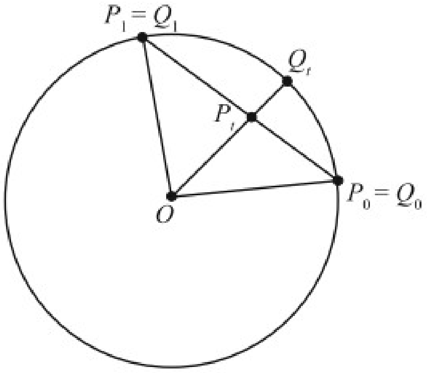

Fig. 5.3 Parametrization of a circular arc.

The other circular arc[24] will be denoted by $\mathcal{C}^c$ and will be called the **complement** of $\mathcal{C}$. For uniformity, for $d(P_0, P_1) = 2$, $\mathcal{C}$ (and $\mathcal{C}^c$) will denote either of the semicircles with end-points P_0 and P_1.

Once again, recall the affine coordinate function that parametrizes the line through P_0 and P_1 under which the point $P_t = (1-t)P_0 + tP_1$ corresponds to the parameter $t \in \mathbb{R}$.

By the computations at the end of the previous section, we have

$$d(O, P_t)^2 = 1 - t(1-t)d(P_0, P_1)^2.$$

For $t \in [0, 1]$, we define[25]

$$Q_t = \frac{1}{d(O, P_t)} P_t + \left(1 - \frac{1}{d(O, P_t)}\right) O, \quad Q_0 = P_0, \ Q_1 = P_1.$$

Clearly, we have $d(O, Q_t) = d(O, P_t)/d(O, P_t) = 1$, or equivalently, $Q_t \in \mathbb{S}_O$, $t \in [0, 1]$ (see Figure 5.3). By the first formula defining the half-planes above, we see that the points Q_t, $t \in [0, 1]$, are in the half-plane that does not contain the point O. This gives

$$\mathcal{C} = \{Q_t \,|\, 0 \leq t \leq 1\}.$$

(If $Q \in \mathcal{C}$, then $[O, Q]$ and $[P_0, P_1]$ must intersect in a point P_t, $t \in [0, 1]$, say, so that $Q = Q_t$ holds.)

With this preparation, we now define the arc length of $\mathcal{C}$.

A **partition** of the interval $[0, 1]$ is a finite strictly increasing sequence:

$$(t_0, t_1, \ldots, t_{n-1}, t_n), \quad 0 = t_0 < t_1 < \cdots < t_{n-1} < t_n = 1, \quad n \in \mathbb{N}.$$

---

[24] The circular arc $\mathcal{C}^c$ is **not** the set-theoretic complement of $\mathcal{C}$ with respect to the whole circle $\mathbb{S}_O$ because $\mathcal{C}$ and $\mathcal{C}^c$ overlap in the two common end-points P_0 and P_1.

[25] Geometrically, the point $Q_t \in \mathcal{C}$ is obtained from P_t by radial projection from the center O.

We denote by Π the set of all partitions of $[0, 1]$ (for all $n \in \mathbb{N}$). A partition $(t_0, t_1, \ldots, t_{n-1}, t_n) \in \Pi$ of $[0, 1]$ defines an open **polygonal path** of $\mathcal{C}$ connecting $Q_0(= P_0)$ and $Q_1(= P_1)$ with consecutive vertices $Q_0 = Q_{t_0}, Q_{t_1}, \ldots, Q_{t_{n-1}}, Q_{t_n} = Q_1 \in \mathcal{C}$ with union $\bigcup_{i=1}^n [Q_{t_{i-1}}, Q_{t_i}]$. The **length** of a polygonal path is $\sum_{i=1}^n d(Q_{t_{i-1}}, Q_{t_i})$, the sum of the lengths of the participating line segments.

We now define the arc length of the circular arc $\mathcal{C} \subset \mathbb{S}_O$ by

$$\mathcal{L}_{\mathcal{C}} = \sup \left\{ \sum_{i=1}^n d(Q_{t_{i-1}}, Q_{t_i}) \,\middle|\, (t_0, t_1, \ldots, t_{n-1}, t_n) \in \Pi \right\}.$$

We need to show that the arc length $\mathcal{L}_{\mathcal{C}}$ is a (finite) real number; that is, the set of lengths of all polygonal paths of $\mathcal{C}$ is bounded above.

Let ℓ_0, resp. ℓ_1, denote the half-line with end-point O and containing P_0, resp. P_1 (For the notations introduced here and below, refer to Figure 5.4.). Let m_0, resp. m_1, be the tangent line to $\mathcal{C}$ through the point $Q_0 = P_0$, resp. $Q_1 = P_1$. By the results of the previous section, m_0, resp. m_1, is perpendicular to the line extension of ℓ_0, resp. ℓ_1. The lines m_0 and m_1 cannot be parallel since $O \notin [P_0, P_1]$. Let M be the intersection point of m_0 and m_1.

We claim that

$$\mathcal{L}_{\mathcal{C}} \le d(Q_0, M) + d(Q_1, M).$$

Consider a polygonal path $\bigcup_{i=1}^n [Q_{t_{i-1}}, Q_{t_i}]$ with vertices $Q_0 = Q_{t_0}, Q_{t_1}, \ldots, Q_{t_{n-1}}, Q_{t_n} = Q_1 \in \mathcal{C}$ corresponding to a partition $(t_0, t_1, \ldots, t_{n-1}, t_n) \in \Pi$ of $[0, 1]$ (see again Figure 5.4). For $i = 0, 1, 2, \ldots, n$, let h_i, resp. k_i, be the line through Q_{t_i} and parallel to m_1, resp. m_0. Let h_i and m_0 meet at the point R_i, $i = 0, \ldots, n$; in particular, $R_0 = Q_0$ and $R_n = M$. Similarly, let k_i and m_1 meet at the point S_i, $i = 0, \ldots, n$; in particular, $S_0 = M$ and $S_n = Q_1$. Finally, for $i = 1, \ldots, n$, let h_i and k_{i-1} meet at the point T_i.

With these notations, by the triangle inequality, we have

$$d(Q_{t_{i-1}}, Q_{t_i}) \le d(Q_{t_{i-1}}, T_i) + d(Q_{t_i}, T_i), \quad i = 1, \ldots, n.$$

On the other hand, $d(Q_{t_{i-1}}, T_i) = d(R_{i-1}, R_i)$ and $d(Q_{t_i}, T_i) = d(S_{i-1}, S_i)$, $i = 1, \ldots, n$, as the respective points are vertices of parallelograms.[26]

The next lemma will imply that $R_{i-1} * R_i * R_{i+1}$ and $S_{i-1} * S_i * S_{i+1}$, $i = 1, \ldots, n-1$. Once this is proved, it will follow that $\sum_{i=1}^n d(R_{i-1}, R_i) = d(R_0, R_n) = d(Q_0, M)$ and $\sum_{i=1}^n d(S_{i-1}, S_i) = d(S_0, S_n) = d(Q_1, M)$, so that the stated upper bound above holds, and the supremum defining the arc length is finite.

---

[26] The opposite sides of a parallelogram have equal lengths. This follows from translation invariance of the distance as shown at the beginning of Section 5.5.

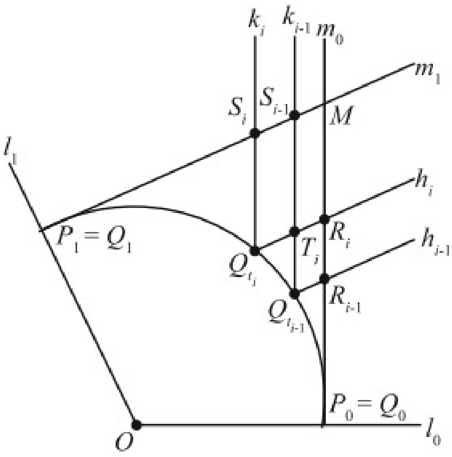

Fig. 5.4 Upper bound for the arc length.

In the lemma, without loss of generality, we assume that the center of the ambient circle is at the origin.

Lemma *Let* $\mathbb{S}$ *be the unit circle with center at the origin and* $P_0, P_1 \in \mathbb{S}$ *two distinct points with* $d(P_0, P_1) < 2$. *For* $t \in [0, 1]$, *let* $Q_t = P_t/d(0, P_t) \in \mathbb{S}$, $P_t = (1-t)P_0 + tP_1$; *and let* sP_0, $s \in \mathbb{R}$, *be the intersection of the radial line extension of* $[0, P_0]$ *and the line through* Q_t *perpendicular to this radial line. Then we have*

$$s = \frac{2 - td^2}{2\sqrt{t^2d^2 - td^2 + 1}}, \quad d = d(P_0, P_1).$$

In particular, s, *as a function of* $t \in [0, 1]$, *is strictly decreasing for* $0 \leq t \leq \min(2/d^2, 1)$ *and strictly increasing*[27] *for* $\min(2/d^2, 1) \leq t \leq 1$ *(see Figure 5.5).*

Proof We let $P_0 = (x_0, y_0)$, $x_0^2 + y_0^2 = 1$, and $P_1 = (x_1, y_1)$, $x_1^2 + y_1^2 = 1$. Setting $d = d(P_0, P_1)$, the computations at the end of the previous section give $d^2 = 2 - 2(x_0x_1 - y_0y_1)$ and $d(0, P_t)^2 = t^2d^2 - td^2 + 1$.

Since $d < 2$, for $t \in [0, 1]$, we have

$$d(0, P_t)^2 = t^2d^2 - td^2 + 1 = (t - 1/2)^2d^2 + 1 - d^2/4 > 0.$$

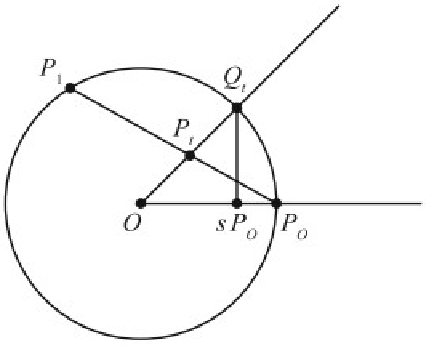
This gives

$$d(0, P_t) = \sqrt{t^2d^2 - td^2 + 1}, \quad t \in [0, 1].$$

---

[27] Monotonicity changes only if $d^2 > 2$, and then it does across $s = 0$, that is, when the sign of s changes from positive to negative; $s = 0$ corresponds to Q_{2/d^2} and P_{2/d^2} being perpendicular to P_0.

Fig. 5.5 Illustration for the monotonicity lemma.



The equation of the line extension of the radial line segment $[0, P_0]$ is of the form $y_0x - x_0y = 0$. The pencil of parallel lines perpendicular to this are described by the equations $x_0x + y_0y = c$, where $c \in \mathbb{R}$. Now, the value of the constant c is determined by the constraint that the perpendicular line must pass through the point $Q_t = P_t/d(0, P_t)$. This gives

$$\begin{aligned} c &= \frac{x_0((1-t)x_0 + tx_1) + y_0((1-t)y_0 + ty_1)}{\sqrt{t^2d^2 - td^2 + 1}} = \frac{1 - t + t(x_0x_1 + y_0y_1)}{\sqrt{t^2d^2 - td^2 + 1}} \\ &= \frac{1 - t + t(1 - d^2/2)}{\sqrt{t^2d^2 - td^2 + 1}} = \frac{2 - td^2}{2\sqrt{t^2d^2 - td^2 + 1}}. \end{aligned}$$

On the other hand, by definition, the point $sP_0 = (sx_0, sy_0)$ must be contained in this perpendicular line. This gives $s = s(x_0^2 + y_0^2) = c$. Putting everything together, we obtain

$$s = \frac{2 - td^2}{2\sqrt{t^2d^2 - td^2 + 1}}.$$

It remains to show the last statement of the lemma, the monotonicity properties of s with respect to t.

First, let $0 \le t \le \min(2/d^2, 1)$. Since in this range $s \ge 0$, it is enough to show that s^2 is strictly decreasing. Now, a simple computation gives

$$s^2 = \frac{d^2}{4} + \left(1 - \frac{d^2}{4}\right) \frac{1 - td^2}{t^2d^2 - td^2 + 1}.$$

Since $d < 2$, we need to show that, for $0 \le t < t' \le \min(2/d^2, 1)$, we have

$$\frac{1 - td^2}{t^2d^2 - td^2 + 1} > \frac{1 - t'd^2}{t'^2d^2 - t'd^2 + 1}.$$

Eliminating the denominators, simplifying and factoring, this becomes

$$(t' - t)(td^2 + t'd^2 - (td^2)(t'd^2)) > 0.$$

This, however, clearly follows[28] since $0 \leq td^2 < t'd^2 \leq 2$. The claimed monotonicity is proved.

Second, for $\min(2/d^2, 1) \leq t \leq 1$, we have $s \leq 0$. Squaring again, the same argument gives the opposite monotonicity property. The lemma follows.

To establish the existence of (an upper bound of) the arc length for a circular arc $\mathcal{C} \subset \mathbb{S}_O$, we followed a **geometric method**. We now describe another essentially **analytic method** to obtain the same result.

First, we derive a geometric formula that will be used several times in the future. Consider a (non-degenerate) triangle $\triangle[A, B, C]$ with (non-collinear) vertices A, B, C. We let

$$A_0 = \frac{1}{d(C, A)} A + \left(1 - \frac{1}{d(C, A)}\right) C$$
$$B_0 = \frac{1}{d(C, B)} B + \left(1 - \frac{1}{d(C, B)}\right) C$$

In other words, A_0, and respectively B_0, is the point at unit distance from C on the half-line with end-point C and containing A, and respectively B. We then have the following important formula:[29]

$$d(A_0, B_0)^2 = 2 + \frac{d(A, B)^2 - d(C, A)^2 - d(C, B)^2}{d(C, A)d(C, B)}.$$

Indeed, using $A_0 - C = (A - C)/d(C, A)$ and $B_0 - C = (B - C)/d(C, B)$, and translation invariance of the distance multiple times, we calculate[30]

$$d(A_0, B_0)^2 = d(A_0 - C, B_0 - C)^2 = d\left(\frac{A - C}{d(A, C)}, \frac{B - C}{d(B, C)}\right)^2$$
$$= d\left(\frac{A - C}{d(A, C)} - \frac{B - C}{d(B, C)}, 0\right)^2 = d\left(\frac{A - C}{d(A, C)}, 0\right)^2 + \left(\frac{B - C}{d(B, C)}, 0\right)^2$$

---

[28] $0 < a, b \leq 2$ implies $(a + b)/(ab) = 1/a + 1/b \geq 1/2 + 1/2 = 1$.

[29] In different (non-axiomatic) developments, this formula is equivalent to the so-called Law of Cosines.

[30] It is customary to set $|P| = d(P, 0)$, the distance of a point P from the origin. Algebraically, $|P|^2$ is then the sum of squares of the two coordinates of P. Translation invariance then gives $d(P, Q)^2 = d(P - Q, 0)^2 = |P - Q|^2$. Using the fact that this is a quadratic form in the coordinates of the points P and Q, the computations above become more familiar.

$$+\frac{1}{d(A,C)d(B,C)}\left(d(A-B,0)^2-d(A-C,0)^2-d(B-C,0)^2\right)$$
$$=d(C,A_0)^2+d(C,B_0)^2+\frac{d(A,B)^2-d(C,A)^2-d(C,B)^2}{d(C,A)d(C,B)}.$$

Since $d(C,A_0)=d(C,B_0)=1$, the formula follows.

Returning to the main line, recall that we use the affine parametrization $P_t=(1-t)P_0+tP_1$, $t\in[0,1]$, for the line segment $[P_0,P_1]$, and the parametrization Q_t, $t\in[0,1]$, for the circular arc $\mathcal{C}$. For $t,t'\in[0,1]$, letting $P_t=A$, $P_{t'}=B$, $O=C$, so that $Q_t=A_0$, $Q_{t'}=B_0$, the formula above is rewritten as

$$d(Q_t,Q_{t'})^2=2+\frac{d(P_t,P_{t'})^2-d(O,P_t)^2-d(O,P_{t'})^2}{d(O,P_t)d(O,P_{t'})}$$

For future reference, we include here a useful equivalent form of this as

$$d(Q_t,Q_{t'})^2=2-\frac{2-(t+t'-2tt')d^2}{\sqrt{t^2d^2-td^2+1}\sqrt{t'^2d^2-t'd^2+1}},\quad d=d(P_0,P_1),$$

where we used $d(P_t,P_{t'})^2=(t-t')^2d^2$, $d(O,P_t)=\sqrt{t^2d^2-td^2+1}$ and $d(O,P_{t'})=\sqrt{t'^2d^2-t'd^2+1}$.

We rewrite the original formula and estimate

$$d(Q_t,Q_{t'})^2=\frac{d(P_t,P_{t'})^2-(d(O,P_t)-d(O,P_{t'}))^2}{d(O,P_t)d(O,P_{t'})}\leq\frac{d(P_t,P_{t'})^2}{d(O,P_t)d(O,P_{t'})}$$

Setting, as usual, $d=d(P_0,P_1)<2$, for the denominator, we have

$$d(O,P_t)^2=t^2d^2-td^2+1=\left(t-\frac{1}{2}\right)^2d^2+1-\frac{d^2}{4}\geq 1-\frac{d^2}{4}.$$

With this, we arrive at

$$d(Q_t,Q_{t'})\leq\frac{d}{\sqrt{1-d^2/4}}|t-t'|,\quad t,t'\in[0,1],\ d=d(P_0,P_1)<2.$$

We express this by saying that the map $Q:[0,1]\to\mathbb{R}^2$, $Q(t)=Q_t$, $t\in[0,1]$, satisfies the **Lipschitz condition** with **Lipschitz constant** $d/\sqrt{1-d^2/4}$.

Applying this to a partition $(t_0,t_1,\dots,t_{n-1},t_n)\in\Pi$ of $[0,1]$, we see that the length of the corresponding polygonal path

$$\sum_{i=1}^n d(Q_{t_{i-1}},Q_{t_i})\leq\frac{d}{\sqrt{1-d^2/4}}\sum_{i=1}^n(t_i-t_{i-1})=\frac{d}{\sqrt{1-d^2/4}}.$$

Taking the supremum for all polygonal paths, we finally obtain

$$\mathcal{L}_{\mathcal{C}} \leq \frac{d}{\sqrt{1-d^2/4}}, \quad d = d(P_0, P_1) < 2.$$

(Note that, as a simple computation shows, this upper estimate is the same as the one we obtained above by our geometric method).

We now explore the properties of the arc length of circular arcs in $\mathbb{S}_O$. We say that **additivity** holds in a circular arc if whenever it is split into two circular arcs $\mathcal{C}_1$ and $\mathcal{C}_2$ (by a common end-point), then we have

$$\mathcal{L}_{\mathcal{C}_1 \cup \mathcal{C}_2} = \mathcal{L}_{\mathcal{C}_1} + \mathcal{L}_{\mathcal{C}_2}.$$

We first claim that additivity holds in a circular arc $\mathcal{C} \subset \mathbb{S}_O$ with end-points P_0 and P_1 satisfying $d(P_0, P_1) < 2$ (and $\mathcal{C}$ and O are in opposite sides of the line extension of $[P_0, P_1]$).

Let $Q \in \mathcal{C}$, $P_0 \neq Q \neq P_1$. Let $\mathcal{C}_1 \subset \mathcal{C}$, resp. $\mathcal{C}_2 \subset \mathcal{C}$, be the circular arc with end-points P_0 and Q, resp. P_1 and Q. We have $\mathcal{C} = \mathcal{C}_1 \cup \mathcal{C}_2$. We claim that

$$\mathcal{L}_{\mathcal{C}} = \mathcal{L}_{\mathcal{C}_1} + \mathcal{L}_{\mathcal{C}_2}.$$

Indeed, since a partition of $[P_0, Q]$ and a partition of $[P_1, Q]$ can be united to define a partition of $[P_0, P_1]$, taking suprema, we see that $\mathcal{L}_{\mathcal{C}} \geq \mathcal{L}_{\mathcal{C}_1} + \mathcal{L}_{\mathcal{C}_2}$. On the other hand, letting $0 < \epsilon \in \mathbb{R}$, we can choose a polygonal path $\bigcup_{i=1}^n [Q_{t_{i-1}}, Q_{t_i}]$ such that

$$\mathcal{L}_{\mathcal{C}} - \epsilon \leq \sum_{i=1}^n d(Q_{t_{i-1}}, Q_{t_i}).$$

By the triangle inequality, adding $Q \in \mathcal{C}$ to a polygonal path for $\mathcal{C}$ increases its length. If Q participates in a polygonal path for $\mathcal{C}$, then this path can be split into the union of two polygonal paths, one for $\mathcal{C}_1$ and the other for $\mathcal{C}_2$. Once again, taking suprema, we obtain $\mathcal{L}_{\mathcal{C}} - \epsilon \leq \mathcal{L}_{\mathcal{C}_1} + \mathcal{L}_{\mathcal{C}_2}$. Since this is true for all $0 < \epsilon \in \mathbb{R}$, we obtain $\mathcal{L}_{\mathcal{C}} \leq \mathcal{L}_{\mathcal{C}_1} + \mathcal{L}_{\mathcal{C}_2}$. Additivity in the circular arc $\mathcal{C}$ follows.

Remark The arc length $\mathcal{L}_{\mathcal{C}}$ of a circular arc $\mathcal{C}$ with end-points P_0 and P_1 depends only on the distance $d(P_0, P_1) < 2$. This means that, if $\mathcal{C}'$ is another circular arc with end-points P_0' and P_1' such that $d(P_0', P_1') = d(P_0, P_1) < 2$, then we have $\mathcal{L}_{\mathcal{C}} = \mathcal{L}_{\mathcal{C}'}$. Indeed, a partition of the interval $[0, 1]$ induces a partition of $[P_0, P_1]$ and $[P_0', P_1']$, and the associated polygonal paths have the same lengths because, by the formula above, the distance $d(Q_t, Q_{t'})$ depends only on $d(P_0', P_1') = d(P_0, P_1)$ and the parameters $t, t' \in [0, 1]$. These equal lengths contribute the same amount to the suprema that define the arc lengths $\mathcal{L}_{\mathcal{C}}$ and $\mathcal{L}_{\mathcal{C}'}$, which thereby must be equal.

Finally, note an important special case. Let $\mathcal{C}$ be a circular arc with the end-points P_0 and P_1. We claim that $d(P_0, P_1) = \sqrt{2}$ if and only if the line extensions of the half-lines ℓ_0 and ℓ_1 (from the center O to the respective end-points) are perpendicular.

Indeed, assuming (for simplicity) that the center is at the origin, the equation of the line extension of the half-line ℓ_0 through P_0 is $y_0 x - x_0 y = 0$. The quarter-turn S_0 sends this line to the perpendicular line with the equation $x_0 x + y_0 y = 0$. This line contains the point $P_1 = (x_1, y_1)$ if and only if $x_0 x_1 + y_0 y_1 = 0$. Since $d(P_0, P_1)^2 = 2 - 2(x_0 x_1 + y_0 y_1)$ (see the end of the previous section), this is equivalent to $d(P_0, P_1)^2 = 2$. The claim follows.

With this, we can introduce the positive real number $\pi \in \mathbb{R}$ such that, for $d(P_0, P_1) = \sqrt{2}$, we have $\mathcal{L}_{\mathcal{C}} = \pi/2$. By the remark above, the arc length of a circular arc depends only on the distance between its end-points, so that π is well-defined.

We now **extend** the definition of the arc length to any circular arc of $\mathbb{S}_O$ using additivity.

If $d(P_0, P_1) < 2$, then the arc length of the circular arc $\mathcal{C}$ with end-points P_0 and P_1 has been defined above as the supremum of the lengths of its polygonal paths. In particular, for any quarter-circle $\mathcal{C}$ ($d(P_0, P_1) = \sqrt{2}$), we have $\mathcal{L}_{\mathcal{C}} = \pi/2$.

If $d(P_0, P_1) = 2$, then, by the sharp triangle inequality, the points P_0 and P_1 are collinear, and the center O is at the midpoint of the line segment $[P_0, P_1]$. We define $\mathcal{L}_{\mathcal{C}} = \mathcal{L}_{\mathcal{C}^c} = \pi$ for either of the semi-circles $\mathcal{C}$ or $\mathcal{C}^c$ with end-points P_0 and P_1. (Note that they are congruent via the half-turn S_O^2.)

If $d(P_0, P_1) < 2$, then we define the arc length of the circular arc $\mathcal{C}^c$ **complementary** to $\mathcal{C}$ by $\mathcal{L}_{\mathcal{C}^c} = 2\pi - \mathcal{L}_{\mathcal{C}}$.

Finally, we define the arc length of the entire circle $\mathbb{S}_O$ to be 2π.

We note that the arc length, being defined in terms of the Cartesian distance, is preserved under translations and half-turns.

We now claim that **additivity** holds in any circular arc of $\mathbb{S}_O$.

First, we show additivity in a semi-circle $\mathcal{C}$. Let $\mathcal{C}$ have end-points P_0 and P_1, and $Q \in \mathcal{C}$ with $P_0 \neq Q \neq P_1$. Then Q splits $\mathcal{C}$ into two circular arcs: $\mathcal{C}_1$ with end-points P_0 and Q and $\mathcal{C}_2$ with end-points P_1 and Q. We claim that $\mathcal{L}_{\mathcal{C}} = \mathcal{L}_{\mathcal{C}_1} + \mathcal{L}_{\mathcal{C}_2} = \pi$.

Indeed, either $\mathcal{C}_1$ or $\mathcal{C}_2$ contains a quarter-circle. Assume, without loss of generality, that the first does. If $\mathcal{C}_1$ is itself a quarter-circle, then so is $\mathcal{C}_2$ and the statement holds. Otherwise, split $\mathcal{C}_1$ into a quarter circle with one end-point at P_0 and a circular arc $\mathcal{C}_1'$ with one end-point at Q. Then, by additivity in $\mathcal{C}_1$ already shown, we have $\mathcal{L}_{\mathcal{C}_1} = \pi/2 + \mathcal{L}_{\mathcal{C}_1'}$. Since $\mathcal{C}_1'$ and $\mathcal{C}_2$ join to form another quarter-circle, again by additivity in quarter-circles already shown, we also have $\mathcal{L}_{\mathcal{C}_1'} + \mathcal{L}_{\mathcal{C}_2} = \pi/2$. Putting these together, we obtain $\mathcal{L}_{\mathcal{C}_1} + \mathcal{L}_{\mathcal{C}_2} = (\pi/2 + \mathcal{L}_{\mathcal{C}_1'}) + (\pi/2 - \mathcal{L}_{\mathcal{C}_1'}) = \pi = \mathcal{L}_{\mathcal{C}}$. Additivity in semi-circles follows.

Next, we need to show additivity in a circular arc of the form $\mathcal{C}^c$ complementary to the circular arc $\mathcal{C}$ with end-points P_0 and P_1 such that $d(P_0, P_1) < 2$. Let $Q \in \mathcal{C}^c$ distinct from P_0 and P_1. Then Q splits $\mathcal{C}^c$ into two circular arcs: $\mathcal{C}_1$ with one end-point at P_0 and another circular arc $\mathcal{C}_2$ with one end-point at P_1. We need to show $\mathcal{L}_{\mathcal{C}^c} = \mathcal{L}_{\mathcal{C}_1} + \mathcal{L}_{\mathcal{C}_2}$.

First, assume that either $\mathcal{C}_1$ or $\mathcal{C}_2$ contains a half-circle. Without loss of generality, we may assume that $\mathcal{C}_1$ does. We have $\mathcal{L}_{\mathcal{C}_1} = \mathcal{L}_{(\mathcal{C}\cup\mathcal{C}_2)^c} = 2\pi - \mathcal{L}_{\mathcal{C}\cup\mathcal{C}_2} = 2\pi - (\mathcal{L}_{\mathcal{C}} + \mathcal{L}_{\mathcal{C}_2})$, where we used additivity in $\mathcal{C} \cup \mathcal{C}_2$ (including the case when $\mathcal{C} \cup \mathcal{C}_2$ is a semi-circle). On the other hand, we have $\mathcal{L}_{\mathcal{C}^c} = 2\pi - \mathcal{L}_{\mathcal{C}} = 2\pi - (2\pi - (\mathcal{L}_{\mathcal{C}_1} + \mathcal{L}_{\mathcal{C}_2})) = \mathcal{L}_{\mathcal{C}_1} + \mathcal{L}_{\mathcal{C}_2}$. Additivity follows in this case.

Second, assume neither $\mathcal{C}_1$ nor $\mathcal{C}_2$ contains a semi-circle. Let $P_2 \in \mathbb{S}_O$ be the opposite to P_0 with respect to O. Since neither $\mathcal{C}$ nor $\mathcal{C}_1$ contains semi-circles, we have $P_2 \in \mathcal{C}_2$, $P_1 \neq P_2 \neq Q$. Then P_2 splits $\mathcal{C}_2$ into two circular arcs: $\mathcal{C}_2'$ with one end-point at P_1 and another $\mathcal{C}_2''$ with one end-point at Q. Clearly, $\mathcal{C}_1 \cup \mathcal{C}_2''$ is a semi-circle, so that, by the previous case, we have $\mathcal{L}_{\mathcal{C}^c} = \mathcal{L}_{\mathcal{C}_1\cup\mathcal{C}_2''} + \mathcal{L}_{\mathcal{C}_2'}$. On the other hand, by additivity in semi-circles, we also have $\mathcal{L}_{\mathcal{C}_1\cup\mathcal{C}_2''} = \mathcal{L}_{\mathcal{C}_1} + \mathcal{L}_{\mathcal{C}_1''}$. Putting these together, we obtain $\mathcal{L}_{\mathcal{C}^c} = \mathcal{L}_{\mathcal{C}_1\cup\mathcal{C}_2''} + \mathcal{L}_{\mathcal{C}_2'} = \mathcal{L}_{\mathcal{C}_1} + \mathcal{L}_{\mathcal{C}_1''} + \mathcal{L}_{\mathcal{C}_2'} = \mathcal{L}_{\mathcal{C}_1} + \mathcal{L}_{\mathcal{C}_2}$. This finishes the second case. Additivity in complementary circular arcs follows.

Finally, note that additivity in the entire circle $\mathbb{S}_O$ follows from the definitions as any split consists of complementary pairs of circular arcs.

The proof of the additivity of the arc length in general is now complete.

Remark In view of the additivity and the forthcoming discussion, it is convenient to define the arc length of a single point on $\mathbb{S}_O$ to be zero.

As the final task in this section, we claim that any given number $0 \leq r \leq 2\pi$ arises as the arc length of a circular arc $\mathcal{C} \subset \mathbb{S}_O$, that is, we have $\mathcal{L}_{\mathcal{C}} = r$. By additivity, it is enough to show this for $0 < r < \pi/2$. Let ℓ_0 and ℓ_1 be perpendicular half-lines with common end-point O such that, for $P_0 \in \ell_0$ and $P_1 \in \ell_1$, $d(O, P_0) = d(O, P_1) = 1$, and hence $d(P_0, P_1) = \sqrt{2}$. The unit interval $[0, 1]$ parametrizes the line segment $[P_0, P_1]$ by the affine coordinate function $P_t = (1-t)P_0 + tP_1$, $t \in [0, 1]$, and the quarter-circle with end-points P_0 and P_1 by $Q_t = P_t/d(O, P_t) \in \mathbb{S}_O$, $t \in [0, 1]$.

For $t \in [0, 1]$, we denote by $\mathcal{C}_t \subset \mathbb{S}_O$ the circular arc with end-points $Q_0 (= P_0)$ and Q_t. The quarter-circle itself is then equal to $\mathcal{C}_1$, and we have

$$\mathcal{L}_{\mathcal{C}_0} = 0 \quad \text{and} \quad \mathcal{L}_{\mathcal{C}_1} = \pi/2.$$

We first study the properties of the arc length $\mathcal{L}_{\mathcal{C}_t}$ as a function of $t \in [0, 1]$. Since $d = d(P_0, P_1) = \sqrt{2}$, we have $d/\sqrt{1 - d^2/4} = 2$, so that the previous Lipschitz estimate gives

$$d(Q_t, Q_{t'}) \leq 2|t - t'|, \quad t, t' \in [0, 1].$$

On the other hand, the explicit formula for this distance specializes to

$$\begin{aligned} d(Q_t, Q_{t'})^2 &= 2 - \frac{2 - 2(t + t' - 2tt')}{\sqrt{2t^2 - 2t + 1}\sqrt{2t'^2 - 2t' + 1}} \\ &= 2 - \frac{2(1-t)(1-t')}{\sqrt{2t^2 - 2t + 1}\sqrt{2t'^2 - 2t' + 1}}, \quad t, t' \in [0, 1]. \end{aligned}$$

This gives

$$\max_{t,t' \in [0,1]} d(Q_t, Q_{t'}) = \sqrt{2}.$$

We now let $t, t' \in [0, 1]$ and consider the circular arc $\mathcal{C}_{t,t'} \subset \mathbb{S}_O$ with end-points Q_t and $Q_{t'}$. The general upper estimate derived earlier for the arc length gives

$$\mathcal{L}_{\mathcal{C}_{t,t'}} \leq \frac{d(Q_t, Q_{t'})}{\sqrt{1 - d(Q_t, Q_{t'})^2/4}} \leq 2\sqrt{2}|t - t'|, \quad t, t' \in [0, 1],$$

where we used the Lipschitz estimate and the maximum above. Finally, by additivity, the arc length of the path $\mathcal{C}_{t,t'}$ is equal to $\mathcal{L}_{\mathcal{C}_{t,t'}} = |\mathcal{L}_{\mathcal{C}_t} - \mathcal{L}_{\mathcal{C}_{t'}}|$. Putting these together, we obtain

$$|\mathcal{L}_{\mathcal{C}_t} - \mathcal{L}_{\mathcal{C}_{t'}}| \leq 2\sqrt{2}|t - t'|, \quad t, t' \in [0, 1].$$

This means that the arc length $\mathcal{L}_{\mathcal{C}_t}$ as a function of $t \in [0, 1]$ satisfies the Lipschitz property with Lipschitz constant $2\sqrt{2}$.

We now note the simple fact that the Lipschitz property above implies **continuity** of the function $t \mapsto \mathcal{L}_{\mathcal{C}_t}$, $t \in [0, 1]$. (Indeed, for any $0 < \epsilon \in \mathbb{R}$, we can choose $\delta = \epsilon/(2\sqrt{2})$, universally.) Hence, by the Intermediate Value Theorem (Section 4.2), for any given $0 \leq r \leq 2\pi$, there exists $t \in [0, 1]$ such that $\mathcal{L}_{\mathcal{C}_t} = r$. The claim follows.

Remark The arc length $\mathcal{L}_{\mathcal{C}}$ of a circular arc $\mathcal{C}$ with end-points P_0 and P_1 depends only on the distance $d(P_0, P_1) < 2$. We now make the additional claim that the correspondence that associates with the arc length $\mathcal{L}_{\mathcal{C}}$ of a circular arc $\mathcal{C}$ with end-points P_0 and P_1 and the distance $d(P_0, P_1)$ is **strictly increasing** in the sense that if $\mathcal{C}'$ and $\mathcal{C}''$ are circular arcs, then $\mathcal{L}_{\mathcal{C}'} < \mathcal{L}_{\mathcal{C}''}$ if and only if $d(P_0', P_1') < d(P_0'', P_1'')$ for the corresponding end-points.

Indeed, let $\mathcal{C}$ be a circular arc with end-points P_0 and P_1, $d(P_0, P_1) < 2$, such that $\max(\mathcal{L}_{\mathcal{C}'}, \mathcal{L}_{\mathcal{C}''}) < \mathcal{L}_{\mathcal{C}}$. Then, by the above, there exist $\mathcal{C}_0' \subset \mathcal{C}$ with one end-point at P_0 and congruent to $\mathcal{C}'$ and $\mathcal{C}_0'' \subset \mathcal{C}$ with one end-point at P_0 and congruent to $\mathcal{C}''$. Now the claim is equivalent to monotonicity of the distance $d(Q_t, Q_0)$ in $t \in [0, 1]$. As for this, first note that, as a special case of the general formula derived earlier, we have

$$d(Q_t, Q_0) = 2 - \frac{2 - td^2}{\sqrt{t^2d^2 + td^2 + 1}}, \quad d = d(P_0, P_1).$$

Now, monotonicity follows from the proof of the lemma above.

Exercise

5.6.1. Let $\triangle[A, B, C]$ be a triangle with vertices $A, B, C \in \mathbb{R}^2$ and side lengths $a, b, c \in \mathbb{R}$. Let $0 < r \in \mathbb{R}$ such that $2r < \min(a, b, c)$. Consider the configuration of three circles with centers A, B, C and radius r. What is the shortest length of a band that stretches around the outside of the three circles?

5.7 The Birkhoff Angle Measure

We now turn to the concept of **angle measure** μ for angles in the **Birkhoff Postulate of Angle Measure** (Section 5.1) in our model $\mathbb{R}^2$.

We first define the **angle measure** for angles in our model $\mathbb{R}^2$. Let $\angle AOB$ be an angle formed by the ordered triple (O, A, B), $A \neq O \neq B$. Let $\mathbb{S}_O$ be the unit radius circle with center O.

If (O, A, B) is a positively oriented triple, then we define the angle measure as the arc length $\mu(\angle AOB) = \mathcal{L}_{\mathcal{C}} \pmod{2\pi}$, where $\mathcal{C} \subset \mathbb{S}_O$ is the circular arc with end-points A_0 and B_0, the points at unit distance from O on the half-line with end-point O and containing A and B.[31]

If A, O, B are collinear, then we define $\mu(\angle AOB) = 0 \pmod{2\pi}$ if O is not between A and B, and $\mu(\angle AOB) = \pi \pmod{2\pi}$ if O is between A and B.

If (O, A, B) is a negatively oriented triple, then we define the angle measure as $\mu(\angle AOB) = -\mathcal{L}_{\mathcal{C}} \pmod{2\pi}$, where $\mathcal{C} \subset \mathbb{S}_O$ is the circular arc with end-points A_0 and B_0 as above.

Note that the angle measure $\mu(\angle AOB)$ depends only on the half-lines ℓ_0 and ℓ_1 with end-point O containing A and B, respectively. Thus, we can write $\mu(\angle \ell_0 O \ell_1) = \mu(\angle AOB)$.

To derive the Birkhoff Postulate of Angle Measure, for $O \in \mathbb{R}^2$, we need to define the function α_O on the set of all half-lines with end-point O to the real numbers modulo 2π. For O at the origin 0, we let $\alpha_0(\ell) = \mu(\angle \ell_+ 0 \ell)$, where ℓ is any half-line with end-point 0 and ℓ_+ is the positive first axis. With this, we define α_O by translating all the geometric entities from O to the origin 0.

---

[31] Note that the triple (O, A_0, B_0) is also positively oriented. Recall also that, according to our conventions, $\mathcal{C}$ is the shorter arc length circular arc with end-points A_0 and B_0.

7.3 Isometries and Orthogonal Mappings

Throughout this section, V will denote a real finite-dimensional inner product space. Recall that the inner product on V defines a distance function $d(\mathbf{a}, \mathbf{b}) = |\mathbf{a} - \mathbf{b}|$. Linear mappings $T : V \to V$ that preserve distances are called *isometries*. (Actually, as we will see below, a distance-preserving map is automatically linear, so the definition can be simplified.) The isometries of V form an important group, called $O(V)$. When $V = \mathbb{R}^n$, $O(V)$ is the matrix group $O(n, \mathbb{R})$ of all orthogonal $n \times n$ matrices over $\mathbb{R}$. We will first consider isometries in general and then specialize to rotations and reflections. Finally, we will consider the isometries of $\mathbb{R}^2$. Here we prove the $O(2, \mathbb{R})$-dichotomy: every isometry of $\mathbb{R}^2$ is either a rotation or a reflection. We will also show that the dihedral group $D(m)$ can be realized as the group of all isometries of a regular m-gon in $\mathbb{R}^2$. This will give another proof that the order of $D(m)$ is $2m$.

7.3.1 Isometries and orthogonal linear mappings

A mapping $S : V \to V$ is said to be *orthogonal* if

$$(S(\mathbf{x}), S(\mathbf{y})) = (\mathbf{x}, \mathbf{y}) \tag{7.5}$$

for all $\mathbf{x}, \mathbf{y} \in V$. The term orthogonal comes from the fact that an orthogonal mapping preserves the orthogonal relationship between orthogonal pairs of vectors. Since orthogonal mappings preserve inner products, they preserve lengths of vectors, distances between vectors, and angles between vectors, since the angle θ between $\mathbf{v}$ and $\mathbf{w}$ is found by the identity

$$\mathbf{v} \cdot \mathbf{w} = |\mathbf{v}||\mathbf{w}| \cos \theta.$$

It turns out that all orthogonal mappings are linear.

Proposition 7.7. *Let $S : V \to V$ be orthogonal. Then S is linear. In fact, the orthogonal mappings are exactly the isometries. In particular, all distance-preserving mappings on V are linear. Conversely, every isometry is orthogonal.*

Proof. To show that S is linear, we first show that for all $\mathbf{a}, \mathbf{b} \in V$, $|S(\mathbf{a} + \mathbf{b}) - S(\mathbf{a}) - S(\mathbf{b})|^2 = 0$. But

$$|S(\mathbf{a}+\mathbf{b}) - S(\mathbf{a}) - S(\mathbf{b})|^2 = (S(\mathbf{a}+\mathbf{b}) - S(\mathbf{a}) - S(\mathbf{b}), S(\mathbf{a}+\mathbf{b}) - S(\mathbf{a}) - S(\mathbf{b}))$$

$$= (S(\mathbf{a} + \mathbf{b}), S(\mathbf{a} + \mathbf{b})) + (S(\mathbf{a}), S(\mathbf{a})) + (S(\mathbf{b}), S(\mathbf{b})) - 2(S(\mathbf{a} + \mathbf{b}), S(\mathbf{a}))$$

$$-2(S(\mathbf{a}+\mathbf{b}),S(\mathbf{b}))+2(S(\mathbf{a}),S(\mathbf{b})).$$

Using the fact that S is orthogonal, it follows that

$$|S(\mathbf{a}+\mathbf{b})-S(\mathbf{a})-S(\mathbf{b})|^2=(\mathbf{a}+\mathbf{b},\mathbf{a}+\mathbf{b})+(\mathbf{a},\mathbf{a})+(\mathbf{b},\mathbf{b})$$
$$-2(\mathbf{a}+\mathbf{b},\mathbf{a})-2(\mathbf{a}+\mathbf{b},\mathbf{b})+2(\mathbf{a},\mathbf{b}).$$

Expanding further, one sees that the right-hand side is zero. Thus, $S(\mathbf{a}+\mathbf{b}) = S(\mathbf{a})+S(\mathbf{b})$. The proof that $S(r\mathbf{a}) = rS(\mathbf{a})$ for all $r \in \mathbb{F}$ is similar. Therefore, every orthogonal mapping is linear. To see that S is an isometry, note that

$$\begin{aligned}|S(\mathbf{b})-S(\mathbf{a})|^2 &= |S(\mathbf{b}-\mathbf{a})|^2\\ &= (S(\mathbf{a}-\mathbf{b}),S(\mathbf{a}-\mathbf{b}))\\ &= (\mathbf{b}-\mathbf{a},\mathbf{b}-\mathbf{a})\\ &= |\mathbf{b}-\mathbf{a}|^2.\end{aligned}$$

This completes the proof that orthogonal mappings are isometries. We will leave the rest of the proof as an exercise. □

More generally, every mapping $F : V \to V$ that preserves distances turns out to be orthogonal, and hence is an isometry (see Exercise 7.3.3).

7.3.2 Orthogonal linear mappings on $\mathbb{R}^n$

We are now going to show that the matrix of an isometry is orthogonal, and conversely, that every orthogonal matrix defines an isometry.

Proposition 7.8. *Every isometry* $T : \mathbb{R}^n \to \mathbb{R}^n$ *is the matrix linear mapping associated with a unique orthogonal matrix. Conversely, every orthogonal matrix defines a unique isometry.*

Proof. Suppose $T : \mathbb{R}^n \to \mathbb{R}^n$ is an isometry. Since T is linear, $T = T_Q$ for a unique $Q \in \mathbb{R}^{n\times n}$. But T is orthogonal, so $T_Q(\mathbf{x}) \cdot T_Q(\mathbf{y}) = Q\mathbf{x} \cdot Q\mathbf{y} = \mathbf{x} \cdot \mathbf{y}$ for all $\mathbf{x}, \mathbf{y} \in \mathbb{R}^n$. Thus

$$(Q\mathbf{x})^T(Q\mathbf{y}) = (\mathbf{x}^TQ^T)(Q\mathbf{y}) = \mathbf{x}^T(Q^TQ)\mathbf{y} = \mathbf{x}^T\mathbf{y} \tag{7.6}$$

for all $\mathbf{x}, \mathbf{y} \in \mathbb{R}^n$. Setting $Q\mathbf{e}_i = \mathbf{q}_i$, (7.6) implies $\mathbf{q}_i^T\mathbf{q}_j = \mathbf{e}_i^T\mathbf{e}_j$. Hence $Q^TQ = I_n$, so Q is orthogonal. We leave the converse to the reader. □

Recall that the set of orthogonal $n \times n$ matrices is the orthogonal group $O(n,\mathbb{R})$, so $O(n,\mathbb{R})$ is also the group of isometries of $\mathbb{R}^n$.

7.3.3 Projections

Let $\mathbf{a} \in \mathbb{R}^2$ be nonzero, and consider the line $\mathbb{R}\mathbf{a}$ spanned by $\mathbf{a}$. In Section 6.6.2, we called the mapping

$$P_{\mathbf{a}}(\mathbf{x}) = \Big(\frac{\mathbf{a} \cdot \mathbf{x}}{\mathbf{a} \cdot \mathbf{a}}\Big)\mathbf{a}$$

the *projection* onto $\mathbb{R}\mathbf{a}$. We leave it as an exercise to show that the projection $P_{\mathbf{a}}$ is linear. Note that if $\mathbf{u}$ is the unit vector determined by $\mathbf{a}$, then since $\mathbf{a} \cdot \mathbf{a} = |\mathbf{a}|^2$, it follows that

$$P_{\mathbf{u}}(\mathbf{x}) = P_{\mathbf{a}}(\mathbf{x}) = (\mathbf{u}^T\mathbf{x})\mathbf{u}.$$

Thus,

$$P_{\mathbf{u}}\begin{pmatrix} x_1 \\ x_2 \end{pmatrix} = (u_1x_1 + u_2x_2)\begin{pmatrix} u_1 \\ u_2 \end{pmatrix},$$

so

$$P_{\mathbf{u}}\begin{pmatrix} x_1 \\ x_2 \end{pmatrix} = \begin{pmatrix} u_1^2 & u_1u_2 \\ u_1u_2 & u_2^2 \end{pmatrix}\begin{pmatrix} x_1 \\ x_2 \end{pmatrix}.$$

Hence the matrix of $P_{\mathbf{u}}$ is

$$\begin{pmatrix} u_1^2 & u_1u_2 \\ u_1u_2 & u_2^2 \end{pmatrix}. \tag{7.7}$$

Note that a projection matrix is symmetric. The image of the projection $P_{\mathbf{u}}$ is the line $\mathbb{R}\mathbf{u}$, while its kernel is the line orthogonal to $\mathbb{R}\mathbf{u}$. A reflection $P_{\mathbf{u}}$ has the property that $P_{\mathbf{u}} \circ P_{\mathbf{u}} = P_{\mathbf{u}}$, since

$$P_{\mathbf{u}} \circ P_{\mathbf{u}}(\mathbf{v}) = P_{\mathbf{u}}((\mathbf{v} \cdot \mathbf{u})\mathbf{u})) = (\mathbf{v} \cdot \mathbf{u})P_{\mathbf{u}}(\mathbf{u}) = (\mathbf{v} \cdot \mathbf{u})\mathbf{u} = P_{\mathbf{u}}(\mathbf{v}).$$

We will next apply projections to find a general formula for the reflection $\mathbb{R}^n$ through a hyperplane.

7.3.4 Reflections

We will first find an expression for a plane reflection and use that to suggest how to define a reflection of $\mathbb{R}^n$ through a hyperplane. Let ℓ be a line through the origin of $\mathbb{R}^2$. We want to consider how to reflect $\mathbb{R}^2$ through ℓ. The sought-after mapping $H : \mathbb{R}^2 \to \mathbb{R}^2$ fixes every vector on ℓ and sends every vector $\mathbf{v}$ orthogonal to ℓ to $-\mathbf{v}$. (If a reflection is linear, this is enough information to determine H.) Suppose $\mathbf{v} \in \mathbb{R}^2$ is on neither ℓ nor $\ell^\perp$. Then $\mathbf{v}$ and its reflection $H(\mathbf{v})$ form an isosceles triangle with equal sides $\mathbf{v}$ and $H(\mathbf{v})$, which H swaps.

Choosing a unit vector $\mathbf{u}$ on $\ell^{\perp}$, let us write

$$\mathbf{v} = P_{\mathbf{u}}(\mathbf{v}) + \mathbf{c},$$

where $\mathbf{c} \in \ell$. This is the orthogonal decomposition of $\mathbf{v}$ with respect to ℓ and $\ell^{\perp}$. Hence the component on ℓ is $\mathbf{c} = \mathbf{v} - P_{\mathbf{u}}(\mathbf{v})$. By Euclidean geometry, $H(\mathbf{v}) = -P_{\mathbf{u}}(\mathbf{v}) + \mathbf{c}$. Replacing $\mathbf{c}$ by $\mathbf{v} - P_{\mathbf{u}}(\mathbf{v})$, we get the formula

$$H(\mathbf{v}) = -P_{\mathbf{u}}(\mathbf{v}) + (\mathbf{v} - P_{\mathbf{u}}(\mathbf{v})) = \mathbf{v} - 2P_{\mathbf{u}}(\mathbf{v}).$$

Therefore,

$$H(\mathbf{v}) = \mathbf{v} - 2P_{\mathbf{u}}(\mathbf{v}) = \mathbf{v} - 2(\mathbf{u} \cdot \mathbf{v})\mathbf{u} = \mathbf{v} - 2(\mathbf{u}^T\mathbf{v})\mathbf{u}. \tag{7.8}$$

This expression immediately establishes the following result.

Proposition 7.9. *The reflection H of $\mathbb{R}^2$ through a line ℓ passing through* $\mathbf{0}$ *is a linear mapping.*

Example 7.7. Let us find the reflection H through the line ℓ given by $x = -y$. Now $\mathbf{u} = (\frac{1}{\sqrt{2}}, \frac{1}{\sqrt{2}})^T$ is a unit vector on $\ell^{\perp}$. Thus,

$$\begin{aligned} H\begin{pmatrix} a \\ b \end{pmatrix} &= \begin{pmatrix} a \\ b \end{pmatrix} - 2(\begin{pmatrix} a \\ b \end{pmatrix} \cdot \begin{pmatrix} \frac{1}{\sqrt{2}} \\ \frac{1}{\sqrt{2}} \end{pmatrix}) \begin{pmatrix} \frac{1}{\sqrt{2}} \\ \frac{1}{\sqrt{2}} \end{pmatrix} \\ &= \begin{pmatrix} a - (a+b) \\ b - (a+b) \end{pmatrix} \\ &= \begin{pmatrix} -b \\ -a \end{pmatrix}. \end{aligned}$$

Thus the matrix of H is

$$\begin{pmatrix} 0 & -1 \\ -1 & 0 \end{pmatrix}.$$

⊠

Now let Q denote the matrix of the reflection through the line orthogonal to a unit vector $\mathbf{u} \in \mathbb{R}^2$. Applying (7.7) and (7.8), one sees that

$$Q = \begin{pmatrix} 1 - 2u_1^2 & -2u_1u_2 \\ -2u_1u_2 & 1 - 2u_2^2 \end{pmatrix} = \begin{pmatrix} u_2^2 - u_1^2 & -2u_1u_2 \\ -2u_1u_2 & u_1^2 - u_2^2 \end{pmatrix}. \tag{7.9}$$

Thus, every 2×2 reflection matrix has the form

$$Q = \begin{pmatrix} a & b \\ b & -a \end{pmatrix}, \tag{7.10}$$

where $a^2 + b^2 = 1$. Conversely, as we will show below, a matrix of the form $Q = \begin{pmatrix} a & b \\ b & -a \end{pmatrix}$, where $a^2 + b^2 = 1$, is a reflection. Hence, the symmetric 2×2 orthogonal matrices are exactly the matrices of reflections.

Let us now ask what the linear mapping H defined by (7.8) does in the case of $\mathbb{R}^n$. The equation $\mathbf{v} \cdot \mathbf{u} = 0$ defines an $(n-1)$-dimensional subspace W of $\mathbb{R}^n$, namely the hyperplane through the origin orthogonal to $\mathbf{u}$. If $\mathbf{v} \in W$, then $H(\mathbf{v}) = \mathbf{v}$. On the other hand, if $\mathbf{v} = r\mathbf{u}$, then $H(\mathbf{v}) = rH(\mathbf{u}) = r(\mathbf{u} - 2\mathbf{u}) = -r\mathbf{u} = -\mathbf{v}$. In particular, H leaves the hyperplane W pointwise fixed and reverses vectors on the line $W^\perp$ orthogonal to this hyperplane.

Definition 7.4. Let $\mathbf{u} \in \mathbb{R}^n$ be a unit vector, and let W be the hyperplane in $\mathbb{R}^n$ orthogonal to the line $\mathbb{R}\mathbf{u}$. Then the linear mapping $H : \mathbb{R}^n \to \mathbb{R}^n$ defined by

$$H(\mathbf{v}) = \mathbf{v} - 2(\mathbf{v} \cdot \mathbf{u})\mathbf{u} = \mathbf{v} - 2(\mathbf{u}^T\mathbf{v})\mathbf{u} \tag{7.11}$$

is called the *reflection of* $\mathbb{R}^n$ *through* W.

Since reflecting $\mathbf{v} \in \mathbb{R}^n$ twice through a hyperplane W returns $\mathbf{v}$ to itself, a reflection H has the property that $H \circ H = I_{\mathbb{R}^n}$. This can be checked directly by matrix multiplication. Let P denote the matrix of the projection $P_{\mathbf{u}}$. Then the matrix Q of H is $Q = I_n - 2P$. Thus,

$$Q^2 = (I_n 2 - 2P)(I_n - 2P) = I_n - 4P + 4P^2 = I_n,$$

since $P^2 = P$.

Since Q is symmetric and $Q^2 = I_n$, Q is by definition orthogonal. Thus we get the following.

Proposition 7.10. *The matrix of a reflection is orthogonal. Hence, reflections are orthogonal linear mappings.*

7.3.5 Projections on a general subspace

As a final example of a linear mapping, let us work out the projection of finite-dimensional inner product space V onto an arbitrary subspace W. As we saw in Proposition 6.38, every $\mathbf{x} \in V$ admits a unique orthogonal decomposition

$$\mathbf{x} = \mathbf{w} + \mathbf{y},$$

where $\mathbf{w} \in W$ and $\mathbf{y} \in W^\perp$. The *projection of* V *onto* W is the mapping $P_W : V \to V$ defined by $P_W(\mathbf{x}) = \mathbf{w}$. The following proposition justifies calling P_W a projection.

Proposition 7.11. *The mapping* $P_W : V \to V$ *has the following properties:*

(*i*) P_W *is linear,*

(*ii*) $P_W(\mathbf{w}) = \mathbf{w}$ *if* $\mathbf{w} \in W$*,*

(*iii*) $P_W(W^\perp) = \{\mathbf{0}\}$*, and finally,*

(*iv*) $P_W + P_{W^\perp} = I$*.*

Proof. Since W is a finite-dimensional inner product space, we have shown that it has an orthonormal basis, say $\mathbf{u}_1, \dots, \mathbf{u}_k$. Assume that $\mathbf{w} \in W$. By Proposition 6.36,

$$\begin{aligned}\mathbf{w} &= \sum_{i=1}^{k}(\mathbf{w}, \mathbf{u}_i)\mathbf{u}_i \\ &= \sum_{i=1}^{k}(\mathbf{x} - \mathbf{y}, \mathbf{u}_i)\mathbf{u}_i \\ &= \sum_{i=1}^{k}(\mathbf{x}, \mathbf{u}_i)\mathbf{u}_i - \sum_{i=1}^{k}(\mathbf{y}, \mathbf{u}_i)\mathbf{u}_i \\ &= \sum_{i=1}^{k}(\mathbf{x}, \mathbf{u}_i)\mathbf{u}_i.\end{aligned}$$

The last identity holds, since $\mathbf{y} \in W^\perp$ and all the $\mathbf{u}_i$ are in in W. Hence,

$$P_W(\mathbf{x}) = \sum_{i=1}^{k}(\mathbf{x}, \mathbf{u}_i)\mathbf{u}_i.$$

This shows that P_W is linear and $P_W(\mathbf{w}) = \mathbf{w}$ if $\mathbf{w} \in W$. Thus, (*i*) and (*ii*) hold. Statement (*iii*) follows from the fact that $(\mathbf{y}, \mathbf{u}_i) = 0$ for all $\mathbf{y} \in W^\perp$, and (*iv*) is a consequence of the decomposition $\mathbf{x} = \mathbf{w} + \mathbf{y}$, since $P_{W^\perp}(\mathbf{x}) = \mathbf{y}$. □

When $V = \mathbb{R}^n$, Exercise 7.3.9 below gives an interesting alternative expression for P_W that doesn't require knowing an orthonormal basis of W.

7.3.6 Dimension two and the $O(2, \mathbb{R})$-dichotomy

The orthogonal group $O(2, \mathbb{R})$ of all isometries of $\mathbb{R}^2$ contains the group $\mathrm{Rot}(2)$ of all rotations of $\mathbb{R}^2$ as a normal subgroup. Recall that every rotation matrix has the form $R_\theta = \begin{pmatrix} \cos\theta & -\sin\theta \\ \sin\theta & \cos\theta \end{pmatrix}$. We are now going to show that $O(2, \mathbb{R})$ has surprising decomposition.

if there exists a one-to-one ^{35}

^{35} the property of being simple, that is, one-to-one, excludes "self-intersections".
As we consider here only open curves and minimize the arc length, imposing this does not restrict the generality.

Isometries and Orthogonal Mapping

The term orthogonal comes from the fact that an orthogonal mapping preserves the orthogonal relationship between orthogonal pairs of vectors.

Since orthogonal mapping preserve inner products, they preserve the lengths of vectors, distance between vectors, and angles between vectors, since the angle θ between

v and w is found by the identity

$V \cdot W = |V| \, |W| \cos \theta$.

It turns out that all orthogonal mapping are linear.

Chapter 4

Quotient Space and Direct Sum of Vector Spaces

1 Homomorphism of Vector Spaces or Linear Transformation

Definition: *Let U (F) and V (F) be two vector spaces. Then a mapping*

$$f : U \rightarrow V$$

is called a homomorphism or a linear transformation of U **into** *V, if*

(i) $f(\alpha + \beta) = f(\alpha) + f(\beta), \forall \alpha, \beta \in U$

and (ii) $f(a\alpha) = af(\alpha) \forall a \in F, \quad \forall \alpha \in U.$

The conditions (i) and (ii) can be combined into a single condition

$$f(a\alpha + b\beta) = af(\alpha) + bf(\beta) \forall a, b \in F \text{ and } \forall \alpha, \beta \in U.$$

If f is a homomorphism of U **onto** V, then V is called a homomorphic image of U.

Theorem: *If f is a homomorphism of U (F) into V (F), then*

(i) $f(\mathbf{0}) = \mathbf{0}'$ *where* $\mathbf{0}$ *and* $\mathbf{0}'$ *are the zero vectors of U and V respectively.*

(ii) $f(-\alpha) = -f(\alpha) \forall \alpha \in U.$

Proof: (i) Let $\alpha \in U$. Then $f(\alpha) \in V$. Since $\mathbf{0}'$ is the zero vector of V, therefore

$$f(\alpha) + \mathbf{0}' = f(\alpha) = f(\alpha + \mathbf{0}) = f(\alpha) + f(\mathbf{0}).$$

Now V is an abelian group with respect to addition of vectors.

$\therefore$ $\quad f(\alpha) + \mathbf{0}' = f(\alpha) + f(\mathbf{0})$

$\Rightarrow$ $\quad \mathbf{0}' = f(\mathbf{0})$ by left cancellation law.

(ii) If $\alpha \in U$, then $-\alpha \in U$. Also we have

$$\mathbf{0}' = f(\mathbf{0}) = f[\alpha + (-\alpha)] = f(\alpha) + f(-\alpha).$$

Now $f(\alpha) + f(-\alpha) = \mathbf{0}' \Rightarrow f(-\alpha) =$ the additive inverse of $f(\alpha)$

$\Rightarrow$ $\quad f(-\alpha) = -f(\alpha).$

2 Isomorphism of Vector Spaces

(Garhwal 2010B)

Definition: *Let $U(F)$ and $V(F)$ be two Vector spaces. Then a mapping*

$$f : U \to V$$

is called an isomorphism of U onto V, if

(i) *f is one-one,*

(ii) *f is onto,*

(iii) $f(a\alpha + b\beta) = a f(\alpha) + b f(\beta) \;\forall\; a, b \in F, \alpha, \beta \in U.$

Also then the two vector spaces U and V are said to be isomorphic and symbolically we write

$$U(F) \cong V(F).$$

The vector space $V(F)$ is also called the isomorphic image of the vector space $U(F)$.

If f is a homomorphism of $U(F)$ into $V(F)$, then f will become an isomorphism of U into V if f is one-one. Also in addition if f is onto V, then f will become an isomorphism of U onto V.

3 Isomorphism of Finite Dimensional Vector Spaces

Theorem 1: *Two finite dimensional vector spaces over the same field are isomorphic if and only if they are of the same dimension.* **(Garhwal 2006, 10B; Kumaun 12)**

Proof: First suppose that $U(F)$ and $V(F)$ are two finite dimensional vector spaces each of dimension n. Then to prove that

$$U(F) \cong V(F).$$

Let the sets of vectors

$$\{\alpha_1, \alpha_2, \ldots, \alpha_n\} \quad \text{and} \quad \{\beta_1, \beta_2, \ldots, \beta_n\}$$

be the bases of U and V respectively.

Any vector $\alpha \in U$ can be uniquely expressed as

$$\alpha = a_1\alpha_1 + a_2\alpha_2 + \ldots + a_n\alpha_n.$$

Let $f : U \in V$ be defined by

$$f(\alpha) = a_1\beta_1 + a_2\beta_2 + \ldots + a_n\beta_n.$$

$$
\begin{aligned}
&= \sup\left\{\frac{\pi^2\|\phi\|_H^2\|f\|_2^2}{6} : \|\phi\|_H \le 1\right\}\\
&= \frac{\pi^2\|f\|_2^2}{6} < \infty.
\end{aligned}
$$

If we take $\phi = \frac{\sqrt{6}}{\pi}\sum_{k=1}^{\infty}\frac{1}{k}\phi_k$, then actually the equality holds in (1.16) and hence $|m_\xi|_w(\mathbb{R},\mathbb{R}) = \frac{\pi^2\|f\|_2^2}{6}$. But $\|\xi\|_s(\mathbb{R}) = \infty$ was shown in (3).

(6) $\|\xi\|_s(\mathbb{R})^2 < |M_\xi|(\mathbb{R},\mathbb{R}) = \infty$: Let ξ be as in (2). Then we see that

$$
\begin{aligned}
\|\xi\|_s(\mathbb{R})^2 &= \sup\left\{\left\|\sum_{k=1}^{\infty}\alpha_k\Big\langle\xi\big(\{k\}\big),\phi_k\Big\rangle_H\right\|_2^2 : \alpha_k = 0,1,\ \|\phi_k\|_H \le 1,\ k \in \mathbb{N}\right\}\\
&= \sup\left\{\left\|\sum_{k=1}^{\infty}\alpha_k\big\langle g_k\phi,\phi_k\big\rangle_H\right\|_2^2 : \alpha_k = 0,1,\ \|\phi_k\|_H \le 1,\ k \in \mathbb{N}\right\}\\
&= \sup\left\{\left\|\sum_{k=1}^{\infty}\alpha_k g_k\right\|_2^2\|\phi\|_H^2 : -1 \le \alpha_k \le 1,\ k \in \mathbb{N}\right\}\\
&= \sup\left\{\sum_{j,k=1}^{\infty}\alpha_j\alpha_k(g_j,g_k)_2\|\phi\|_H^2 : -1 \le \alpha_k \le 1,\ k \in \mathbb{N}\right\}\\
&\le \alpha\|\phi\|_H^2 < \infty
\end{aligned}
$$

(cf. (1.15)). Clearly $|M_\xi|(\mathbb{R},\mathbb{R}) \ge |m_\xi|(\mathbb{R},\mathbb{R}) = \infty$ by (2).

Remark 25. As will be seen in Section 3, $\|\xi\|_s(A) < \infty$ if and only if $\|\xi\|_o(A) < \infty$ (cf. Theorem 3.15). Hence Example 24 (6) serves as one for which $\|\xi\|_o(\mathbb{R})^2 < |M_\xi|(\mathbb{R},\mathbb{R}) = \infty$. But it is possible to construct a $\xi \in ca(\mathfrak{B}, X)$ such that $\|\xi\|_s(\mathbb{R}) < \|\xi\|_o(\mathbb{R}) < \infty$.

3.2. Orthogonally scattered dilations

In this section we discuss the orthogonally scattered dilation of Hilbert space-valued measures. In doing this, we use the Grothendieck inequality and the notion of absolutely 2-summing operators. As in the previous section, let $(\Theta, \mathfrak{A})$ be a measurable space.

We begin with the integration of scalar-valued functions with respect to a Banach space-valued measure. By a **$\mathbb{C}$-valued $\mathfrak{A}$-simple** (or, merely, **simple**) **function** we mean a function f of the form $f = \sum_{k=1}^{n}\alpha_k 1_{A_k}$ for $\alpha_1, \dots, \alpha_n \in \mathbb{C}$ and $\{A_1, \dots, A_n\} \in \Pi(\Theta)$, where 1_A denotes the **indicator function** of A. $L^0(\Theta)$

denotes the set of all $\mathbb{C}$-valued $\mathfrak{A}$-simple functions on Θ. If f is a $\mathbb{C}$-valued function on Θ, then the **sup-norm,** $\|f\|_\infty$, of f is defined by $\|f\|_\infty = \sup_{t\in\Theta} |f(t)|$.

Definition 1. Let $\mathfrak{X}$ be a Banach space and $\xi \in ca(\mathfrak{A}, \mathfrak{X})$. $A \in \mathfrak{A}$ is said to be **ξ-null** if $\|\xi\|(A) = 0$. Thus **ξ-a.e.** (= **ξ-almost everywhere**) refers to the complement of a ξ-null set. The **ξ-essential sup-norm** $\|f\|_{\infty,\xi}$ of a $\mathbb{C}$-valued $\mathfrak{A}$-measurable function f on Θ is defined by

$$\|f\|_{\infty,\xi} = \inf\Big\{\alpha > 0 : \big[|f| \ge \alpha\big] \text{ is } \xi\text{-null}\Big\},$$

where $[|f| \ge \alpha] = \{t \in \Theta : |f(t)| \ge \alpha\}$. It is easy to check that $\|\cdot\|_{\infty,\xi}$ is actually a norm, where we identify two functions if they agree ξ-*a.e.* For a simple function $f = \sum_{k=1}^n \alpha_k 1_{A_k} \in L^0(\Theta)$, the **integral** of f over $A \in \mathfrak{A}$ with respect to ξ is defined by

$$\int_A f\,d\xi = \sum_{k=1}^n \alpha_k \xi(A_k \cap A). \tag{2.1}$$

In this case we have

$$\left\| \int_A f\,d\xi \right\|_{\mathfrak{X}} \le \|f\|_{\infty,\xi}\|\xi\|(A). \tag{2.2}$$

$L^\infty(\xi) = L^\infty(\xi\,;\mathbb{C})$ denotes the set of all $\mathbb{C}$-valued functions f on Θ such that $\|f_n - f\|_{\infty,\xi} \to 0$ for some sequence $\{f_n\}_{n=1}^\infty \subseteq L^0(\Theta)$. It is not hard to see that $L^\infty(\xi)$ is a Banach space with the norm $\|\cdot\|_{\infty,\xi}$. For $f \in L^\infty(\xi)$ let $\{f_n\}_{n=1}^\infty \subseteq L^0(\Theta)$ be as above. Then, $\{\int_A f_n\,d\xi\}_{n=1}^\infty \subseteq \mathfrak{X}$ is a Cauchy sequence in view of the inequality (2.2) since $\{f_n\}_{n=1}^\infty$ is Cauchy in $L^\infty(\xi)$. Thus we can define the **integral** of f over A with respect to ξ by

$$\int_A f\,d\xi = \lim_{n\to\infty} \int_A f_n\,d\xi.$$

A more sophisticated definition of the integral of $\mathbb{C}$-valued functions with respect to a Banach space-valued measure is given as follows.

Definition 2. Let $\mathfrak{X}$ be a Banach space and $\xi \in ca(\mathfrak{A}, \mathfrak{X})$. A $\mathbb{C}$-valued $\mathfrak{A}$-measurable function f on Θ is said to be **ξ-integrable in the DS-sense** if there is a sequence $\{f_n\}_{n=1}^\infty \subseteq L^0(\Theta)$ of simple functions such that

a) $f_n(t) \to f(t)$ ξ-*a.e.* t;

b) $\{\int_A f_n\,d\xi\}_{n=1}^\infty \subseteq \mathfrak{X}$ is a Cauchy sequence for every $A \in \mathfrak{A}$.

In this case the **integral** of f over A with respect to ξ is defined by

$$\int_A f\,d\xi = \lim_{n\to\infty} \int_A f_n\,d\xi, \tag{2.3}$$

which is also termed the **DS-integral.** The sequence $\{f_n\}_{n=1}^{\infty}$ is called a **determining sequence** for f. $L^1_{DS}(\xi) = L^1_{DS}(\xi\,;\mathbb{C})$ denotes the set of all $\mathbb{C}$-valued $\mathfrak{A}$-measurable functions on Θ which are ξ-integrable in the DS-sense.

Remark 3. Let $\xi \in ca(\mathfrak{A}, \mathfrak{X})$, $\mathfrak{X}$ being a Banach space. As was shown in Dunford and Schwartz [1, IV.10.7] we have the following.

(1) The DS-integral (2.3) is well-defined, i.e., it is independent of the determining sequences of simple functions.

(2) For $f \in L^1_{DS}(\xi)$ and $A \in \mathfrak{A}$ it holds that

$$\left\| \int_A f\,d\xi \right\|_{\mathfrak{X}} \le \|f\|_{\infty,\xi} \|\xi\|(A).$$

(3) $L^1_{DS}(\xi)$ is a linear space and the DS-integral is linear.

(4) $L^\infty(\xi)$ is a subspace of $L^1_{DS}(\xi)$.

(5) If $f \in L^1_{DS}(\xi)$ and $\xi_f(A) = \int_A f\,d\xi$ for $A \in \mathfrak{A}$, then $\xi_f \in ca(\mathfrak{A}, \mathfrak{X})$.

Moreover, the following are true.

(6) For $A \in \mathfrak{A}$ it holds that

$$\begin{aligned}\|\xi\|(A) &= \sup\left\{ \left\| \int_A f\,d\xi \right\|_{\mathfrak{X}} : f \in L^0(\Theta),\ \|f\|_{\infty,\xi} \le 1 \right\} \\ &= \sup\left\{ \left\| \int_A f\,d\xi \right\|_{\mathfrak{X}} : f \in L^1_{DS}(\xi),\ \|f\|_{\infty,\xi} \le 1 \right\}.\end{aligned}$$

This follows from Definition 1.1 and (2) above.

(7) For $f \in L^1_{DS}(\xi)$, $\|\xi_f\|(\Theta) = 0$ if and only if $f = 0$ ξ-*a.e.* Hence, if we identify $f, g \in L^1_{DS}(\xi)$ when $f = g$ ξ-*a.e.*, then

$$\|f\|_{s,\xi} = \|\xi_f\|(\Theta)$$

(*"s"* for semivariation) defines a norm in $L^1_{DS}(\xi)$, which may be termed the "semivariation norm" of f. In fact, assume that $\|\xi_f\|(\Theta) = 0$. Put

$$A_n = \left[0 < |f| < \frac{1}{n}\right] = \left\{ t \in \Theta : 0 < |f(t)| < \frac{1}{n} \right\}$$

for $n \in \mathbb{N}$. Then, $\|\xi\|(A_n) \to 0$ by Remark 1.2 (2) since $A_n \downarrow \emptyset$. If we set $B = [f \ne 0]$, then it holds that for $n \in \mathbb{N}$

$$\|\xi\|(B\backslash A_n) = \sup\left\{ \left\| \int_{B\backslash A_n} g\,d\xi \right\|_{\mathfrak{X}} : g \in L^1_{DS}(\xi),\ \|g\|_{\infty,\xi} \le 1 \right\}$$

$$\begin{aligned}&\le \sup\left\{\left\|\int_{B\setminus A_n} gnf\,d\xi\right\|_{\mathfrak{X}} : g \in L^1_{DS}(\xi),\ \|g\|_{\infty,\xi} \le 1\right\}\\ &\le n\|\xi_f\|(B\setminus A_n) \le n\|\xi_f\|(\Theta) = 0.\end{aligned}$$

Thus, $\|\xi\|(B) \le \|\xi\|(B\setminus A_n) + \|\xi\|(A_n) = \|\xi\|(A_n) \to 0$, so that $\|\xi\|(B) = 0$. Therefore $f = 0$ *ξ-a.e.*

Theorem 4. *If* $\mathfrak{X}$ *is a Banach space and* $\xi \in ca(\mathfrak{A}, \mathfrak{X})$, *then* $(L^1_{DS}(\xi), \|\cdot\|_{s,\xi})$ *is a Banach space and the set of all simple functions* $L^0(\Theta)$ *is dense in it. Moreover, the set* $\{\xi_f : f \in L^1_{DS}(\xi)\}$ *is a closed subspace of* $ca(\mathfrak{A}, \mathfrak{X})$.

Proof. Clearly $(L^1_{DS}(\xi), \|\cdot\|_{s,\xi})$ is a normed linear space. We first prove that $L^0(\Theta)$ is dense in $L^1_{DS}(\xi)$. Let $f \in L^1_{DS}(\xi)$ and $\varepsilon > 0$ be given. Define $A_n = [|f| > n]$ for $n \in \mathbb{N}$. Then $\|\xi_f\|(A_n) \to 0$ by Remark 1.2 (2) since $A_n \downarrow \emptyset$. Choose $n_0 \in \mathbb{N}$ such that $\|\xi_f\|(A_{n_0}) < \frac{\varepsilon}{2}$ and choose $g \in L^0(\Theta)$ such that $g = 0$ on A_{n_0} and $|g - f| < \frac{\varepsilon}{2\|\xi\|(A^c_{n_0})}$ on $A^c_{n_0}$. Then it holds that

$$\begin{aligned}\|g - f\|_{s,\xi} &= \|\xi_g - \xi_f\|(\Theta) \le \|\xi_{g-f}\|(A^c_{n_0}) + \|\xi_f\|(A_{n_0})\\ &\le \frac{\varepsilon}{2\|\xi\|(A^c_{n_0})}\|\xi\|(A^c_{n_0}) + \frac{\varepsilon}{2} = \varepsilon.\end{aligned}$$

Thus $L^0(\Theta)$ is dense in $L^1_{DS}(\xi)$.

To see that $L^1_{DS}(\xi)$ is a Banach space we only have to show the completeness of $L^1_{DS}(\xi)$. So let $\{f_n\}_{n=1}^\infty \subseteq L^1_{DS}(\xi)$ be a Cauchy sequence. Since $L^0(\Theta)$ is dense in $L^1_{DS}(\xi)$ we can find a sequence $\{g_n\}_{n=1}^\infty \subseteq L^0(\Theta)$ such that $\|g_n - f_n\|_{s,\xi} \to 0$ as $n \to \infty$. Note that $\{g_n\}_{n=1}^\infty$ is also a Cauchy sequence in $L^1_{DS}(\xi)$. We can assume that

$$\sum_{k=1}^\infty \|g_{k+1} - g_k\|_{s,\xi} \equiv \alpha < \infty,$$

since, otherwise we can consider a suitable subsequence of $\{g_n\}_{n=1}^\infty$. Put

$$B = \left\{t \in \Theta : \sum_{k=1}^\infty \left|g_{k+1}(t) - g_k(t)\right| = \infty\right\}$$

and we shall show that $\|\xi\|(B) = 0$. So suppose that $\|\xi\|(B) = \varepsilon > 0$. Define

$$B_n = \left\{t \in \Theta : \sum_{k=1}^n \left|g_{k+1}(t) - g_k(t)\right| > \frac{2\alpha}{\varepsilon}\right\}, \qquad n \in \mathbb{N}.$$

Letting $B_0 = \bigcup_{n=1}^\infty B_n$, we see that $B_n \uparrow B_0$ and $\|\xi\|(B_0\setminus B_n) \to 0$. Hence we can find $n_0 \in \mathbb{N}$ such that $\|\xi\|(B_{n_0}) > \frac{\varepsilon}{2}$ since $\|\xi\|(B_0) \ge \|\xi\|(B) = \varepsilon$. Thus we have

$$\alpha = \sum_{k=1}^\infty \|g_{k+1} - g_k\|_{s,\xi} \ge \sum_{k=1}^{n_0} \left\|\xi_{(g_{k+1}-g_k)}\right\|(B_{n_0})$$

$$\geq \big\| \xi_{\Sigma_{k=1}^{n_0} |g_{k+1} - g_k|} \big\| (B_{n_0}) \geq \frac{2\alpha}{\varepsilon} \|\xi\|(B_{n_0}) > \alpha,$$

a contradiction. Consequently $\|\xi\|(B) = 0$.

Define a function f on Θ by

$$f(t) = \begin{cases} g_1(t) + \sum\limits_{k=1}^{\infty} \big(g_{k+1}(t) - g_k(t)\big), & \text{if } t \in B^c \\ 0, & \text{if } t \in B \end{cases}$$

and observe that $g_n \to f$ ξ-*a.e.* and, for $A \in \mathfrak{A}$, $\{\int_A g_n \, d\xi\}_{n=1}^{\infty}$ is a Cauchy sequence in $\mathfrak{X}$, since for $n, m \in \mathbb{N}$

$$\begin{aligned} \left\| \int_A g_{n+m} \, d\xi - \int_A g_n \, d\xi \right\|_{\mathfrak{X}} &\leq \|\xi_{(g_{n+m} - g_n)}\|(\Theta) \\ &\leq \sum_{k=n}^{\infty} \|g_{k+1} - g_k\|_{s,\xi} \to 0 \qquad (n \to \infty), \end{aligned}$$

which implies that $f \in L^1_{DS}(\xi)$. Since $ca(\mathfrak{A}, \mathfrak{X})$ is complete (cf. Remark 1.2 (3)) there exists an $\eta \in ca(\mathfrak{A}, \mathfrak{X})$ such that $\|\xi_{g_n} - \eta\|(\Theta) \to 0$. But since $\xi_{g_n}(A) \to \xi_f(A)$ for $A \in \mathfrak{A}$, we see that $\eta = \xi_f$. Therefore $\|g_n - f\|_{s,\xi} \to 0$ and hence $\|f_n - f\|_{s,\xi} \to 0$. The last assertion is obvious. □

Let us now consider H-valued measures. If $\xi \in caos(\mathfrak{A}, H)$, then $\nu_\xi(\cdot) \equiv \|\xi(\cdot)\|_H^2 \in ca(\mathfrak{A}, \mathbb{R}^+)$. Note that ν_ξ is a control measure of ξ (cf. Remark 1.2 (2)). For $f \in L^0(\Theta)$ we can define the **integral** of f over $A \in \mathfrak{A}$ with respect to ξ by (2.1). Observe that for $f = \sum_{k=1}^n \alpha_k 1_{A_k} \in L^0(\Theta)$

$$\begin{aligned} \left\| \int_A f \, d\xi \right\|_H^2 &= \left(\sum_{j=1}^n \alpha_j \xi(A_j \cap A), \sum_{k=1}^n \alpha_k \xi(A_k \cap A) \right)_H \\ &= \sum_{j,k=1}^n \alpha_j \overline{\alpha}_k \big(\xi(A_j \cap A), \xi(A_k \cap A)\big)_H \\ &= \sum_{k=1}^n |\alpha_k|^2 \nu_\xi(A_k \cap A) \\ &= \int_A |f|^2 \, d\nu_\xi = \|1_A f\|_{2,\nu_\xi}^2, \end{aligned} \tag{2.4}$$

where $\|\cdot\|_{2,\nu_\xi}$ is the norm in $L^2(\nu_\xi) = L^2(\Theta, \nu_\xi)$. For $f \in L^2(\nu_\xi)$ we can find a sequence $\{f_n\}_{n=1}^{\infty} \subseteq L^0(\Theta)$ such that $\|f_n - f\|_{2,\nu_\xi} \to 0$ and $f_n \to f$ ξ-*a.e.*, since

ξ-*a.e.* and ν_ξ-*a.e.* are equivalent because of $\|\xi\|(A)^2 = \|\xi(A)\|_H^2 = \nu_\xi(A)$ for $A \in \mathfrak{A}$ by Theorem 1.5 (4). By (2.4) we have for $A \in \mathfrak{A}$

$$\begin{aligned}\left\| \int_A f_n \, d\xi - \int_A f_m \, d\xi \right\|_H &= \big\| 1_A (f_n - f_m) \big\|_{2,\nu_\xi} \\ &\le \|f_n - f_m\|_{2,\nu_\xi} \to 0 \qquad (n, m \to \infty),\end{aligned}$$

i.e., $\{\int_A f_n \, d\xi\}_{n=1}^\infty$ is a Cauchy sequence in H. Thus f is ξ-integrable in the DS-sense. Moreover, (2.4) holds for $f \in L^2(\nu_\xi)$ and $A \in \mathfrak{A}$. Consequently $L^2(\nu_\xi) \subseteq L^1_{DS}(\xi)$.

Actually we see that the equality $L^2(\nu_\xi) = L^1_{DS}(\xi)$ is valid. In fact, for any $f \in L^1_{DS}(\xi)$ we have that by (2.4)

$$\|f\|_{s,\xi} = \|\xi_f\|(\Theta) = \big\|\xi_f(\Theta)\big\|_H = \left\| \int_\Theta f \, d\xi \right\|_H = \|f\|_{2,\nu_\xi},$$

since $\xi_f \in caos(\mathfrak{A}, H)$, which can be easily verified, and we can apply Theorem 1.5 (4) again. Thus the closure of $L^0(\Theta)$ with respect to $\|\cdot\|_{s,\xi}$ and $\|\cdot\|_{2,\nu_\xi}$ are the same. Therefore we have the following.

Proposition 5. *If* $\xi \in caos(\mathfrak{A}, H)$, *then* $(L^2(\nu_\xi), \|\cdot\|_{2,\nu_\xi}) = (L^1_{DS}(\xi), \|\cdot\|_{s,\xi})$, *where* $\nu_\xi(\cdot) = \|\xi(\cdot)\|_H^2$.

Definition 6. $\xi \in ca(\mathfrak{A}, H)$ is said to have an **orthogonally scattered dilation** if there exist a Hilbert space $\mathfrak{H}$ containing H as a closed subspace and an $\eta \in caos(\mathfrak{A}, \mathfrak{H})$ such that $\xi = J\eta$, where $J : \mathfrak{H} \to H$ is the orthogonal projection. The triple $\{\eta, \mathfrak{H}, J\}$ is also called an **orthogonally scattered dilation** of ξ.

ξ is said to have a **spectral dilation** if there exist a Hilbert space $\mathfrak{H}$, a countably additive spectral measure $E(\cdot)$ in $\mathfrak{H}$, an operator $S \in B(\mathfrak{H}, H)$ and a vector $\psi \in \mathfrak{H}$ such that

$$\xi(\cdot) = SE(\cdot)\psi.$$

Now the question is: Does every measure $\xi \in ca(\mathfrak{A}, H)$ have an orthogonally scattered dilation? An affirmative answer will be given after some considerations.

Definition 7. Let $\mathfrak{X}$ and $\mathfrak{Y}$ be two normed linear spaces and $p > 0$. A linear operator $T : \mathfrak{X} \to \mathfrak{Y}$ is said to be **absolutely** p**-summing** if $\pi_p(T) < \infty$, where $\pi_p(T) = \inf\{C > 0 : (2.5) \text{ holds}\}$:

$$\left(\sum_{j=1}^n \|Tx_j\|_{\mathfrak{Y}}^p \right)^{\frac{1}{p}} \le C \sup \left\{ \left(\sum_{j=1}^n \big| x^*(x_j) \big|^p \right)^{\frac{1}{p}} : x^* \in \mathfrak{X}^*, \ \|x^*\|_{\mathfrak{X}^*} \le 1 \right\} \tag{2.5}$$

for any $n \in \mathbb{N}$ and $x_1, \dots, x_n \in \mathfrak{X}$. $\pi_p(T)$ is called the **absolutely p-summing norm** of T. We denote by $\Pi_p(\mathfrak{X}, \mathfrak{Y})$ the set of all absolutely p-summing operators from $\mathfrak{X}$ into $\mathfrak{Y}$.

Remark 8. Let $\mathfrak{W}, \mathfrak{X}, \mathfrak{Y}$ and $\mathfrak{Z}$ be Banach spaces.

(1) $(\Pi_p(\mathfrak{X}, \mathfrak{Y}), \pi_p(\cdot))$ is a Banach space for $1 \le p \le \infty$. In particular, $\Pi_\infty(\mathfrak{X}, \mathfrak{Y}) = B(\mathfrak{X}, \mathfrak{Y})$.

(2) Let $1 \le p < \infty$. If $T \in \Pi_p(\mathfrak{X}, \mathfrak{Y})$, $V \in B(\mathfrak{W}, \mathfrak{X})$ and $U \in B(\mathfrak{Y}, \mathfrak{Z})$, then $UTV \in \Pi_p(\mathfrak{W}, \mathfrak{Z})$ and $\pi_p(UTV) \le \|U\|\pi_p(T)\|V\|$.

(3) If $\mathfrak{H}$ and $\mathfrak{K}$ are Hilbert spaces, then $\Pi_2(\mathfrak{H}, \mathfrak{K}) = S(\mathfrak{H}, \mathfrak{K})$ and $\pi_2(T) = \|T\|_\sigma$ for $T \in S(\mathfrak{H}, \mathfrak{K})$ (cf. Wojtaszczyk [1, pp. 243–244] and Diestel, Jarchow and Tonge [1] (1995)).

Note that $(L^0(\Theta), \|\cdot\|_\infty)$ is a normed linear space and $(L^0(\Theta), \|\cdot\|_\infty)^* = fa(\mathfrak{A}, \mathbb{C})$, where $fa(\mathfrak{A}, \mathbb{C})$ is the Banach space of all $\mathbb{C}$-valued finitely additive measures on $\mathfrak{A}$ with the total variation norm $|\cdot|(\Theta)$ and the isometric isomorphism $U : fa(\mathfrak{A}, \mathbb{C}) \to L^0(\Theta)^*$ is given by

$$(U\nu)(f) = \int_\Theta f \, d\nu, \qquad f \in L^0(\Theta), \ \nu \in fa(\mathfrak{A}, \mathbb{C})$$

(cf. Lemma 3.3 in the next section). Here, the variation and the semivariation of a (scalar- or vector-valued) finitely additive measure are defined in the same manner as in Definition 1.1, and the integral with respect to a finitely additive measure is in Dunford and Schwartz [1, Chapter III].

We need one technical lemma.

Lemma 9. *Let $\nu_0 \in fa(\mathfrak{A}, \mathbb{R}^+)$ and define ν on $\mathfrak{A}$ by*

$$\nu(A) = \inf\left\{ \sum_{k=1}^{\infty} \nu_0(A_k) : \{A_k\}_{k=1}^{\infty} \text{ is a countable } \mathfrak{A}\text{-measurable partition of } A \right\}. \tag{2.6}$$

Then $\nu \in ca(\mathfrak{A}, \mathbb{R}^+)$ and $\nu(A) \le \nu_0(A)$ for every $A \in \mathfrak{A}$.

Proof. For $A \in \mathfrak{A}$ denote by $\Pi^c(A)$ the set of all countable $\mathfrak{A}$-measurable partitions of A. ν is finitely additive. In fact, let $A, B \in \mathfrak{A}$ be disjoint. Then we have

$$\begin{aligned}\nu(A \cup B) &= \inf\left\{ \sum_{k=1}^{\infty} \nu_0(C_k) : \{C_k\}_{k=1}^{\infty} \in \Pi^c(A \cup B) \right\} \\ &= \inf\left\{ \sum_{k=1}^{\infty} \bigl\{\nu_0(A \cap C_k) + \nu_0(B \cap C_k)\bigr\} : \{C_k\}_{k=1}^{\infty} \in \Pi^c(A \cup B) \right\}\end{aligned}$$

$$\geq \nu(A) + \nu(B).$$

On the other hand, let $\varepsilon > 0$ be given and choose $\{A_k\}_{k=1}^\infty \in \Pi^c(A)$ and $\{B_k\}_{k=1}^\infty \in \Pi^c(B)$ such that

$$\nu(A) > \sum_{k=1}^\infty \nu_0(A_k) - \frac{\varepsilon}{2}, \qquad \nu(B) > \sum_{k=1}^\infty \nu_0(B_k) - \frac{\varepsilon}{2}.$$

Then we have that

$$\begin{aligned} \nu(A) + \nu(B) &> \sum_{k=1}^\infty \big\{\nu_0(A_k) + \nu_0(B_k)\big\} - \varepsilon \\ &= \sum_{k=1}^\infty \nu_0(A_k \cup B_k) - \varepsilon \geq \nu(A \cup B) - \varepsilon. \end{aligned}$$

Thus $\nu(A) + \nu(B) \geq \nu(A \cup B)$. Consequently ν is finitely additive.

To show that ν is countably additive, let $\{A_n\}_{n=1}^\infty \subseteq \mathfrak{A}$ and $A_n \downarrow \emptyset$. For each $n \in \mathbb{N}$, $A_n = \bigcup_{k=n}^\infty (A_k \backslash A_{k+1})$ and $\{A_k \backslash A_{k+1}\}_{k=n}^\infty \in \Pi^c(A_n)$. Hence

$$\sum_{k=1}^\infty \nu_0(A_k \backslash A_{k+1}) \leq \nu_0(A_1) < \infty.$$

Thus $0 \leq \nu(A_n) \leq \sum_{k=n}^\infty \nu_0(A_k \backslash A_{k+1}) \to 0$ as $n \to \infty$. Therefore ν is countably additive. □

Now we can give some necessary and sufficient conditions for orthogonally scattered dilation.

Theorem 10. *Let $\xi \in ca(\mathfrak{A}, H)$. Then the following conditions are equivalent.*

(1) *ξ has an orthogonally scattered dilation.*

(2) *ξ has a spectral dilation.*

(3) *There exists a constant $C > 0$ such that for any $n \in \mathbb{N}$ and $f_1, \dots, f_n \in L^0(\Theta)$ it holds that*

$$\sum_{j=1}^n \bigg\| \int_\Theta f_j \, d\xi \bigg\|_H^2 \leq C \bigg\| \sum_{j=1}^n |f_j|^2 \bigg\|_\infty. \tag{2.7}$$

(4) *The operator $S_\xi : (L^0(\Theta), \|\cdot\|_\infty) \to H$ is absolutely 2-summing, where S_ξ is defined by $S_\xi f = \int_\Theta f \, d\xi$ for $f \in L^0(\Theta)$.*

(5) *There exists a positive finite measure $\nu \in ca(\mathfrak{A}, \mathbb{R}^+)$ such that*

$$\bigg\| \int_\Theta f \, d\xi \bigg\|_H^2 \leq \int_\Theta |f|^2 \, d\nu, \qquad f \in L^0(\Theta). \tag{2.8}$$

In this case ν *is called a* **2-majorant** *of* ξ.

Proof. (1) $\Rightarrow$ (2). Suppose that ξ has an orthogonally scattered dilation $\{\eta, \mathfrak{H}, J\}$, so that $\xi = J\eta$ where $J : \mathfrak{H} \to H$ is the orthogonal projection. We can assume that

$$\mathfrak{H} = \mathfrak{S}_0\big\{\eta(A) : A \in \mathfrak{A}\big\},$$

the closed subspace of $\mathfrak{H}$ generated by the set $\{\eta(A) : A \in \mathfrak{A}\}$. For $A \in \mathfrak{A}$ let $E(A)$ be the orthogonal projection of $\mathfrak{H}$ onto $\mathfrak{H}(A) = \mathfrak{S}_0\{\eta(A \cap B) : B \in \mathfrak{A}\}$. Then it is not hard to check that $E(\cdot)$ is a countably additive spectral measure in $\mathfrak{H}$ such that

$$\eta(A) = E(A)\eta(\Theta), \qquad A \in \mathfrak{A}.$$

Therefore, $\xi(\cdot) = JE(\cdot)\eta(\Theta)$, i.e., ξ has a spectral dilation.

(2) $\Rightarrow$ (3). Suppose that (2) holds, so that $\xi(\cdot) = SE(\cdot)\psi$ as stated in Definition 6. Note that $\eta(\cdot) = E(\cdot)\psi \in caos(\mathfrak{A}, \mathfrak{H})$ and $\nu(\cdot) = \|\eta(\cdot)\|_{\mathfrak{H}}^2 \in ca(\mathfrak{A}, \mathbb{R}^+)$ with the total mass $\nu(\Theta) = \|\psi\|_{\mathfrak{H}}^2$. Now for any $n \in \mathbb{N}$ and $f_1, \dots, f_n \in L^0(\Theta)$ we have

$$\begin{aligned}\sum_{j=1}^{n} \left\| \int_{\Theta} f_j \, d\xi \right\|_H^2 &= \sum_{j=1}^{n} \left\| S \int_{\Theta} f_j \, d\eta \right\|_H^2 \\ &\le \|S\|^2 \sum_{j=1}^{n} \int_{\Theta} |f_j|^2 \, d\nu \le \|S\|^2 \|\psi\|_{\mathfrak{H}}^2 \left\| \sum_{j=1}^{n} |f_j|^2 \right\|_{\infty}.\end{aligned}$$

Thus (2.7) holds with $C = \|S\|^2 \|\psi\|_{\mathfrak{H}}^2$.

(3) $\Leftrightarrow$ (4). Since $L^0(\Theta)^* = fa(\mathfrak{A}, \mathbb{C})$ it is sufficient to show that for any $n \in \mathbb{N}$ and $f_1, \dots, f_n \in L^0(\Theta)$

$$\left\| \sum_{j=1}^{n} |f_j|^2 \right\|_{\infty} = \sup \left\{ \sum_{j=1}^{n} \left| \int_{\Theta} f_j \, d\nu \right|^2 : \nu \in fa(\mathfrak{A}, \mathbb{C}),\ |\nu|(\Theta) \le 1 \right\}. \tag{2.9}$$

The inequality "$\le$" is seen from

$$\begin{aligned}\text{LHS of (2.9)} &= \sup_{t \in \Theta} \sum_{j=1}^{n} \big| f_j(t) \big|^2 \\ &= \sup_{t \in \Theta} \int_{\Theta} \sum_{j=1}^{n} |f_j|^2 \, d\delta_t \le \text{RHS of (2.9)},\end{aligned}$$

where δ_t is the point mass at $t \in \Theta$, i.e., $\delta_t(A) = 1$ if $t \in A$ and $= 0$ otherwise. To see the converse inequality "$\ge$" let $\nu \in fa(\mathfrak{A}, \mathbb{C})$ be such that $|\nu|(\Theta) \le 1$ and $f_1, \dots, f_n \in L^0(\Theta)$ be arbitrary. We can write them as

$$f_j = \sum_{k=1}^{q} \alpha_{j,k} 1_{A_k}, \qquad 1 \le j \le n,$$

where $\{A_1, \dots, A_q\} \in \Pi(\Theta)$. Then we see that

$$\begin{aligned}\sum_{j=1}^{n} \left| \int_{\Theta} f_j \, d\nu \right|^2 &= \sum_{j=1}^{n} \sum_{k,\ell=1}^{q} \nu(A_k)\overline{\nu(A_\ell)}\alpha_{j,k}\overline{\alpha}_{j,\ell} = \sum_{k,\ell=1}^{q} \nu(A_k)\overline{\nu(A_\ell)}(\mathbf{x}_k, \mathbf{x}_\ell)_{\mathbb{C}^n} \\ &= \left\| \sum_{k=1}^{q} \nu(A_k)\mathbf{x}_k \right\|_{\mathbb{C}^n}^2 \le \left(\sum_{k=1}^{q} \big|\nu(A_k)\big| \|\mathbf{x}_k\|_{\mathbb{C}^n} \right)^2 \\ &\le \max_{1\le k\le q} \|\mathbf{x}_k\|_{\mathbb{C}^n}^2 \left(\sum_{k=1}^{q} |\nu(A_k)| \right)^2 \le \max_{1\le k\le q} \sum_{j=1}^{n} |\alpha_{j,k}|^2 |\nu|(\Theta)^2 \\ &\le \left\| \sum_{j=1}^{n} |f_j|^2 \right\|_{\infty},\end{aligned}$$

where $\mathbf{x}_k = (\alpha_{j,k})_{j=1}^{q} \in \mathbb{C}^n$ for $1 \le k \le q$, and $(\cdot,\cdot)_{\mathbb{C}^n}$ and $\|\cdot\|_{\mathbb{C}^n}$ are the inner product and the norm in $\mathbb{C}^n$, respectively.

(3) ⇒ (5). Assume that (3) holds. Let $L^0_{\mathbb{R}}(\Theta) = \{f \in L^0(\Theta) : f \text{ is } \mathbb{R}\text{-valued}\}$ and define $\rho_0(f)$ for $f \in L^0_{\mathbb{R}}(\Theta)$ by

$$\rho_0(f) = \inf \left\{ \sup_{t\in\Theta} \left\{ Cf(t) + C\sum_{k=1}^{n} |f_k(t)|^2 - \sum_{k=1}^{n} \left\| \int_{\Theta} f_k \, d\xi \right\|_H^2 \right\} : \right. \\ \left. f_1, \dots, f_n \in L^0_{\mathbb{R}}(\Theta),\, n \in \mathbb{N} \right\}.$$

Then we see that ρ_0 is a **sublinear** (i.e., positive homogeneous and subadditive) functional on $L^0_{\mathbb{R}}(\Theta)$ such that

$$C \inf_{t\in\Theta} f(t) \le \rho_0(f) \le C \sup_{t\in\Theta} f(t).$$

It follows from the Hahn-Banach Theorem that there exists a linear functional ρ on $L^0_{\mathbb{R}}(\Theta)$ such that $\rho(f) \le \rho_0(f)$ for $f \in L^0_{\mathbb{R}}(\Theta)$. Hence we have that

$$C \inf_{t\in\Theta} f(t) \le -\rho_0(-f) \le \rho(f) \le \rho_0(f) \le C \sup_{t\in\Theta} f(t).$$

Moreover, (2.7) implies that for $f \in L^0(\Theta)$

$$\rho_0(-|f|^2) \le \sup_{t\in\Theta} \left\{ -C|f(t)|^2 + C|f(t)|^2 - \left\| \int_{\Theta} f \, d\xi \right\|_H^2 \right\} = -\left\| \int_{\Theta} f \, d\xi \right\|_H^2$$

and hence by $-\rho(|f|^2) = \rho(-|f|^2) \le \rho_0(-|f|^2)$

$$\left\| \int_{\Theta} f \, d\xi \right\|_H^2 \le \rho(|f|^2). \tag{2.10}$$

Define ν_0 on $\mathfrak{A}$ by $\nu_0(A) = \rho(1_A)$ for $A \in \mathfrak{A}$. Then it is easily verified that $\nu_0 \in fa(\mathfrak{A}, \mathbb{R}^+)$ since $\nu_0(\Theta) = \rho(1_\Theta) = C$ and ρ is linear. Furthermore, define ν on $\mathfrak{A}$ by (2.6). Then, Lemma 9 implies that ν is countably additive and $\nu(A) \le \nu_0(A)$ for $A \in \mathfrak{A}$.

Now we shall show that (2.8) holds. So let $f = \sum_{j=1}^n \alpha_j 1_{A_j} \in L^0(\Theta)$. For $j = 1, \dots, n$ and $q \in \mathbb{N}$ let $\{A_{j,k}^q\}_{k=1}^\infty \subseteq \mathfrak{A}$ be a countable partition of A_j such that $\lim_{q\to\infty} \sum_{k=1}^\infty \nu_0(A_{j,k}^q) = \nu(A_j)$, which can be a nonincreasing limit. Define for $q, N \in \mathbb{N}$

$$f_N^q = \sum_{j=1}^n \sum_{k=1}^N \alpha_j 1_{A_{j,k}^q}$$

and observe that $f_N^q \to f$, pointwise, as $N \to \infty$ for $q \in \mathbb{N}$ and that by (2.10)

$$\left\| \int_\Theta f_N^q \, d\xi \right\|_H^2 \le \sum_{j=1}^n |\alpha_j|^2 \sum_{k=1}^N \nu_0(A_{j,k}^q), \qquad N, q \in \mathbb{N}.$$

Since for $q \in \mathbb{N}$ we have that

$$\int_\Theta f_N^q \, d\xi = \sum_{j=1}^n \alpha_j \xi\Big(\bigcup_{k=1}^N A_{j,k}^q \Big) \to \sum_{j=1}^n \alpha_j \xi(A_j) = \int_\Theta f \, d\xi \qquad (N \to \infty),$$

it follows that

$$\left\| \int_\Theta f \, d\xi \right\|_H^2 \le \sum_{j=1}^n |\alpha_j|^2 \sum_{k=1}^\infty \nu_0(A_{j,k}^q), \qquad q \in \mathbb{N}.$$

Letting $q \to \infty$, we see that the RHS of the above inequality converges in an nonincreasing manner to $\sum_{j=1}^n |\alpha_j|^2 \nu(A_j) = \int_\Theta |f|^2 \, d\nu$ and the desired inequality (2.8) is obtained.

(5) ⇒ (1). Suppose that (5) holds. Define $m : \mathfrak{A} \times \mathfrak{A} \to \mathbb{C}$ by

$$m(A, B) = \nu(A \cap B) - m_\xi(A, B), \qquad A, B \in \mathfrak{A},$$

where $m_\xi(A, B) = (\xi(A), \xi(B))_H$. To see that m is a positive definite kernel let $n \in \mathbb{N}$, $A_1, \dots, A_n \in \mathfrak{A}$ and $\alpha_1, \dots, \alpha_n \in \mathbb{C}$. If $f = \sum_{i=1}^n \alpha_i 1_{A_i} \in L^0(\Theta)$, then (2.8) implies that

$$\begin{aligned} \sum_{i=1}^n \sum_{j=1}^n \alpha_i \overline{\alpha}_j m_\xi(A_i, A_j) &= \left\| \sum_{i=1}^n \alpha_i \xi(A_i) \right\|_H^2 = \left\| \int_\Theta f \, d\xi \right\|_H^2 \\ &\le \int_\Theta |f|^2 \, d\nu = \sum_{i=1}^n \sum_{j=1}^n \alpha_i \overline{\alpha}_j \nu(A_i \cap A_j). \end{aligned}$$

Hence, it follows that

$$\sum_{i=1}^{n}\sum_{j=1}^{n}\alpha_i\overline{\alpha}_j m(A_i,A_j)=\sum_{i=1}^{n}\sum_{j=1}^{n}\alpha_i\overline{\alpha}_j\big[\nu(A_i\cap A_j)-m_\xi(A_i,A_j)\big]\geq 0.$$

Thus, m is a positive definite kernel and hence there exist the RKHS $\mathfrak{H}_m$ of m and a $\zeta\in ca(\mathfrak{A},\mathfrak{H}_m)$ such that $m=m_\zeta$, i.e., $m(A,B)=(\zeta(A),\zeta(B))_{\mathfrak{H}_m}$ for $A,B\in\mathfrak{A}$. Put $\mathfrak{H}=H\oplus\mathfrak{H}_m$, the direct sum, and let $J:\mathfrak{H}\to H$ be the orthogonal projection, where H is identified with $H\oplus\{0\}\subset\mathfrak{H}$. Now define $\eta\in ca(\mathfrak{A},\mathfrak{H})$ by

$$\eta(A)=\big(\xi(A),0\big)+\big(0,\zeta(A)\big)=\big(\xi(A),\zeta(A)\big),\qquad A\in\mathfrak{A}.$$

Then we see that η is orthogonally scattered since for disjoint $A,B\in\mathfrak{A}$ it holds that

$$\begin{aligned}\big(\eta(A),\eta(B)\big)_{\mathfrak{H}}&=\big((\xi(A),\zeta(A)),(\xi(B),\zeta(B))\big)_{\mathfrak{H}}\\&=\big(\xi(A),\xi(B)\big)_H+\big(\zeta(A),\zeta(B)\big)_{\mathfrak{H}_m}\\&=m_\xi(A,B)+m(A,B)\\&=\nu(A\cap B)=0.\end{aligned}$$

Moreover, it holds that $\xi=J\eta$. Therefore $\{\eta,\mathfrak{H},J\}$ is an orthogonally scattered dilation of ξ. □

The condition (2.7) is of particular interest and is closely related to the following Grothendieck inequality (cf. Grothendieck [1, p. 59]). The proof may be found in several books such as Diestel [1, pp. 174–180], Jameson [1, pp. 104–108], Lindenstrauss and Tzafriri [1, pp. 68–69] and Wojtaszczyk [1, pp. 210–211].

Theorem 11 (Grothendieck inequality). *Let $n\in\mathbb{N}$ be arbitrary and $\mathfrak{H}$ be any Hilbert space. If $(a_{jk})_{j,k=1}^n$ is an $n\times n$ matrix such that*

$$\left|\sum_{j,k=1}^{n}a_{jk}s_jt_k\right|\leq\alpha\max_{1\leq j,k\leq n}|s_j||t_k|\tag{2.11}$$

for every $s_1,\dots,s_n,t_1,\dots,t_n\in\mathbb{C}$, then, for every $x_1,\dots,x_n,y_1,\dots,y_n\in\mathfrak{H}$ it holds that

$$\left|\sum_{j,k=1}^{n}a_{jk}(x_j,y_k)_{\mathfrak{H}}\right|\leq K_G\,\alpha\max_{1\leq j,k\leq n}\|x_j\|_{\mathfrak{H}}\|y_k\|_{\mathfrak{H}},\tag{2.12}$$

where $K_G>0$ is the **Grothendieck universal constant**, *independent of n and $\mathfrak{H}$, and $(\cdot,\cdot)_{\mathfrak{H}}$ and $\|\cdot\|_{\mathfrak{H}}$ are the inner product and the norm in $\mathfrak{H}$, respectively.*

Using the above inequality we can derive the condition (2.7) as follows.

Lemma 12. *Let* $\xi \in ca(\mathfrak{A}, H)$*. Then there exists a* $C > 0$ *such that for any* $q \in \mathbb{N}$ *and* $f_1, \dots, f_q \in L^0(\Theta)$

$$\sum_{\ell=1}^{q} \left\| \int_\Theta f_\ell \, d\xi \right\|_H^2 \leq C \left\| \sum_{\ell=1}^{q} |f_\ell|^2 \right\|_\infty . \tag{2.13}$$

Proof. Let $f = \sum_{j=1}^n \alpha_j 1_{A_j},\ g = \sum_{k=1}^n \beta_k 1_{A_k} \in L^0(\Theta)$. Then we have that

$$\begin{aligned}\Big| \sum_{j,k=1}^{n} \alpha_j \overline{\beta}_k \big(\xi(A_j), \xi(A_k)\big)_H \Big| &= \left| \left(\int_\Theta f \, d\xi, \int_\Theta g \, d\xi \right)_H \right| \\ &\leq \left\| \int_\Theta f \, d\xi \right\|_H \left\| \int_\Theta g \, d\xi \right\|_H \\ &\leq \|\xi\|(\Theta)^2 \|f\|_\infty \|g\|_\infty \\ &= \|\xi\|(\Theta)^2 \max_{1 \leq j,k \leq n} |\alpha_j||\beta_k|. \end{aligned} \tag{2.14}$$

Let $f_1, \dots, f_q \in L^0(\Theta)$ and write them as

$$f_\ell = \sum_{j=1}^{n} \alpha_{\ell,j} 1_{A_j}, \qquad 1 \leq \ell \leq q,$$

where $\{A_1, \dots, A_n\} \in \Pi(\Theta)$. Then it holds that

$$\begin{aligned}\sum_{\ell=1}^{q} \left\| \int_\Theta f_\ell \, d\xi \right\|_H^2 &= \sum_{\ell=1}^{q} \sum_{j,k=1}^{n} \alpha_{\ell,j} \overline{\alpha}_{\ell,k} \big(\xi(A_j), \xi(A_k)\big)_H \\ &= \sum_{j,k=1}^{n} \left(\sum_{\ell=1}^{q} \alpha_{\ell,j} \overline{\alpha}_{\ell,k} \right) \big(\xi(A_j), \xi(A_k)\big)_H. \end{aligned} \tag{2.15}$$

Considering the $n \times n$ matrix $((\xi(A_j), \xi(A_k))_H)_{j,k=1}^n$ and the vectors $\mathbf{x}_j = (\alpha_{\ell,j})_{\ell=1}^q \in \mathbb{C}^q,\ 1 \leq j \leq n$ and noting that $(\mathbf{x}_j, \mathbf{x}_k)_{\mathbb{C}^q} = \sum_{\ell=1}^q \alpha_{\ell,j} \overline{\alpha}_{\ell,k}$, we can apply Theorem 11, so that we have by (2.11), (2.12), (2.14) and (2.15)

$$\begin{aligned}\sum_{\ell=1}^{q} \left\| \int_\Theta f_\ell \, d\xi \right\|_H^2 &\leq K_G \|\xi\|(\Theta)^2 \max_{1 \leq j \leq n} \|\mathbf{x}_j\|_{\mathbb{C}^q}^2 \\ &= K_G \|\xi\|(\Theta)^2 \max_{1 \leq j \leq n} \sum_{\ell=1}^{q} |\alpha_{\ell,j}|^2 \end{aligned}$$

$$= K_G \|\xi\|(\Theta)^2 \left\| \sum_{\ell=1}^{q} |f_\ell|^2 \right\|_\infty,$$

which implies that (2.13) holds with $C = K_G\|\xi\|(\Theta)^2$. □

It follows from Theorem 10 and Lemma 12 that:

Theorem 13. *Every* $\xi \in ca(\mathfrak{A}, H)$ *has an orthogonally scattered dilation.*

In this chapter we assumed that H is separable. However, Theorem 13 is true for arbitrary Hilbert space H. It follows from Lemma 12 and the proof of Theorem 10 that, if $\xi \in ca(\mathfrak{A}, H)$ has a spectral dilation $\xi = SE\psi$, then we can take S and ψ to satisfy $\|S\|\|\psi\|_{\mathfrak{H}} \le \sqrt{K_G}\|\xi\|(\Theta)$.

3.3. Gramian orthogonally scattered dilations

In this section we consider the gramian orthogonally scattered dilation of $X = L_0^2(\Omega\,; H)$-valued measures. Although every Hilbert space-valued (bounded) measure has an orthogonally scattered dilation, not every X-valued measure has a gramian orthogonally scattered dilation. So we shall give some necessary and sufficient conditions for that. As before let $(\Theta, \mathfrak{A})$ be a measurable space.

Definition 1. An X-valued measure $\xi \in ca(\mathfrak{A}, X)$ is said to have a **gramian orthogonally scattered dilation** if there exist a normal Hilbert $B(H)$-module Y containing X as a closed submodule and an $\eta \in cagos(\mathfrak{A}, Y)$ such that $\xi = P\eta$, where $P : Y \to X$ is the gramian orthogonal projection. The triple $\{\eta, Y, P\}$ is also called a **gramian orthogonally scattered dilation** of ξ.

Let $\xi \in ca(\mathfrak{A}, X)$ and consider $L_0^2(\Omega)$-valued measures $\xi_\phi \in ca(\mathfrak{A}, L_0^2(\Omega))$ for $\phi \in H$, i.e., $\xi_\phi(\cdot) = \langle \xi(\cdot), \phi\rangle_H$ (cf. (1.2) and Definition 1.4 (3)). It follows from Theorem 2.13 that, for each $\phi \in H$, ξ_ϕ has an orthogonally scattered dilation $\{\eta_\phi, \mathfrak{K}_\phi, J_\phi\}$, i.e., there exist a Hilbert space $\mathfrak{K}_\phi$ and $\eta_\phi \in caos(\mathfrak{A}, \mathfrak{K}_\phi)$ such that $\xi_\phi = J_\phi \eta_\phi$, where $J_\phi : \mathfrak{K}_\phi \to L_0^2(\Omega)$ is the orthogonal projection. If $\dim H = q < \infty$, then, letting $\{\phi_1, \dots, \phi_q\}$ be an orthonormal basis in H, we put $\mathfrak{K} = \bigoplus_{j=1}^q \mathfrak{K}_{\phi_j}$, $\eta = (\eta_{\phi_j})_{j=1}^q$ and $J = \bigoplus_{j=1}^q J_{\phi_j}$. So we see that $\{\eta, \mathfrak{K}, J\}$ is a gramian orthogonally scattered dilation of ξ. If $\dim H = \infty$, we have to work a bit more.

Let $\xi \in ca(\mathfrak{A}, X)$. $L^0(\Theta\,; B(H))$ denotes the set of all $B(H)$-valued $\mathfrak{A}$-simple functions on Θ. The **sup-norm** $\|\Phi\|_\infty$ of $\Phi \in L^0(\Theta\,; B(H))$ is defined by $\|\Phi\|_\infty = \sup_{t\in\Theta} \|\Phi(t)\|$. The **integral** of $\Phi \in L^0(\Theta\,; B(H))$ with respect to ξ over $A \in \mathfrak{A}$ is

Pág. 41(45) 2.5 Axiomatic Design Theory. (ADT)

ADT uses two basic axioms as several other corollaries and theorems, to support the design theory.

First axiom is to maintain the independence of FRs and the

Second axiom is to minimize the information content of the resulting design solution.

The act of design consists of the mapping of FRs into design parameters (DPs), and eventually to arrive at a solution, which satisfies these two axiomas (axioms).

⇒ Parallelogram representation of the velocity vectors.

transformations using the

E :G & *< 8H ?=25 5=2 9*5
(%' " <

Since the total kinetic energy is conserved, taking the velocities obtained above for the neutron and for the target, before and after the elastic collision, the energy conservation equation for the CM system is given by,

$$\frac{1}{2}(1)\left(\frac{Av_L}{A+1}\right)^2+\frac{1}{2}(A)\left(\frac{v_L}{A+1}\right)^2=\frac{1}{2}(1)\left(v_C'\right)^2+\frac{1}{2}(A)\left(V_C'\right)^2 \tag{1.32}$$

Using the relation $v_C' = AV_C'$ in the above, the velocities in the CM system after the collision can be obtained in terms of the neuron velocity in the L system before collision, that is,

$$v_C' = \frac{Av_L}{A+1} \tag{1.33}$$

and

$$V_C' = \frac{v_L}{A+1} \tag{1.34}$$

Comparing the velocities after the collision with those before the collision in the CM system, both in terms of the initial neutron velocity in the LAB system, it is seen that the magnitudes of the CM system velocities do not change on account of the collision, though there is a change in the direction, indicated as φ in Fig. 1.20.

When observed from the LAB system, the CM system is moving with a velocity V_{CM}. The final velocities of the neutron in the LAB and CM systems, namely, v_L' and v_C' may therefore be obtained by the transformation using the parallelogram law of vectors, as given in the Fig. 1.21.

By vector addition we get

$$v_L'^2 = V_{CM}^2 + v_C'^2 + 2(V_{CM})(v_C')\cos\varphi \tag{1.35}$$

$$v_L'^2 = \left(\frac{v_L}{A+1}\right)^2 + \left(\frac{Av_L}{A+1}\right)^2 + 2\left(\frac{v_L}{A+1}\right)\left(\frac{Av_L}{A+1}\right)\cos\varphi \tag{1.36}$$

$$v_L'^2 = v_L^2\frac{A^2+2A\cos\varphi+1}{(A+1)^2} \tag{1.37}$$

The above equation connects the velocity of the neutron after the collision to that before the collision in the LAB system. The appearance of squares of the velocities obviously indicates the relationship in kinetic energies after and before the collision. Thus

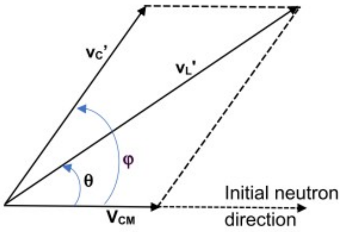

FIG. 1.21 Parallelogram representation of the velocity vectors.

$$E_L' = E_L \frac{A^2 + 2A\cos\varphi + 1}{(A+1)^2} \tag{1.38}$$

The maximum of the kinetic energy $E_{\max}$ after the collision occurs when $\cos\varphi = 1$, that is, when the scattering angle is zero. Thus

$$E_{\max} = E_L \tag{1.39}$$

The minimum energy $E_{\min}$ occurs when $\cos\varphi = -1$, that is, when the scattering angle $\varphi = \pi$ (=180°). Thus

$$E_{\min} = E_L \frac{A^2 - 2A + 1}{(A+1)^2} = \frac{(A-1)^2}{(A+1)^2} E_L = \alpha E_L \tag{1.40}$$

where

$$\alpha = \frac{(A-1)^2}{(A+1)^2} \tag{1.41}$$

Eq. (1.39) indicates the obvious fact that the projectile cannot gain energy by colliding with a stationary target, and at most, it can scatter without an energy loss. The minimum energy $E_{\min}$ depends on α, which is a property of the target through its mass. It is also clear that, only when $A = 1$, that is, when the target is ^{1}H, $E_{\min} = 0$, which means the neutron can lose all its energy in the elastic collision. For elastic collision with any other nuclide, the neutron has no chance to lose its entire energy. The energy lost in the collision is given by $E_L - E_L'$. The maximum energy loss occurs when the scattered neutron comes out with the minimum energy $= \alpha E_L$, which is given by

$$E_L - E_{\min} = E_L - \alpha E_L = (1-\alpha)E_L \tag{1.42}$$

As A increases, the value of α increases toward unity, indicating lower energy loss. Thus elastic scattering with a heavy nuclide (say ^{238}U) will result in little energy loss, and substantial energy loss is possible only with light nuclides.

In general, if the incident neutron energy is E, then the probability that the elastically scattered neutron has its energy in the range E' and $E' + \mathrm{d}E'$ is given by

$$P_{\mathrm{el}}(E \to E')\mathrm{d}E' = \frac{\mathrm{d}E'}{(E - \alpha E)} \tag{1.43}$$

This is based on the assumption that the elastic scattering is isotropic in the CM system, which is practically true except for very light nuclides. The following relationships, not derived herein, are also important results from the elastic scattering kinematics:

Referring to the velocity vectors in the LAB and the CM systems, it is easy to see that

$$\cos\theta = \frac{A\cos\varphi + 1}{\sqrt{(A^2 + 2A\cos\varphi + 1)}} \tag{1.44}$$

is the cosine of the scattering angle in the LAB system. The average value of this quantity is approximately given by

$$\overline{\mu_L} = \overline{\cos\theta} = \frac{2}{3A} \tag{1.45}$$

The energy of a scattered neutron with initial energy E_1, will be in the range between E_1 and αE_1, as seen above. If the energy after scattering is E_2. The energy decrement is E_1–E_2. The decrement in the logarithms of the two energies, namely, $\ln E_1 - \ln E_2$ or $\ln(E_1/E_2)$ is called the "logarithmic energy decrement." The average of this is an important quantity, called the "average logarithmic energy decrement" of elastic scattering, given as

$$\xi = 1 + \frac{(A-1)^2}{2\mathrm{A}} \ln\left(\frac{A-1}{A+1}\right) = 1 + \frac{\alpha}{1-\alpha} \ln\alpha \tag{1.46}$$

It is interesting to note that the average logarithmic energy decrement of a neutron in an elastic scattering collision with a target of mass A (i.e., A times as heavy as the neutron) depends on A, but not on its initial energy. In other words, the ratio of the initial to the final energies, that is, E_1/E_2, of the neutron in an elastic scattering, on an average, is always the same.

1.12.2 The moderator

All the quantities, called the "scattering parameters," derived above, are important, specifically, in the selection of materials for a "moderator," whose function in a reactor is to slow down fast neutrons to very low speeds. As seen in Eqs. (1.40)–(1.43), only a light nuclide with $\alpha << 1$ appears suitable for the purpose. Further, the average number of elastic collisions a neutron needs for a nuclide, such that its energy is reduced from a given initial energy E_1 to a specified final energy E_2 is given by

$$\text{Average number of collisions} = \frac{\ln\left(\frac{E_1}{E_2}\right)}{\xi}. \tag{1.47}$$

Nuclear Forces

3.1 The Interactions between Nucleons

Gluons and quarks are confined in a limited space, and the forces in nuclei are produced due to the interchange of mesons whose field is similar to the electromagnetic field, yet is of a much shorter range. Keeping in mind the above fact, we will calculate the interaction radius of nucleons in nuclei. For the $^{197}_{79}Au$ nucleus, both neutrons and protons are diffusing in the region $R_d = 2R$ of physical vacuum defined by radius R in the coordinates of the center of mass. The formula A[21] for calculating the distance of interaction of an external proton with bound energy 7.73 MeV can be given as follows:

$$R_d = 2R = \frac{\hbar}{\sqrt{2m|E_B|}} = 1.638 \cdot 10^{-15}\,\text{m} = 1.638\,\text{fm}. \tag{3.1}$$

Yukawa declared that the interaction with a short interaction radius was generated for field quanta with negligible rest mass. The electromagnetic field is occupied by photons of zero rest mass that satisfy the wave equation

$$\left(\nabla^2 - \frac{1}{c^2}\frac{\partial^2}{\partial t^2}\right) U(r,t) = 0, \tag{3.2}$$

which can be written as

$$-p^2 + \frac{1}{c^2}E^2 = 0. \tag{3.3}$$

The corresponding relativistic equation for particles having the rest mass is

$$-p^2 - m^2c^2 + \frac{1}{c^2}E^2 = 0. \tag{3.4}$$

After the introduction of the quantum mechanics operators

$$\vec{p} = -i\hbar\vec{\nabla}, \quad E = i\hbar\frac{\partial}{\partial t}, \tag{3.5}$$

we can transform it into the below Klein–Gordon equation for a spinless relativistic free particle

$$\left(\nabla^2 - \frac{m^2c^2}{\hbar^2} - \frac{1}{c^2}\frac{\partial^2}{\partial t^2}\right)\phi = 0. \tag{3.6}$$

This wave equation for the time-independent meson field

$$(\nabla^2 - \mu^2)\phi = 0, \quad \mu = \frac{mc}{\hbar} \tag{3.7}$$

was solved similar to the following the spherically symmetric solution

$$\phi = g\frac{e^{-\mu\cdot r}}{r}, \tag{3.8}$$

where g is an undetermined constant which plays the same role as the charge in the electrostatic case. In this case, it depends on the source at the origin but in a different way, where the mass and binding energy of the nucleon must be included (3.1). The potential energy between two electrical charges is $V_C = qU = q^2/4\pi \cdot r$. Then, [1] can be written similarly for the nucleon interaction potential of strength g

$$V(r) = g\frac{e^{-\mu\cdot r}}{r}, \tag{3.9}$$

arising from the continuous transfer of virtual mesons of rest mass m between two nucleons.

The interactions can be classified according to the value of a characteristic dimensionless constant related through a coupling constant. The strong interactions increase the interaction cross section and reduce the interaction time [2, 3]. The interaction strength gives a dimensionless constant for the strong interactions, i.e., $g^2/\hbar c \approx 1, \dots, 10$. For the electromagnetic interaction, $e^2/\hbar c = 1/137$. The weak interaction has the potential shown in (3.9) and

$g_w^2 \approx 10^{-5}$. The gravitation interaction between two protons can be represented by the constant [3] $Gm_p/\hbar c \approx 6.0 \cdot 10^{-39}$, which is so small that it can be usually neglected in particle physics. The duration of expedition of virtual mesons from nucleon to nucleon can be found from the uncertainty principle

$$\Delta t \Delta E \approx \hbar, \quad \Delta E \approx mc^2, \quad \Delta r \approx c\Delta t \approx \frac{\hbar}{mc}, \tag{3.10}$$

and the range of force Δr is equal to the Compton wave length. Calculating the range of potentials given in (3.9) arising from the different types of meson exchange and considering

$$\mu \cdot r_0 = 1, \quad r_0 = \frac{1}{\mu} = \frac{\hbar}{mc}, \tag{3.11}$$

we obtain a result similar to Δr in (3.10). Considering the mass [2] as $135\,\mathrm{MeV/c^2}$ for the lightest pi meson π^0, from (3.11) we obtain the range for the force between nucleons as 1.429 fm. The calculations (3.1) using mass and binding energies of nucleons, diffusing in excited physical vacuum, give a similar result, i.e., 1.638 fm. However, the result in formula (3.1) depends on the quantum states of sources of virtual mesons that are in the nuclei. More massive virtual mesons [3] $(\pi, \sigma, \rho, \omega)$ with spins and isospins (J^π, T) are described by the different ranges and kinds of potential, which can also play an important part in the interactions that occur between nucleons. The term virtual indicates that the meson cannot be released from the nucleus when the energy is less than m_0c^2. Emission of virtual mesons and re-capture must occur under the violation of conservation of energy within a short time interval Δt. The resulting potential between two nucleons [2] depends on the spin, i.e.,

$$V(\vec{r}) = V_C(r) + V_{C\cdot S}(r)\frac{\vec{S}_1 \cdot \vec{S}_2}{\hbar^2} + V_T(r)\frac{\hat{S}_{12}}{\hbar^2} + V_{SL}(r)(\vec{L} \cdot \vec{S}). \tag{3.12}$$

The potential presented is invariant with regard to the rotations, mirror reflections, and interchange of the spins of the interacting nucleons. For this case, the states of interacting nucleons can be classified using quantum numbers $\vec{J} = \vec{L} + \vec{S}$ representing the squares of the sum of orbital momentum $\vec{L}$ and total spin $\vec{S} = \vec{s}_1 + \vec{s}_2$ moments, their projection M_J, the sum of spins S and the parity $(-1)^L$. The total orbital quantum number L can be used when the tensor of non-central forces is not included for singlet states of ${}^{2S+1}L_j$, $S = 0$.

Here, we have $V_C(r)$, the spin-independent central potential; $V_{CS}(r)$, the spin-dependent central potential, $V_T(r)$, tensor potential, V_{LS}, the two-body spin–orbit potential, and $\vec{s} = \frac{1}{2}\hat{\sigma} \cdot \hbar$, where $\vec{\sigma}$ is the Pauli spin matrix. The non-central interaction represents the tensor potential which depends on the angles between the spin vectors of the neutron and the proton and the radius vector. Tensor forces are proportional to the below non-central tensor operator

$$\hat{S}_{12} = \frac{3}{r^2}(\vec{\sigma}_1 \cdot \vec{r})(\vec{\sigma}_2 \cdot \vec{r}) - \vec{\sigma}_1 \cdot \vec{\sigma}_2, \tag{3.13}$$

which is equal to zero for the singlet state $S = 0$. The tensor potential $\hat{S}_{12}$ can explain the electric quadruple moment of the deuteron described by mixed triplet states, $a \cdot \psi({}^3S_1) + b \cdot \psi({}^3D_1)$. For the normalized function of triple states [1] $a^2 + b^2 = 1$, $b^2 = 0.004$, influence of state ${}^3D_1$ is small, about 4%. The spin–orbit potential V_{SL} can be expressed as follows:

$$\begin{aligned} V_{SL} &= V_{SL}(r)(\vec{L} \cdot \vec{S}), (\vec{L} \cdot \vec{S}) \\ &= \frac{1}{2}[J(J+1) - L(L+1) - S(S+1)]. \end{aligned} \tag{3.14}$$

This last expression is equal to zero when $S = 0$, $(L = J)$ or $L = 0$, $(S = J)$. Using the total spin dependence and tensor terms, (3.12) can be rewritten [2] as follows:

$$(\vec{s}_1 \cdot \vec{s}_2) = \frac{1}{4}[2S(S+1) - 3], \tag{3.15}$$

$$\hat{S}_{12} = 6(\vec{n}\vec{S})^2 - 2\vec{S}^2. \tag{3.16}$$

From the above formulas we see that the spin-dependent expectation values of $(\vec{s}_1 \cdot \vec{s}_2)$ and the tensor force operators are different for singlet $S = 0$ and triplet $S = 1$ states. The operator $\hat{S}_{12}$ depends on the angle between the unit vector $\vec{n}$ directed from one nucleon to another and $\vec{S}$. The wave function Y_{lSJM} that depends on the eigenfunctions of the orbital moment $Y_{lm}(\vartheta, \varphi)$ and the spin moment $\chi_{S\mu}$ as follows:

$$Y_{lSJM} = \sum_{m+\mu=M} (lmS\mu|JM) Y_{lm} \chi_{S\mu} \tag{3.17}$$

is expressed by Clebsch–Gordan coefficients. Interaction of the potential (3.12) and energy of the two potentials depend on the quantum states ISJ. The wave function of the deuteron representing the bound states of both neutron and proton is a linear combination of the following functions [2] that are expressed by orthonormal functions Y_{lSJM}.

$$\psi(^3S_1) = \frac{u(r)}{r} Y_{011M}, \quad \psi(^3D_1) = \frac{\omega(r)}{r} Y_{211M} \tag{3.18}$$

Then the required normalization of the deuteron function

$$\int |\psi_0|^2 d\vec{r} = 1 \tag{3.19}$$

can be obtained by using

$$\int_0^\infty (u^2 + \omega^2) dr = 1 \tag{3.20}$$

and the probabilities of deuterons in states $^3S_1$ and $^3D_1$, i.e.,

$$P(^3S_1) = \int_0^\infty u^2 dr, \;\; P(^3D_1) = \int_0^\infty \omega^2 dr, \;\; P(^3S_1) + P(^3D_1) = 1. \tag{3.21}$$

The Schrödinger equation for the neutron–proton bounded system or the deuteron [2]

$$[-(\hbar^2/M)\Delta + V_C + V_T S_{12} - E]\psi = 0 \tag{3.22}$$

was solved for the function $\psi_d = a \cdot \psi(^3S_1) + b \cdot \psi(^3D_1)$ only at large distances for the spin function $r > r_0$, when the total spin coincides with the projection of the total moment of the deuteron. The asymptotes of solutions are expressed by the binding energy E, i.e.,

$$u(r) = C_U \exp[-\alpha \cdot r], \tag{3.23}$$

$$\begin{gathered}\omega(r) = C_W \left[1 + \frac{3}{\alpha r} + \frac{3}{(\alpha r)^2}\right] \exp[-\alpha \cdot r], \\ \alpha = \sqrt{2ME}/\hbar, \quad E = 2.226\,\mathrm{MeV}.\end{gathered} \tag{3.24}$$

The range of central (3.22) and tensor forces can be approximately expressed by the radius of the quantum diffusion A[21] region of the nucleus, $R = \hbar/\sqrt{2ME}$ which is defined as $R = 2.158 \cdot 10^{-15}$ fm for deuterons or as 2.158 fm for the interaction energy E of nucleons.

At small distances, the asymptotic solutions are $u \cong r$ and $\omega \cong r^3$ and also r^2 in Ref. A[19] for $l = 0$, when the relativistic correction for kinetic energy is included. The component of the quadruple moment operator for the deuteron in the case $M = J = 1$ is given as

$$Q = \frac{1}{4} e(3z^2 - r^2) \tag{3.25}$$

and can be used for the calculation of the expectation value, i.e.,

$$\langle Q \rangle = \int_0^\infty \psi_d{}^* Q \psi_d dr, \tag{3.26}$$

which for $P(^3D_1) = 0.04$ gives [1, 2] $\langle Q \rangle = 2.82 \cdot 10^{-27} \mathrm{e} \cdot \mathrm{cm}^2$.

3.2 The Shell Model and Mean Field Potentials

The simplest shell model of hydrogen atom was proposed by Niels Bohr by introducing the quantization of angular momentum

$$mv\ r = l\hbar, \quad l = 1, 2, 3, \ldots \tag{3.27}$$

for an electron moving with velocity v at a distance r from the positive proton or any nucleus with charge eZ. For a circular orbit the centrifugal forces are equal to the attractive forces as shown below:

$$\frac{mv^2}{r} = \frac{Ze^2}{r^2}. \tag{3.28}$$

(%/

parallelogram law of vectors, as given in the Fig. 1 2 1

By vector addition we get

$$v_L'^2 = V_{CM}^2 + v_C'^2 + 2(V_{CM})(v_C')\cos\varphi$$

$$v_L'^2 = \left(\frac{v_L}{A+1}\right)^2 + \left(\frac{A v_L}{A+1}\right)^2 + 2\left(\frac{v_L}{A+1}\right)\left(\frac{A v_L}{A+1}\right)\cos\varphi$$

$$v_L'^2 = v_L^2 \, \frac{A^2+2A\cos\varphi+1}{(A+1)^2}$$

Chapter 11

Quantum Mechanics

In this chapter we shall show how the mathematical theory developed in the book can be applied to questions in quantum mechanics. We shall begin with simpler situations and work up to more general systems.

11.1 The Schrödinger operator for a particle

The energy operator corresponding to a single particle subjected to a static potential is of the form

$$H = -\frac{h^2}{8\pi^2 m}\Delta + q(x) = \frac{h^2}{8\pi^2 m}(\mathrm{D}_1^2 + \mathrm{D}_2^2 + \mathrm{D}_3^2) + q(x) \tag{11.1.1}$$

in E^3, where h is Planck's constant, m is the mass of the particle and $q(x)$ is a real valued function describing the potential energy. Here Δ represents the Laplacian in E^3 (recall that $\mathrm{D}_k = \partial/\mathrm{i}\partial x_k$).

Theorem 11.1.1. *Suppose that $q(x)$ is locally integrable, and define*

$$\rho(x)^2 = \max[q(x), 0],\ \sigma(x)^2 = \rho(x)^2 - q(x). \tag{11.1.2}$$

Assume that $\sigma \in N_1(E^3)$ and that

$$N_1'(\sigma) = 0. \tag{11.1.3}$$

Then H on $\mathrm{C}_0^\infty \cap D(q)$ has a regularly accretive self-adjoint extension in L^2. If

$$N_{1,R}(\sigma) \to 0 \text{ as } R \to \infty, \tag{11.1.4}$$

then it has such an extension B satisfying

$$\sigma_e(B) \subset [0,\infty). \tag{11.1.5}$$

If, in addition, $\rho \in N_2(E^3)$ *and*

$$N_{2,R}(\rho) \to 0 \text{ as } R \to \infty, \tag{11.1.6}$$

then

$$\sigma_e(B) = [0,\infty). \tag{11.1.7}$$

If $q \in L^2_{loc}$*, then* $D(q) \supset C_0^\infty$ *and* H *on* C_0^∞ *is essentially self-adjoint. Thus* B *is the closure in* L^2 *of* H *on* C_0^∞.

Proof. The first statement follows from Theorem 9.1.6. The second and third follow from Theorems 9.2.7 and 9.2.3, respectively. The last statement follows from Theorem 10.2.1. □

We consider several examples.

(a) *Free particle.* In this case $q(x) = 0$. H is a constant coefficient operator with real coefficients. Its closure H_0 in L^2 is self-adjoint (Corollary 5.2.3) and

$$\sigma_e(H_0) = \sigma(H_0) = [0,\infty) \tag{11.1.8}$$

(Corollary 5.3.3 and Lemma 10.4.5).

(b) *Coulomb potential.* In this case $q(x) = -e^2/|x|$, where e is a constant (charge). Here $\rho = 0$ and all of the hypotheses of Theorem 11.1.1 are satisfied. Thus H on C_0^∞ is essentially self-adjoint and its closure in L^2 satisfies

$$\sigma_e(H_0) = [0,\infty). \tag{11.1.9}$$

This of course is classical. The spectrum of H_0 represents the energy states of the hydrogen atom. We know that the spectrum of this operator consists of the non-negative real axis and the negative eigenvalues

$$\lambda_n = -2m\pi^2 e^4/h^2 n^2, \quad n = 1, 2 \ldots, \tag{11.1.10}$$

with multiplicities n^2. Note that the lowest eigenvalue is

$$\lambda_1 = -2m\pi^2 e^4/h^2$$

(ground state) and the only limit point is 0 (escape energy).

(c) Consider the potential

$$q(x) = \sum_1^N c_k \mathrm{e}^{-a_k|x|}/|x|^{b_k}, \tag{11.1.11}$$

where the a_k, b_k, c_k are constants and $a_k \geqslant 0, b_k < 3$ for each k. Thus $q(x)$ is locally integrable. If $b_k < 2$ for each k such that $c_k < 0$ and $a_k = 0$, then (11.1.3) and (11.1.4) hold. In this case H on $C_0^\infty \cap D(q)$ has a self-adjoint extension B satisfying (11.1.5). If, in addition, $b_k > 0$ whenever $a_k = 0$, then (11.1.6) is also satisfied. In this case B satisfies (11.1.7). If, in addition, $b_k < 2$ for each k, then B is the closure in L^2 of H on C_0^∞.

Examples of such potentials arising in practice are e^{-ar}/r and $\mathrm{d}(\mathrm{e}^{-ar}/r)\mathrm{d}r$ where $r = |x|$.

(d) *Hydrogen molecular ion.* Suppose we have two stationary positive charges $+e$ a distance R apart and one negative charge $-e$ in motion. We may assume that the first positive charge is at the origin and that the second is at a point r with $|r| = R$. The Hamiltonian (energy) operator for this system is

$$H = -\frac{h^2}{8\pi^2 m}\Delta + \frac{e^2}{R} - \frac{e^2}{|x|} - \frac{e^2}{|x-r|}. \tag{11.1.12}$$

We write this in the form

$$H = P(\mathrm{D}) + q(x), \tag{11.1.13}$$

where

$$P(\mathrm{D}) = -\frac{h^2}{8\pi^2}\Delta + \frac{e^2}{R} \tag{11.1.14}$$

and

$$q(x) = -\frac{e^2}{|x|} - \frac{e^2}{|x-r|}. \tag{11.1.15}$$

Since $P(\mathrm{D})$ is a constant coefficient operator, we know that

$$\sigma(P_0) = \left[\frac{e^2}{R}, \infty\right) \tag{11.1.16}$$

(Corollary 5.3.4). Moreover q is P_0-compact by Corollary 7.4.2. Hence H on C_0^∞ is essentially self-adjoint and its closure B satisfies

$$\sigma_{\mathrm{e}}(B) = \left[\frac{e^2}{R}, \infty\right). \tag{11.1.17}$$

11.2 Two particle systems

Consider a nucleus fixed at the origin in E^3 with a positive charge $2e$ and two moving particles each with negative charge $-e$ subject to Coulomb potentials. The corresponding energy operator is

$$\begin{aligned} H = {} & \frac{h^2}{8\pi^2 m_1}(\mathrm{D}_1^2 + \mathrm{D}_2^2 + \mathrm{D}_3^2) + \frac{h^2}{8\pi^2 m_2}(\mathrm{D}_4^2 + \mathrm{D}_5^2 + \mathrm{D}_6^2) \\ & - \frac{2e^2}{|x^{(1)}|} - \frac{2e^2}{|x^{(2)}|} + \frac{e^2}{|x^{(1)} - x^{(2)}|} \end{aligned} \tag{11.2.1}$$

where $x^{(1)} = (x_1, x_2, x_3)$ represents the coordinates of the first particle and $x^{(2)} = (x_4, x_5, x_6)$ those of the second. The masses of the particles are m_1 and m_2, respectively. Here H is an operator on $C_0^\infty(E^6)$ with E^6 represented by $x = (x^{(1)}, x^{(2)}) = (x_1, \dots, x_6)$.

Theorem 11.2.1. *The operator H given by (11.2.1) is essentially self-adjoint on C_0^∞ and its closure H_0 satisfies*

$$\sigma_{\mathrm{e}}(H_0) = \left[-\frac{8m\pi^2 e^4}{h^2}, \infty\right), \tag{11.2.2}$$

where $m = \max(m_1, m_2)$.

Proof. Set

$$H_1 = \frac{h^2}{8\pi^2 m_1}(\mathrm{D}_1^2 + \mathrm{D}_2^2 + \mathrm{D}_3^2) - \frac{2e^2}{|x^{(1)}|} \tag{11.2.3}$$

$$H_2 = \frac{h^2}{8\pi^2 m_2}(\mathrm{D}_4^2 + \mathrm{D}_5^2 + \mathrm{D}_6^2) - \frac{2e^2}{|x^{(2)}|}. \tag{11.2.4}$$

According to (11.1.10) the lowest eigenvalue of H_k on $C_0^\infty(E^3)$ is

$$-8m_k\pi^2 e^4/h^2, \quad k = 1, 2. \tag{11.2.5}$$

We now apply Lemma 10.8.1 and Theorem 10.8.2. We take $T_i = H_i$, $i = 1$, 2 and

$$U_i = V = \frac{e^2}{|x^{(1)} - x^{(2)}|}, \quad i = 1, 2. \tag{11.2.6}$$

Note that $V_i = Q_i = S_i = 0$ and

$$q_i(x^{(i)}) = -\frac{2e^2}{|x^{(i)}|}, \quad i = 1, 2. \tag{11.2.7}$$

In order to apply the theorem we need

$$\int_{|y_{(i)}|<1} |q_i(x^{(i)} - y^{(i)})|\ |y^{(i)}|^{-1} \mathrm{d}y^{(i)} \to 0 \text{ as } |x^{(i)}| \to \infty, \tag{11.2.8}$$

which is clearly satisfied. By (11.2.5)

$$\varkappa = \min_{i=1,2} \min_{\lambda \in \sigma(H_i)} \lambda = -8m\pi^2 e^4/h^2. \tag{11.2.9}$$

Hence we may conclude that

$$\sigma_{\mathrm{e}}(H_0) \subset [\varkappa, \infty). \tag{11.2.10}$$

In order to obtain the other conclusion, we apply Theorem 10.8.3. Let $\{\xi_{(m)}\}$ be any sequence of vectors in E^3 such that $|\xi_{(m)}| \to \infty$. Then

$$\int_{|x-y|<1} [q_i(x^{(i)} + \xi_{(m)})]^2 \mathrm{d}x \to 0 \text{ as } m \to \infty \tag{11.2.11}$$

for each $y \in E^6$. This is all that is needed to conclude that

$$\sigma_{\mathrm{e}}(H_0) \supset [\varkappa, \infty). \tag{11.2.12}$$

The proof is complete. □

Let us now consider a slightly different situation. Suppose that the second particle is free, i.e., has no interaction with either the nucleus or the first particle. The Hamiltonian in this case is

$$H = \frac{h^2}{8\pi^2 m_1}(\mathrm{D}_1^2 + \mathrm{D}_2^2 + \mathrm{D}_3^2) + \frac{h^2}{8\pi^2 m_2}(\mathrm{D}_4^2 + \mathrm{D}_5^2 + \mathrm{D}_6^2) - \frac{2e^2}{|x^{(1)}|}. \tag{11.2.13}$$

Theorem 11.2.2. *The operator H given by* (2.13) *is essentially self-adjoint on C_0^∞ and its closure H_0 satisfies*

$$\sigma(H_0) = [-8m_1\pi^2 e^4/h^2, \infty). \tag{11.2.14}$$

Proof. Set

$$P(\mathrm{D}) = \frac{h^2}{8\pi^2 m_2}(\mathrm{D}_4^2 + \mathrm{D}_5^2 + \mathrm{D}_6^2).$$

The spectrum of its closure P_0 satisfies (11.1.8). Since the lowest eigenvalue of H_1 given by (11.2.3) is $\varkappa_1 = -8m_1\pi^2 e^4/h^2$, we know that

$$\sigma(H_0) \supset [\varkappa_1, \infty)$$

by Lemma 10.7.1. On the other hand for $\varphi \in C_0^\infty(E^6)$

$$\begin{aligned}(H\varphi, \varphi) &= (H_1\varphi, \varphi) \geqslant (P(\mathrm{D})\varphi, \varphi)\\ &= (H_1\varphi, \varphi) + \frac{h^2}{8\pi^2 m_2}(||\mathrm{D}_4\varphi||^2 + ||\mathrm{D}_5\varphi||^2 + ||\mathrm{D}_6\varphi||^2)\\ &\geqslant \varkappa_1 ||\varphi||^2\end{aligned}$$

(see Lemma 2.7.17). This gives

$$\sigma(H_0) \subset [\varkappa_1, \infty),$$

and the proof is complete. □

As a contrast, consider the case of two moving particles, the first with positive charge e and the second with negative charge $-e$, attracting each other with Coulomb forces. The Hamiltonian is

$$\begin{aligned}H = \frac{h^2}{8\pi^2 m_1}(\mathrm{D}_1^2 + \mathrm{D}_2^2 + \mathrm{D}_3^2) + \frac{h^2}{8\pi^2 m_2}(\mathrm{D}_4^2 + \mathrm{D}_5^2 + \mathrm{D}_6^2)\\ - \frac{e^2}{|x^{(1)} - x^{(2)}|}.\end{aligned} \tag{11.2.15}$$

Theorem 11.2.3. *The operator H given by (11.2.15) is essentially self-adjoint on C_0^∞ and its closure H_0 satisfies*

$$\sigma(H_0) = \left[-\frac{2m_1 m_2 \pi^2 e^4}{(m_1 + m_2)h^2}, \infty\right). \tag{11.2.16}$$

Proof. Let z be a non-vanishing vector in E^3 and set $\xi = (z, z)$. Since $x^{(1)} + tz - (x^{(2)} + tz) = x^{(1)} - x^{(2)}$, we see that

$$q(x + t\xi) = q(x), \quad x \in E^6, t \text{ real},$$

where

$$q(x) = \frac{-e^2}{|x^{(1)} - x^{(2)}|}.$$

Thus we may apply Theorem 10.7.3 to conclude that $\sigma(H_0)$ consists of an interval of the form $[\varkappa, \infty)$. It remains to compute $\varkappa$. To this end make the following coordinate transformation:

$$\tilde{x}^{(1)} = x^{(1)} - x^{(2)}, \quad \tilde{x}^{(2)} = m_1 x^{(1)} + m_2 x^{(2)}. \tag{11.2.17}$$

A simple calculation shows that H transforms into

$$\begin{aligned} H = {} & \frac{h^2}{8\pi^2 m}(\tilde{\mathrm{D}}_1^2 + \tilde{\mathrm{D}}_2^2 + \tilde{\mathrm{D}}_3^2) \\ & + (m_1 + m_2)\frac{h^2}{8\pi^2}(\mathrm{D}_4^2 + \mathrm{D}_5^2 + \mathrm{D}_6^2) \\ & - \frac{e^2}{|\tilde{x}^{(1)}|} \end{aligned} \tag{11.2.18}$$

in the new coordinates, where $m = m_1 m_2/(m_1 + m_2)$. This is of the form (11.2.13) with m_1 replaced by m, m_2 replaced by $1/(m_1 + m_2)$ and e replaced by $e/\sqrt{2}$. Thus our result follows from Theorem 11.2.2. □

11.3 The existence of bound states

If H is the Hamiltonian corresponding to a system of particles and its closure H_0 satisfies

$$\sigma_{\mathrm{e}}(H_0) = [\nu, \infty), \tag{11.3.1}$$

this interval is said to represent *free states* because they correspond to the situation when at least one of the particles is free, i.e., it has the energy to move far from the others. Any $\lambda \in \sigma(H_0)$ below ν must be an eigenvalue of finite multiplicity. The corresponding eigenfunctions are called *bound* or *stationary states.* The eigenfunction corresponding to the lowest eigenvalue is called the *ground state.* Equation (11.3.1) does not tell us whether or not there exist bound states. Since the existence of bound states (and consequently of a ground state) is important in quantum theory (see section 6), we shall give a simple method of demonstrating their existence and estimating the corresponding eigenvalues.

The theory is very simple. Suppose we can find a function u in $D(H_0)$ such that

$$(H_0 u, u) = \mu ||u||^2, \tag{11.3.2}$$

where $\mu < \nu$. Then we know that the spectrum of H_0 extends below ν at least down to μ (Theorem 2.7.17). Since every point of $\sigma(H_0)$ below ν must be an eigenvalue of finite multiplicity, the existence of bound states with energies $\leqslant \mu$ is established. In particular, there is a ground state with energy $\leqslant \mu$.

Let us illustrate the method for the two particle system described at the beginning of section 2. We write

$$H = H_1 + H_2 + W, \tag{11.3.3}$$

where

$$H_1 = \frac{h^2}{8\pi^2 m_1}(\mathrm{D}_1^2 + \mathrm{D}_2^2 + \mathrm{D}_3^2) - \frac{2e^2}{|x^{(1)}|} \tag{11.3.4}$$

$$H_2 = \frac{h^2}{8\pi^2 m_2}(\mathrm{D}_4^2 + \mathrm{D}_5^2 + \mathrm{D}_6^2) - \frac{e^2}{|x^{(2)}|} \tag{11.3.5}$$

and

$$W = \frac{e^2}{|x^{(1)} - x^{(2)}|} - \frac{e^2}{|x^{(2)}|}. \tag{11.3.6}$$

From the discussion of section 1 we know that the operators H_1 and H_2 in E^3 have ground states with energies

$$\lambda_1 = -8m_1\pi^2 e^4/h^2, \quad \lambda_2 = -2m_2\pi e^4/h^2, \tag{11.3.7}$$

respectively. We note also that the corresponding normalized eigenfunctions (states) are

$$\varphi_1(x^{(1)}) = \frac{2^{\frac{9}{2}}\pi^{\frac{5}{2}} m_1^{\frac{3}{2}} e^3}{h^3} \exp\left\{-\frac{8\pi^2 m_1 e^2}{h^2}|x^{(1)}|\right\} \tag{11.3.8}$$

and

$$\varphi_2(x^{(2)}) = \frac{8\pi^{\frac{5}{2}} m_2^{\frac{3}{2}} e^3}{h^3} \exp\left\{-\frac{4\pi^2 m_2 e^2}{h^2}|x^{(2)}|\right\}, \tag{11.3.9}$$

respectively. Actually, all we need to know is that $\varphi_1(x^{(1)})$ depends only on $|x^{(1)}|$. Set

$$\varphi(x) = \varphi_1(x^{(1)})\varphi_2(x^{(2)}). \tag{11.3.10}$$

Then $\varphi(x)$ is in S and consequently in the domain of H_0. Furthermore

$$(H_1\varphi, \varphi) = (H_1\varphi_1, \varphi_1)_{E^3}||\varphi_2||^2_{E^3} = \lambda_1 \tag{11.3.11}$$

and

$$(H_2\varphi, \varphi) = (H_2\varphi_2, \varphi_2)_{E^3} = \lambda_2. \tag{11.3.12}$$

We also have

$$\begin{aligned}(W\varphi, \varphi) = e^2 \int |\varphi_2(x^{(2)})|^2 \mathrm{d}x^{(2)} \int |\varphi_1(x^{(1)})|^2 \\ \times \left\{\frac{1}{|x^{(1)} - x^{(2)}|} - \frac{1}{|x^{(1)}|}\right\} \mathrm{d}x^{(1)}.\end{aligned} \tag{11.3.13}$$

Let R be any positive number, and set

$$f(x^{(2)}) = \int_{|x^{(1)}|=R} \frac{\mathrm{d}S}{|x^{(1)} - x^{(2)}|}. \tag{11.3.14}$$

If $|x^{(2)}| > R$, then $1/|x^{(1)} - x^{(2)}|$ is harmonic in $|x^{(1)}| \leqslant R$ and consequently

$$f(x^{(2)}) = \frac{1}{|x^{(2)}|} \int_{|x^{(1)}|=R} \mathrm{d}S = \frac{4\pi R^2}{|x^{(2)}|}, \quad |x^{(2)}| > R, \tag{11.3.15}$$

by the mean value theorem. If $|x^{(2)}| < R$, set

$$h(x^{(1)}) = \frac{1}{R} - \frac{1}{|x^{(1)}|}.$$

Since h is harmonic in $\varepsilon < |x^{(1)}| < R$ for $0 < \varepsilon < |x^{(2)}|$, we have

$$\begin{aligned} 4\pi h(x^{(2)}) = &\int_{|x^{(1)}|=\varepsilon} \frac{\partial h}{\partial |x^{(1)}|} \frac{\mathrm{d}S}{|x^{(1)} - x^{(2)}|} \\ &- \int_{|x^{(1)}|=\varepsilon} \frac{\partial h}{\partial |x^{(1)}|} \frac{\mathrm{d}S}{|x^{(1)} - x^{(2)}|} \\ &+ \left(\frac{1}{R} - \frac{1}{\varepsilon}\right) \int_{|x^{(1)}|=\varepsilon} \frac{\partial}{\partial |x^{(1)}|} \left(\frac{1}{|x^{(1)} - x^{(2)}|}\right) \mathrm{d}S, \end{aligned} \tag{11.3.16}$$

where we used the fact that $h(x^{(1)}) = 0$ for $|x^{(1)}| = R$. Since $1/|x^{(1)} - x^{(2)}|$ is harmonic in $|x^{(1)}| < \varepsilon$, we have

$$\int_{|x^{(1)}|=\varepsilon} \frac{\partial}{\partial |x^{(1)}|} \left(\frac{1}{|x^{(1)} - x^{(2)}|}\right) \mathrm{d}S = 0.$$

Thus (11.3.16) yields

$$4\pi \left(\frac{1}{R} - \frac{1}{|x^{(2)}|}\right) = \frac{1}{R^2} \int_{|x^{(1)}|=R} \frac{\mathrm{d}S}{|x^{(1)} - x^{(2)}|} - \frac{4\pi}{|x^{(2)}|}$$

by (11.3.15). This gives

$$f(x^{(2)}) = 4\pi R, \quad |x^{(2)}| < R. \tag{11.3.17}$$

On the other hand, we always have

$$\int_{|x^{(1)}|=R} \left\{ \frac{1}{|x^{(1)} - x^{(2)}|} - \frac{1}{|x^{(1)}|} \right\} \mathrm{d}S \leqslant 0. \tag{11.3.18}$$

We now use the fact that $\varphi_1(x^{(1)})$ depends only on $|x^{(1)}|$. Thus if we evaluate the integral in (11.3.13) by first integrating over $|x^{(1)}| = R$ and apply (11.3.18), we see that $(W\varphi, \varphi) \leqslant 0$. This in conjunction with (11.3.11) and (11.3.12) shows that

$$(H\varphi, \varphi) \leqslant \lambda_1 + \lambda_2.$$

By Theorem 11.2.1, the smallest value of $\sigma_{\mathrm{e}}(H_0)$ is λ_1 (note that $m_1 = \max(m_1, m_2)$). Since $\lambda_2 < 0$, we see that there must be bound states. In particular we have shown the existence of bound states for the helium atom.

which are left ambiguous by the text – which the text does not specify fully, *given the mathematical purposes*.

Now to the results.[33] In Euclid's *Elements* XIII, about 47% of the letters are completely specified, about 8% are underspecified, about 19% are completely unspecified, and about 25% begin as completely unspecified or underspecified, and get increased specification later. In Apollonius' *Conics* I, about 42% are completely specified, about 37% are underspecified, about 4% are completely unspecified, and about 16% begin as completely unspecified or underspecified, and get increased specification later. The total number of letters in both surveys is 838.

Very often – most often – letters are not completely specified. So how do we know what they stand for? Very simple: we see this in the diagram.

In fact the difficult thing is to 'unsee' the diagram, to teach oneself to disregard it and to imagine that the only information there is is that supplied by the text. Visual information is compelling itself in an unobtrusive way. Here the confessional mode may help to convert my readers. It took me a long time to realise how ubiquitous lack of specification is. The following example came to me as a shock. It is, in fact, a very typical case.

Look at Apollonius' *Conics* I.11 (fig. 1.5). The letter Λ is specified at 38.26, where it is asserted to be on a parallel to ΔΕ, which passes through Κ. Λ is thus on a definite line. But as far as the text is concerned, there is no way of knowing that Λ is a very specific point on that line, the one intersecting with the line ΖΗ. But I had never even thought about this insufficiency of the text: I always read the diagram into the text. This moment of shock started me on this survey. Having completed the survey, its implications should be considered.

First, why are there so many cases falling short of full specification? To begin to answer this question, it must be made clear that my results have little quantitative significance. It is clear that the way in which letters in Apollonius fail to get full specification is different from that in Euclid. I expect that there is a strong variability between works by the same author. The *way* in which letters are not fully specified depends upon mathematical situations. Euclid, for instance, in book XIII, may construct a circle, e.g. ΑΒΓΔΕ and then construct a pentagon within

---

[33] The complete tables, with a more technical analysis of the semantics of specification, are to appear in Netz (forthcoming).

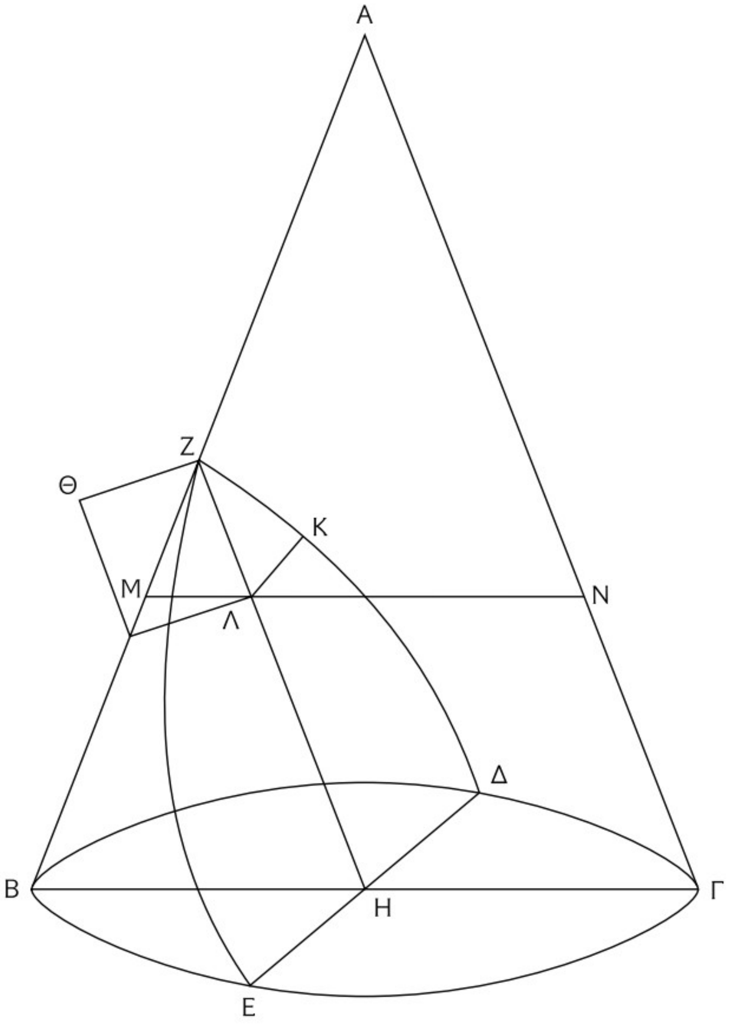

Figure 1.5. Apollonius' *Conics* 1.11.

the same circle, such that its vertices are the very same ΑΒ ΓΔΕThis is moving from underspecification to complete specification, and is demanded by the subject matter dealt with in his book. In the *Conics*, parallel lines and ordinates are the common constructions, and letters on them are often underspecified (basically, they are similar to 'BC' in figs. 1.2a, 1.2b above).

What seems to be more stable is the percentage of fully specified letters. Less than half the letters are fully specified – but not much less than half. It is as if the authors were indifferent to the question of whether a letter were specified or not, full specification being left as a random result.

This, I claim, is the case. Nowhere in Greek mathematics do we find a moment of specification *per se*, a moment whose purpose is to make sure that the attribution of letters in the text is fixed. Such moments are very common in modern mathematics, at least since Descartes.[34] But specifications in Greek mathematics are done, literally, *ambulando*. The essence of the 'imperative' element in Greek mathematics – 'let a line be drawn . . .', etc. – is to do some job upon the geometric space, to get things moving there. When a line is drawn from one point to another, the letters corresponding to the start and end positions of movement ought to be mentioned. But they need not be carefully differentiated; one need not know precisely which is the start and which is the end – both would do the same job, produce the same line (hence underspecification); and points traversed through this movement may be left unmentioned (hence complete unspecification).

What we see, in short, is that while the text is being worked through, the diagram is assumed to exist. The text takes the diagram for granted. This reflects the material implementation discussed above. This, in fact, is the simple explanation for the use of *perfect* imperatives in the references to the setting out – 'let the point *A* have been taken'. It reflects nothing more than the fact that, by the time one comes to discuss the diagram, it has already been drawn.[35]

The next point is that, conversely, the text is not recoverable from the diagram. Of course, the diagram does not tell us what the proposition asserts. It could do so, theoretically, by the aid of some symbolic apparatus; it does not. Further, the diagram does not specify all the objects on its own. For one thing, at least in the case of sphaerics, it does not even look like its object. When the diagram is 'dense', saturated in detail, even the attribution of letters to points may not be obvious from the diagram, and modern readers, at least, reading modern diagrams, use the text, to some extent, in order to elucidate the diagram. The stress of this section is on *inter*-dependence. I have not merely tried to upset the traditional balance between text and diagram; I have tried to show that they cannot be taken apart, that neither makes sense in the absence of the other.

---

[34] In Descartes, the same thing is both geometric and algebraic: it is a line (called *AB*), and it is an algebraic variable (called *a*). When the geometrical configuration is being discussed, '*AB*' will be used; when the algebraic relation is being supplied, '*a*' is used. The square on the line is 'the square on *AB*' (if we look at it geometrically) or a^2 (if we look at it algebraically). To make this double-accounting system workable, Descartes must introduce explicit, *per se* specifications, identifying *symbols*. This happens first in Descartes (1637) 300. This may well be the first *per se* moment of specification in the history of mathematics.

[35] The suggestion of Lachterman (1989) 65–7, that past imperatives reflect a certain *horror operandi*, is therefore unmotivated, besides resting on the very unsound methodology of deducing a detailed philosophy, presumably shared by each and every ancient mathematician, from linguistic practices. The methodology adopted in my work is to explain shared linguistic practices by shared situations of communication.

2.1.2 The role of text and diagram for derivations

In general, assertions may be derived from the text alone, from the diagram alone, or from a combination of the two. In chapter 5, I shall discuss grounds for assertions in more detail. What is offered here is an introduction.

First, some assertions do derive from the text alone. For instance, take the following:[36]

> As BE is to EΔ, so are four times the rectangle contained by BE, EA to four times the rectangle contained by AE, EΔ.

One brings to bear here all sorts of facts, for instance the relations between rectangles and sides, and indeed some basic arithmetic. One hardly brings to bear the diagram, for, in fact, 'rectangles' of this type often involve lines which do not stand at right angles to each other; the lines often do not actually have any point in common.[37]

So this is one type of assertion: assertions which may be viewed as verbal and *not* visual.[38] Another class is that of assertions which are based on the visual alone. To say that such assertions exist means that the text hides implicit assumptions that are contained in the diagram.

That such cases occur in Greek mathematics is of course at the heart of the Hilbertian geometric programme. Hilbert, one of the greatest mathematicians of the twentieth century, who repeatedly returned to foundational issues, attempted, in Hilbert (1899), to rewrite geometry without any unarticulated assumptions. Whatever the text assumes in Hilbert (1899), it either proves or explicitly sets as an axiom. This was never done before Hilbert, mainly because much information was taken from the diagram. As is well known, the very first proposition

---

[36] Apollonius' *Conics* I.33, 100.7–8. The Greek text is more elliptic than my translation.

[37] Here the lines mentioned do share a point, but they are not at right angles to each other. See, for instance, *Conics* I.34, 104.3, the rectangle contained by KB, AN – lines which do not share a point.

[38] This class is not exhausted by examples such as the above (so-called 'geometrical algebra'). For instance, any calculation, as e.g. in Aristarchus' *On Sizes and Distances*, owes nothing to the diagram. It should be noted that even 'geometrical algebra' is still 'geometrical': the text does not speak about multiplications, but about rectangles. This of course testifies to the primacy of the visual over the verbal. In general, see Unguru (1975, 1979), Unguru and Rowe (1981–2), Unguru and Fried (forthcoming), Hoyrup (1990a), for a detailed criticism of any interpretation of 'geometrical algebra' which misses its visual motivation. The term itself is misleading, but helps to identify a well-recognised group of propositions, and I therefore use it, quotation marks and all.

the Mandelstam plane

We use here the well know geometrical fact that the sum of the distances from

If I were to tell you that a Cremona transformation is "a birational automorphism of projective space," I would just be flinging phonemes at you, so let me put it a different way: What is 0/0? You have probably learned at some point that you're supposed to say "undefined," and that is, in a way, correct, but it's also the coward's way out. It really depends which zeroes you're dividing! What is the ratio of the area of a size-zero square to its perimeter? Sure, you could say it's undefined, but why not be bold and define it? If the square has a side of length 1, that ratio is 1/4 or 0.25. When the side length shrinks to 1/2, the area is 1/4 and the perimeter is 2, so the ratio has gone down to 1/8. If the side length is 0.1, the ratio is 0.01/0.4 or 0.025. The ratio gets smaller and smaller as the square does, which means there's only one good answer for what happens when the square shrinks to a point: in *this* case, 0/0 = 0. On the other hand, what if we ask about the ratio of a line segment measured in centimeters to its length measured in inches? That ratio is 2.54 for a long segment and it's 2.54 for a short segment, and if the segment shrinks down to a point, *that* 0/0 should be 2.54.

Geometrically, you can follow Descartes's example and think of a pair of numbers as a point in the plane. The point (1,2) is the point 1 unit to the right and 2 units up from the center. And the ratio 2/1 is the slope of the line joining the center to (1,2). When the point is (0,0), the center itself, there *is* no line segment, so there's no slope. The very simplest type of Cremona transformation swaps out the plane for a very similar geometry, in which (0,0) is replaced with multiple points—infinitely many, in fact! Each one remembers not just its location at (0,0) but a slope as well, as if you were keeping track not just of where you were but the direction of the path you took to get there.fn1 This kind of transformation, in which one point explodes into infinitely many, is called a *blow-up*. The higher-dimensional Cremona transformations Hudson studied are decidedly more involved; you might call them a general geometric theory of assigning values to those "undefined" ratios a more timid calculator would back away from.

Although the amplitude of the $2 \to 2$ process depends evidently on two independent variables, that is the energy of the incoming particles and the scattering angle, it is more convenient to consider A as a function of three Mandelstam variables

$$s = (p_1 + p_2)^2, \quad t = (p_1 - p_3)^2, \quad u = (p_1 - p_4)^2 .$$

They are related to each other by

$$s + t + u = \sum_{i=1}^{4} m_i^2$$

where the sum runs over the masses of all particles participating in the collision.

For the sake of simplicity, in what follows we restrict ourselves to the case of equal particle masses, $m_i = \mu$.

The Mandelstam variables have a simple physical meaning. For instance, in the centre-of-mass system (cms) of the reaction $a + b \to c + d$ (the so-called s-channel), s is the square of the total energy of the colliding particles and $t = -(\boldsymbol{p}_1 - \boldsymbol{p}_3)^2$ is the square of the momentum transfer from a to c. In the cms of the reaction $a + \bar{c} \to \bar{b} + d$ (t-channel), t plays the role of the total energy squared, and s is the square of momentum transfer. The variables u and t, respectively, play similar rôles in the u-channel reaction $a + \bar{d} \to \bar{b} + c$.

1.2.1 The Mandelstam plane

It is convenient, following Landau, to represent the kinematics of the three reactions graphically on the Mandelstam plane. We use here the well known geometrical fact that the sum of the distances from a point on the plane to the sides of an equilateral triangle does not depend on the position of the point. Therefore, taking into account the condition $s + t + u = 4\mu^2$, let us measure s, t and u as the distances to the sides of the triangle.

It is easy then to represent the physical region of any reaction on such a plane. For instance, the physical region of the reaction $a + \bar{c} \to \bar{b} + d$ corresponds to $t \geq 4\mu^2$, $s \leq 0$, $u \leq 0$ and it is shown on Fig. 1.2 as the upper shaded area. The physical regions of the other reactions can be identified in a similar manner.

In the case of the scattering of *identical* neutral particles the amplitude in each physical region is the same and it satisfies the unitarity condition separately in each region.

Examining the Mandelstam plane Fig. 1.2 we notice an interesting feature: as we move from positive to negative values of s (from the physical

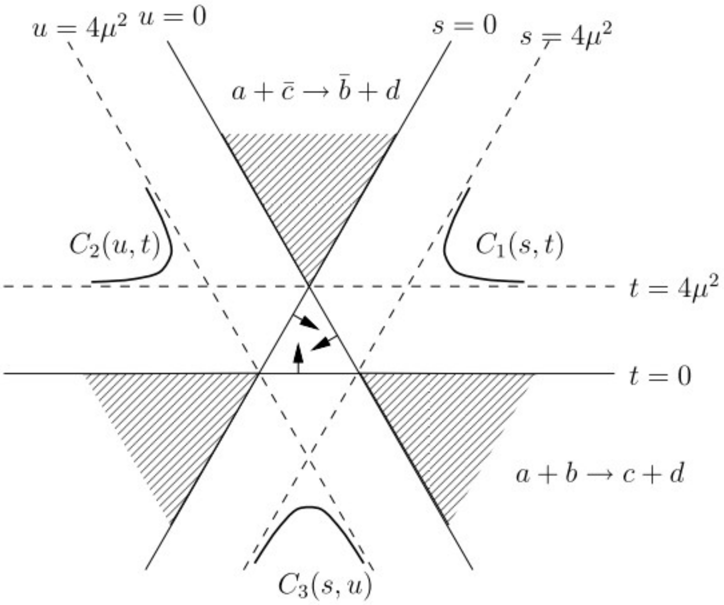

Fig. 1.2. Crossing reactions on the Mandelstam plane

region of the s-channel to the u-channel), the energy dependence of the scattering amplitude turns into the angular dependence.

1.2.2 Threshold singularities on the Mandelstam plane

Let us discuss now singularities of the amplitude. As an illustration, we consider elastic scattering of neutral pions: $\pi^0 + \pi^0 \to \pi^0 + \pi^0$. We will assume that (in accordance with experiment) pions are the lightest stable hadrons and that there is no bound state of two neutral pions. Then, the amplitude has no singularities at $s < 4\mu^2$. The first threshold lies at $s = (2\mu)^2$. It corresponds to the two-particle intermediate state. The next, three-particle threshold could have appeared at $s = (3\mu)^2$. In reality, the second threshold in the pion scattering amplitude is situated at $s = (4\mu)^2$ – the four-particle state, since the transition of two pions into three is forbidden by G-parity conservation.

Similar singularities in *energy* are known to appear in quantum mechanics, for instance the threshold singularity at $s \to 4\mu^2$.

There is however a principal difference between relativistic and nonrelativistic theories in the interpretation of the singularities in *momentum transfer*.

In quantum mechanics such singularities are determined by the potential. For instance, the Yukawa potential

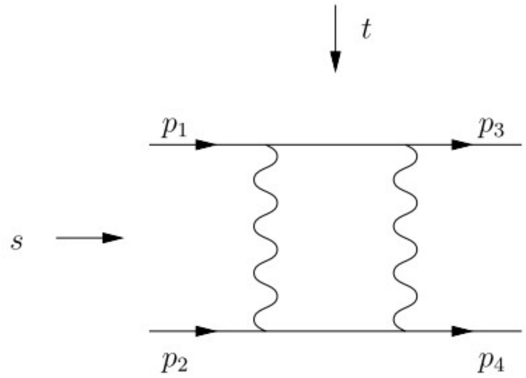
$$V(r) \propto \frac{\exp(-\alpha r)}{r}$$

corresponds to a pole of the scattering amplitude in the plane of the squared momentum transfer k:

$$A(k^2) \propto \frac{1}{k^2+\alpha^2}.$$

In the relativistic theory the rôle of the potential is played by energy singularities in the t-channel, thresholds at $t = 4\mu^2$, $16\mu^2$ and so on.

Let us illustrate this statement by considering the box diagram



whose contribution we may interpret as defining the potential in the *next-to-Born* approximation. It is easy to see that the radius of this potential is $r = 1/2\mu$.

Thus, the assumption that all the singularities of the scattering amplitude are determined by the masses of real particles implies that there are no potentials with an infinite radius (since all hadrons have non-zero masses).

1.3 Partial wave expansion and unitarity

In order to obtain more concrete results, we must exploit analyticity and unitarity of the S-matrix.

Due to conservation of angular momentum, the unitarity condition for scattering amplitudes with given angular momentum ℓ becomes diagonal. It is convenient, therefore, to expand the s-channel amplitude into partial waves:

$$A(s,t) = \sum_{\ell=0}^{\infty} f_\ell(s)(2\ell+1)P_\ell(z), \tag{1.3a}$$

Chapter 7

The Riemann Integral

1 Introduction

In elementary treatments, the process of integration is generally introduced as the inverse of differentiation. If $F'(x) = f(x)$ for all x belonging to the domain of the function f, F is called an integral of the given function f.

Historically, however, the subject of integral arose in connection with the problem of finding areas of plane regions in which the area of a plane region is calculated as the limit of a sum. This notion of integral as summation is based on geometrical concepts.

A German mathematician G.F.B. Riemann gave the first rigorous arithmetic treatment of definite integral free from geometrical concepts. Riemann's definition covered only bounded functions. It was Cauchy who extended this definition to unbounded functions. Later on early in the twentieth century Lebesgue introduced the integral on a firm foundation with many refinements and generalisations.

In the present chapter we shall study the Riemann integral of real valued, bounded functions defined on some closed interval.

2 Partitions and Riemann Sums

Definition 1: *Let* $I = [a, b]$ *be a closed and bounded interval. Then by a* **partition** *(or a* **dissection** *or a* **net***) of* I *we mean a finite set of real numbers* $P = \{x_0, x_1, \dots, x_{n-1}, x_n\}$ *having the property that* $a = x_0 < x_1 < \dots < x_{n-1} < x_n = b$.

The closed sub-intervals

$$I_1 = [x_0, x_1], I_2 = [x_1, x_2], \dots, I_n = [x_{n-1}, x_n]$$

determined by P *constitute the* **segments** *of the partition.*

By changing the set of points, the partition can be changed. Thus there can be an infinite number of partitions of the interval $[a, b]$. The family of all partitions of $[a, b]$ shall be denoted by $\mathbf{P}[a, b]$.

We write $\Delta x_r = x_r - x_{r-1}$ for $r = 1, 2, \dots, n$ so that Δx_r is the length of the segment $[x_{r-1}, x_r]$. The **norm** (or **mesh**) of a partition P is the greatest of the lengths of the segments of a partition P and it is denoted by $||P||$. Thus

$$||P|| = \text{max.} (\Delta x_r : r = 1, 2, \dots, n).$$

Sometimes the norm of a partition P is also denoted by $\mu(P)$.

Definition 2: *A partition* P^* *is called a* **refinement** *of another partition* P *or we say that* P^* *is* **finer than** P *iff* $P^* \supset P$, *i.e., if every point of* P *is used in the construction of* P^*.

If $P^* = P_1 \cup P_2$, *then* P^* *is called the* **common refinement** *of the given two partitions* P_1 *and* P_2.

Definition 3: *Let* f *be a bounded function defined on a bounded interval* $[a, b]$. *Also let* $P = \{a = x_0, x_1, \dots, x_n = b\}$ *be any partition of* $[a, b]$. *Also let* m_r *and* M_r *be the infimum and supremum respectively of the function* f *on* I_r, *for* $r = 1, 2, \dots, n$ *i.e.,*

$$m_r = inf \{ f(x) : x_{r-1} \le x \le x_r \}$$

and $$M_r = sup \{ f(x) : x_{r-1} \le x \le x_r \}.$$

Let us now form two sums

$$L(P, f) = \sum_{r=1}^{n} m_r \Delta x_r \text{ and } U(P, f) = \sum_{r=1}^{n} M_r \Delta x_r .$$

Then $L(P, f)$ *is called the* **lower Riemann sum** (*or* **lower Darboux sum**) *of* f *on* $[a, b]$ *with respect to the partition* P *and* $U(P, f)$ *is called the* **upper Riemann sum** (*or* **upper Darboux sum**) *of* f *on* $[a, b]$ *with respect to the partition* P.

In brief, we shall refer to these sums as the *lower and upper R-sums* of f with respect to P. Obviously $L(P, f) \le U(P, f)$.

Theorem 1: *Let* f *be a bounded function defined on* $[a, b]$ *and let* m *and* M *be the infimum and supremum of* $f(x)$ *in* $[a, b]$. *Then for any partition* $\mathbf{P}$ *of* $[a, b]$, *we have*

$$m(b - a) \le L(P, f) \le U(P, f) \le M(b - a).$$ **(Garhwal 2008)**

Proof: Let $P = \{a = x_0, x_1, \dots, x_n = b\}$ be any partition of $[a, b]$. Then $I_r = [x_{r-1}, x_r], r = 1, 2, \dots, n$ are the subintervals of $[a, b]$. Let m_r and M_r be the infimum and supremum of $f(x)$ in $[x_{r-1}, x_r]$. Then for every value of r, we have

$$m \le m_r \le M_r \le M$$

$\Rightarrow$ $$m\,\Delta x_r \le m_r\,\Delta x_r \le M_r\,\Delta x_r \le M\,\Delta x_r \qquad [\because \Delta x_r > 0]$$

$\Rightarrow$ $$\sum_{r=1}^{n} m\,\Delta x_r \le \sum_{r=1}^{n} m_r\,\Delta x_r \le \sum_{r=1}^{n} M_r\,\Delta x_r \le \sum_{r=1}^{n} M\,\Delta x_r\,. \qquad \text{...(1)}$$

Now $$\sum_{r=1}^{n} m\,\Delta x_r = m \sum_{r=1}^{n} \Delta x_r = m \sum_{r=1}^{n} (x_r - x_{r-1})$$
$$= m\,(x_1 - x_0 + x_2 - x_1 + \ldots + x_n - x_{n-1})$$
$$= m\,(x_n - x_0) = m\,(b-a).$$

Similarly $$\sum_{r=1}^{n} M\Delta\,x_r = M\,(b-a).$$

Also $$\sum_{r=1}^{n} m_r\,\Delta x_r = L\,(P, f\,) \text{ and } \sum_{r=1}^{n} M_r\,\Delta x_r = U\,(P, f\,).$$

Hence, from (1), we conclude that

$$m\,(b-a) \le L\,(P, f\,) \le U\,(P, f\,) \le M\,(b-a)\ \forall\, P \in \boldsymbol{P}\,[a, b].$$

It follows that the sets of upper sums and lower sums are bounded.

Theorem 2: *If* $f : [a, b] \to \mathrm{R}$ *is a bounded function, then*

$$U\,(P, -f\,) = -L\,(P, f\,) \text{ and } L\,(P, -f\,) = -U\,(P, f\,). \qquad \textbf{(Meerut 2012)}$$

Proof: Let $P = \{a = x_0, x_1, \ldots, x_n = b\}$ be any partition of $[a, b]$. Let M_r and m_r be the supremum and infimum of f in I_r.

Now f is bounded on $[a, b] \Rightarrow -f$ is bounded on $[a, b]$.

Again M_r, m_r are supremum and infimum of f in I_r

$\Rightarrow$ $-m_r, -M_r$ are supremum and infimum of $-f$ in I_r.

We have $$U\,(P, -f\,) = \sum_{r=1}^{n} (-m_r)\,\Delta x_r\,, \text{by definition of upper } R\text{-sum}$$
$$= -\sum_{r=1}^{n} m_r\,\Delta x_r = -L\,(P, f\,).$$

Also $$L\,(P, -f\,) = \sum_{r=1}^{n} (-M_r)\,\Delta x_r\,, \text{by definition of lower } R\text{-sum}$$
$$= -\sum_{r=1}^{n} M_r\,\Delta x_r = -U\,(P, f\,).$$

Theorem 3: *Let f be a bounded function defined on $[a, b]$ and let P be a partition of $[a, b]$. If P^* is a refinement of P, then*

$$L\,(P^*, f\,) \ge L\,(P, f\,) \textit{ and } U\,(P^*, f\,) \le U\,(P, f\,).$$

Proof: Let $P = \{a = x_0, x_1, x_2, \ldots, x_{r-1}, x_r, \ldots, x_n = b\}$

and $P^* = \{a = x_0, x_1, x_2, \ldots, x_{r-1}, y_1, x_r, \ldots, x_n = b\}$,

so that P^* has one more partition point y_1 than P.

Let m_r and M_r be the infimum and supremum of f in $[x_{r-1}, x_r]$. Let M_r', M_r'' be the suprema of f in $[x_{r-1}, y_1], [y_1, x_r]$ and m_r', m_r'' be the infima of f in $[x_{r-1}, y_1], [y_1, x_r]$ respectively.

Then $M_r \ge M_r', M_r''$ and $m_r \le m_r', m_r''$.

Since the rth subinterval only of P is split into two more subintervals of P^* and the remaining subintervals are identical in P and P^*, therefore, we have

$$U(P, f) - U(P^*, f)$$
$$= M_r(x_r - x_{r-1}) - \{M_r'(y_1 - x_{r-1}) + M_r''(x_r - y_1)\}.$$

But $\quad M_r'(y_1 - x_{r-1}) + M_r''(x_r - y_1) \leq M_r(y_1 - x_{r-1}) + M_r(x_r - y_1)$
$$= M_r(x_r - x_{r-1}).$$

It gives $\quad U(P, f) - U(P^*, f) \geq M_r(x_r - x_{r-1}) - M_r(x_r - x_{r-1}) = 0$

i.e., $\quad U(P, f) \geq U(P^*, f)$ or $U(P^*, f) \leq U(P, f)$.

If P^* contains p more partition points than P then repeating p times the above argument we can show that

$$U(P^*, f) \leq U(P, f). \qquad \text{...(1)}$$

In a similar manner we can show that

$$L(P^*, f) \geq L(P, f). \qquad \text{...(2)}$$

Note: We know that for any partition P^*,

$$L(P^*, f) \leq U(P^*, f). \qquad \text{...(3)}$$

Thus from (1), (2) and (3), we get

$$L(P, f) \leq L(P^*, f) \leq U(P^*, f) \leq U(P, f).$$

Theorem 4: *If P_1 and P_2 be any two partitions of $[a, b]$ then*

$$U(P_1, f) \geq L(P_2, f).$$

Proof: Let $P = P_1 \cup P_2$. Then P is the common refinement of both the partitions P_1 and P_2. Therefore by the theorem 3 above, we get

$$L(P_2, f) \leq L(P, f) \text{ and } U(P, f) \leq U(P_1, f).$$

But we have $\quad L(P, f) \leq U(P, f)$.

Thus $\quad L(P_2, f) \leq L(P, f) \leq U(P, f) \leq U(P_1, f)$.

It follows that $L(P_2, f) \leq U(P_1, f)$ or $U(P_1, f) \geq L(P_2, f)$, *that is, every upper sum for f is greater than or equal to every lower sum for f.*

Theorem 5: *Let f, g be bounded functions defined on $[a, b]$ and let P be any partition of $[a, b]$. Then*

$$L(P, f + g) \geq L(P, f) + L(P, g)$$

and $$U(P, f + g) \leq U(P, f) + U(P, g).$$

Proof: Let $P = \{a = x_0, x_1, x_2, \ldots, x_n = b\}$ be any partition of $[a, b]$. Since f and g are bounded functions on $[a, b]$, $f + g$ is also bounded on $[a, b]$.

Let m_r', M_r' be the infimum and supremum of f on I_r,

m_r'', M_r'' be the infimum and supremum of g on I_r

and m_r, M_r be the infimum and supremum of $f + g$ on I_r.

By definition of infimum we find that

$$f(x) \geq m_r', \; g(x) \geq m_r'' \;\forall\, x \in I_r$$

$$\Rightarrow \quad f(x) + g(x) \geq m_r' + m_r'' \;\forall\, x \in I_r$$

$$\Rightarrow \qquad (f+g)(x) \geq m_r' + m_r'' \ \forall\, x \in I_r$$

$$\Rightarrow \qquad m_r' + m_r'' \text{ is a lower bound of } f+g \text{ on } I_r .$$

But m_r is the greatest lower bound of $f + g$ on I_r .

$$\therefore \qquad m_r \geq m_r' + m_r'' \Rightarrow m_r\, \Delta x_r \geq m_r'\, \Delta x_r + m_r''\, \Delta x_r$$

$$\Rightarrow \qquad \sum_{r=1}^{n} m_r\, \Delta x_r \geq \sum_{r=1}^{n} m_r'\, \Delta x_r + \sum_{r=1}^{n} m_r''\, \Delta x_r$$

$$\Rightarrow \qquad L(P, f+g) \geq L(P, f) + L(P, g).$$

Similarly we can prove the other result.

3 Lower and Upper Riemann Integrals

(Purvanchal 2009, 12)

Let f be a real valued bounded function defined on $[a, b]$. We know that the set of all numbers $L(P, f)$ with respect to all possible partitions P of $[a, b]$ is bounded above by $M(b-a)$ and hence there exists a supremum of $L(P, f)$. The **lower Riemann integral (lower *R*-integral)** of f over $[a, b]$ is the supremum of $L(P, f)$ over all partitions $P \in \mathbf{P}[a, b]$. It is denoted by

$$\underline{\int_a^b} f(x)\, dx.$$

Similarly the set of numbers $U(P, f)$ is bounded below by $m(b-a)$ and so it possesses an infimum. The **upper Riemann integral** (**upper *R*-integral**) of f over $[a, b]$ is the infimum of $U(P, f)$ over all partitions $P \in \mathbf{P}[a, b]$. It is denoted by

$$\overline{\int_a^b} f(x)\, dx.$$

Thus
$$\underline{\int_a^b} f(x)\, dx = \sup \{L(P, f) : P \text{ is a partition of } [a, b]\}$$

and
$$\overline{\int_a^b} f(x)\, dx = \inf \{U(P, f) : P \text{ is a partition of } [a, b]\}.$$

We denote the lower and upper integrals of f simply by

$$\underline{\int_a^b} f \qquad \text{and} \qquad \overline{\int_a^b} f .$$

Since $L(P, -f) = -U(P, f)$ and $U(P, -f) = -L(P, f)$, it gives that

$$\underline{\int_a^b} (-f) = -\overline{\int_a^b} f \quad \text{and} \quad \overline{\int_a^b} (-f) = -\underline{\int_a^b} f.$$

Theorem 1: *The lower R-integral cannot exceed the upper R-integral, i.e.,*

$$\underline{\int_a^b} f \leq \overline{\int_a^b} f.$$

(Purvanchal 2007, 09; Rohilkhand 11)

Proof: If P_1 and P_2 are any two partitions of $[a, b]$, then by theorem 4 of article 2, we have

$$L(P_1, f) \leq U(P_2, f). \qquad \text{...(1)}$$

First, keeping P_2 fixed and taking the supremum over all partitions P_1, (1) gives

Chapter 8

The Riemann-Stieltjes Integral

1 A Generalization of the Riemann Integral

In the preceding chapter we have seen that the definitions of Riemann integral are founded on finite sums of the form

$$\sum_{r=1}^{n} m_r \, \Delta \, x_r\,, \quad \sum_{r=1}^{n} M_r \, \Delta \, x_r \quad \text{or} \quad \sum_{r=1}^{n} f\,(\xi_r)\, \Delta \, x_r.$$

If in the above sums we introduce $\Delta g_r = g\,(x_r) - g\,(x_{r-1})$ in place of $\Delta \, x_r$, where g is a more or less an arbitrary function, then a generalization of the Riemann integral is achieved which reduces to the Riemann case in the particular case $g\,(x) = x$. It was Thomas Jan Stieltjes who gave a generalization of Riemann integral. In the present chapter we shall not discuss the Stieltjes integrals as such but only a sort of special case thereof known as Riemann-Stieltjes integral in some detail.

2 Some Definitions

For convenience we repeat some definitions again here although we have given them in the preceding chapter.

Partition: **Definition.** *By a partition of a closed interval* $I = [a, b]$ *we mean a finite set of real numbers*

$$P = \{x_0, x_1, \ldots, x_{n-1}, x_n\} \text{ having the property that}$$

$$a = x_0 < x_1 < \ldots < x_{n-1} < x_n = b.$$

The closed sub-intervals

$$I_1 = [x_0, x_1], I_2 = [x_1, x_2], \ldots, I_n = [x_{n-1}, x_n]$$

determined by P constitute the **segments** of the partition.

We write $\Delta x_r = x_r - x_{r-1}$ for $r = 1, 2, \ldots, n$, so that Δx_r is the **length** of the segment $[x_{r-1}, x_r]$. The **norm** of a partition P is the greatest of the lengths of the segments of a partition P and it is denoted by $\|P\|$. Thus

$$\|P\| = \max. (\Delta x_r : r = 1, 2, \ldots, n).$$

A partition P^* *is called a* ***refinement*** *of another partition* P *or we say that* P^* *is* ***finer than*** P *iff* $P^* \supset P$, *i.e., if every point of* P *is used in the construction of* P^*.

If $P^* = P_1 \cup P_2$, *then* P^* *is called the* ***common refinement*** *of the given two partitions* P_1 *and* P_2.

By an ***intermediate partition*** *of* P, *we mean a set* $Q = \{\xi_1, \xi_2, \ldots, \xi_n\}$ *of at most* n *points having the property that* $x_{r-1} \le \xi_r \le x_r$ *for* $r = 1, 2, \ldots, n$.

According to this definition, two consecutive points of Q can be identical. Thus, it may happen that $\xi_{r-1} = \xi_r = x_r$ for some value of r. But three or more points cannot coincide.

3 Lower and Upper Riemann-Stieltjes Sums

Let f be a bounded real valued function defined on $[a, b]$ and let g be a monotonically non-decreasing (real valued) function on $[a, b]$. We shall write

$$\Delta g_r = g(x_r) - g(x_{r-1})$$

corresponding to each partition $P = \{x_0, x_1, \ldots, x_n\}$ of $[a, b]$.

Note that $\Delta g_r \ge 0$ since g is monotonically non-decreasing on $[a, b]$. Also, we define

$$m_r = \inf \{f(x) : x_{r-1} \le x \le x_r\},$$

$$M_r = \sup \{f(x) : x_{r-1} \le x \le x_r\},$$

$$m = \inf \{f(x) : a \le x \le b\}, M = \sup \{f(x) : a \le x \le b\}.$$

Let us now form the two sums

$$L(P, f, g) = \sum_{r=1}^{n} m_r \Delta g_r \text{ and } U(P, f, g) = \sum_{r=1}^{n} M_r \Delta g_r.$$

These two numbers are called the **lower** and **upper Riemann Stieltjes Sums** (or in brief lower and upper RS sums) respectively, of f with respect to g and corresponding to the partition P.

In case $g(x) = x$, these reduce to the lower and upper Riemann sums defined in the preceding chapter.

Obviously $L(P, f, g) \le U(P, f, g)$, for any partition P.

If P^* is a refinement of P, then

$$L(P, f, g) \le L(P^*, f, g) \qquad \text{...(1)}$$

and $$U(P^*, f, g) \le U(P, f, g). \qquad \text{...(2)}$$

For any partitions P_1, P_2 of $[a, b]$, we have

$$L(P_1, f, g) \le U(P_2, f, g). \qquad \text{...(3)}$$

The results (1), (2) and (3) can be proved similarly as proved in the preceding chapter with x's replaced by $g(x)$'s and Δx_r by Δg_r etc.

4 The Lower and Upper Riemann-Stieltjes Integrals

(Gorakhpur 2010)

Definition: *Let f be a bounded function and g a non-decreasing function defined on $[a, b]$. The **lower Riemann-Stieltjes integral** of f relative to g over $[a, b]$ is the supremum of $L(P, f, g)$ over all partitions P of $[a, b]$.* It is denoted by

$$\underline{\int_a^b} f\,dg \quad or \quad \underline{\int_a^b} f(x)\,dg(x).$$

*The **upper Riemann-Stieltjes integral** of f relative to g over $[a, b]$ is the infimum of $U(P, f, g)$ over all partitions P of $[a, b]$.* It is denoted by

$$\overline{\int_a^b} f\,dg \quad or \quad \overline{\int_a^b} f(x)\,dg(x).$$

Theorem: *Let f be a bounded function and g a non-decreasing function on $[a, b]$. Then the lower RS-integral of f relative to g cannot exceed the upper RS-integral*

i.e., $$\underline{\int_a^b} f\,dg \le \overline{\int_a^b} f\,dg.$$

(Gorakhpur 2010)

Proof: If P_1 and P_2 are any two partitions of $[a, b]$ then by (3) of article 3, we get

$$L(P_1, f, g) \le U(P_2, f, g). \qquad \text{...(1)}$$

First, keeping P_2 fixed and taking the supremum over all partitions P_1, (1) gives

$$\underline{\int_a^b} f\,dg \le U(P_2, f, g). \qquad \text{...(2)}$$

Now taking infimum over all partitions P_2, (2) gives

$$\underline{\int_a^b} f\,dg \le \overline{\int_a^b} f\,dg.$$

5 The Riemann-Stieltjes Integral

Definition: *Let f be a bounded function and g a non-decreasing function on $[a, b]$. Then f is called* ***Riemann-Stieltjes integrable*** *(or simply RS-integrable) on $[a, b]$ relative to g iff*

$$\underline{\int_a^b} f\,dg = \overline{\int_a^b} f\,dg$$

and their common value is called the RS-integral of f on $[a, b]$ relative to g and is denoted by

$$\int_a^b f\,dg \quad or \quad \int_a^b f(x)\,dg(x).$$

f is called the ***Integrand*** *and g the* ***Integrator.*** **(Gorakhpur 2012)**

The class of all RS-integrable functions relative to g over $[a, b]$ is denoted by $RS([a, b], g)$ or simply by $RS(g)$.

From the above definition, it is obvious that quite apart from conditions which might be necessary to the existence of an RS-integral, the integrand f must be bounded and the integrator g non-decreasing.

As in the case of Riemann integral, we define

$$\int_a^b f\,dg = -\int_b^a f\,dg \text{ for } b < a \text{ and } \int_a^a f\,dg = 0.$$

If $g(x) = x$, then the lower and upper RS-integrals reduce respectively to the lower and upper R-integrals. Hence the RS-integral of f relative to x is the same as the R-integral of f.

Note: The integral depends on f, g, a and b and not on the so-called variable of integration

i.e.,
$$\int_a^b f(x)\,dg(x) = \int_a^b f(y)\,dg(y).$$

So omitting the variable of integration we shall prefer to write

$$\int_a^b f\,dg \text{ in place of } \int_a^b f(x)\,dg(x).$$

6 Necessary and Sufficient Condition for RS-Integrability

Theorem: *Let f be a bounded and g a non-decreasing function on $[a, b]$. Then $f \in RS(g)$ if and only if for every $\varepsilon > 0$ there exists a partition P of $[a, b]$ such that*

$$U(P, f, g) - L(P, f, g) < \varepsilon.$$ **(Gorakhpur 2012)**

Proof: The condition is necessary (Only if part).

Let $f \in RS(g)$ so that

$$\underline{\int_a^b} f\,dg = \overline{\int_a^b} f\,dg. \qquad \text{...(1)}$$

Since $\underline{\int_a^b} f\,dg$ is the supremum of $L(P, f, g)$ over all partitions P, there exists a partition P_1 such that

$$\underline{\int_a^b} f\,dg < L(P_1, f, g) + \frac{\varepsilon}{2}\cdot$$

Similarly since $\overline{\int_a^b} f\,dg$ is the infimum of $U(P, f, g)$ over all partitions P, there exists a partition P_2 such that

$$U(P_2, f, g) < \overline{\int_a^b} f\,dg + \frac{\varepsilon}{2}\cdot$$

If $P = P_1 \cup P_2$, then P is the common refinement of P_1 and P_2. It follows from (1) and (2) of article 3 that

$$\underline{\int_a^b} f\,dg < L(P, f, g) + \frac{\varepsilon}{2} \qquad \text{...(2)}$$

and $$U(P, f, g) < \int_a^b f\,dg + \frac{\varepsilon}{2}\cdot \qquad \text{...(3)}$$

Adding the inequalities (2) and (3), we get

$$\underline{\int_a^b} f\,dg + U(P, f, g) < L(P, f, g) + \overline{\int_a^b} f\,dg + \varepsilon\,.$$

In view of (1), this gives

$$U(P, f, g) < L(P, f, g) + \varepsilon \text{ i.e., } U(P, f, g) - L(P, f, g) < \varepsilon.$$

Hence the condition is necessary.

The condition is sufficient (if part).

Let for every $\varepsilon > 0$, there exists a partition P of $[a, b]$ such that

$$U(P, f, g) - L(P, f, g) < \varepsilon. \qquad \text{...(4)}$$

By the definition of upper and lower RS-integrals, we have

$$\overline{\int_a^b} f\,dg \le U(P, f, g) \text{ and } \underline{\int_a^b} f\,dg \ge L(P, f, g)$$

i.e., $$L(P, f, g) \le \underline{\int_a^b} f\,dg \le \overline{\int_a^b} f\,dg \le U(P, f, g). \qquad \text{...(5)}$$

It follows from (4) and (5) that

$$\overline{\int_a^b} f\,dg - \underline{\int_a^b} f\,dg \le U(P, f, g) - L(P, f, g) < \varepsilon$$

or $$\overline{\int_a^b} f\,dg - \underline{\int_a^b} f\,dg < \varepsilon.$$

Since $\varepsilon > 0$ is arbitrary, we have $\overline{\int_a^b} f\, dg = \underline{\int_a^b} f\, dg$ *i.e.*, the function f is *RS*-integrable with respect to g.

Note: It is worth while to observe that the details of the proof of this theorem are exactly similar to those of the corresponding theorem for *R*-integrals given in the preceding chapter. In fact most of the elementary properties of *R*-integrals remain valid for *RS*-integrals with their corresponding proofs exactly similar except for the notation used for the two types of integrals.

Illustrative Examples

Example 1: *Let f be a constant function on $[a, b]$ defined by $f(x) = k$ and g a monotonically non-decreasing function on $[a, b]$. Prove that $\int_a^b f\, dg$ exists and $\int_a^b f\, dg = k\,[g(b) - g(a)]$.*

(Meerut 2004)

Solution: Obviously the given function is bounded over $[a, b]$. Let $P = \{a = x_0, x_1, x_2, \ldots, x_n = b\}$ be any partition of $[a, b]$. Then for any sub-interval $[x_{r-1}, x_r]$, we have

$$m_r = k,\ M_r = k.$$

Now
$$U(P, f, g) = \sum_{r=1}^{n} k\, \Delta g_r = k \sum_{r=1}^{n} [g(x_r) - g(x_{r-1})]$$

$$= k\,[g(x_1) - g(x_0) + g(x_2) - g(x_1) + \ldots + g(x_n) - g(x_{n-1})]$$

$$= k\,[g(x_n) - g(x_0)] = k\,[g(b) - g(a)],$$

and
$$L(P, f, g) = \sum_{r=1}^{n} k\, \Delta g_r = k\,[g(b) - g(a)].$$

$\therefore$
$$\overline{\int_a^b} f\, dg = \inf U(P, f, g) = \inf k\,[g(b) - g(a)]$$

$$= k\,[g(b) - g(a)]$$

and
$$\underline{\int_a^b} f\, dg = \sup L(P, f, g) = \sup k\,[g(b) - g(a)] = k\,[g(b) - g(a)].$$

Since $\underline{\int_a^b} f\, dg = \overline{\int_a^b} f\, dg$, the integral $\int_a^b f\, dg$ exists

and
$$\int_a^b f\, dg = k\,[g(b) - g(a)].$$

Example 2: *If f is non-negative and integrable function with respect to α on $[a, b]$ and if α is an increasing function on $[a, b]$, then show that*

$$\int_a^b f\, d\alpha \geq 0.$$

Chapter 1

Analytic Functions

1 Curves in the Argand Plane

We know that the equations of the type $x = x(t)$, $y = y(t)$, where t is the parameter, give the parametric representation of a curve in the plane. Using the complex variable z, these equations can be written as a single equation

$$z = z(t) = x(t) + i\,y(t) \text{ where } z = x + iy.$$

Definitions: (a) *In the Argand plane, a continuous complex valued function* $z(t) = x(t) + iy(t)$, *where* $x(t)$ *and* $y(t)$ *are real valued continuous functions of a real variable t, defined in the range* $\alpha \le t \le \beta$ *where* $\alpha < \beta$ *is called a continuous* ***arc*** *or a* ***curve***. We call $z(\alpha)$ and $z(\beta)$ the end points of the curve, $z(\alpha)$ is the initial point and $z(\beta)$ the terminal point of the curve. If $z(\alpha) = z(\beta)$ *i.e.,* if the initial and terminal points of a curve coincide, the curve is said to be a **closed curve.**

A point z_1 is a multiple point of the curve if the equation $z_1 = x(t) + iy(t)$ is satisfied by more than one value of t in the given range. In particular the multiple point is called a double point if the above equation is satisfied by two values of t in the given range.

(b) A curve Γ given by, $z(t) = x(t) + iy(t), \alpha \le t \le \beta$ is called a **Jordan arc** or a **simple**

curve if $t_1 \neq t_2$ implies $z\ (t_1) \neq z\ (t_2)$ *i.e.*, $z\ (t)$ is one-one. A Jordan arc is a curve without multiple points.

(c) A closed curve Γ given by $z\ (t) = x\ (t) + iy\ (t), \alpha \leq t \leq \beta$, is called **simple** if $t_1 < t_2$ and $z\ (t_1) = z\ (t_2)$ imply $t_1 = \alpha$ and $t_2 = \beta$.

We usually refer to such curves as **simple closed Jordan curves.**

Example: The circle $z = \cos t + i \sin t, 0 \leq t \leq 2\pi$ is a simple closed Jordan curve since the values of $z\ (t)$ coincide only at the end points $t = 0$ and $t = 2\pi$.

The Jordan curve theorem: The theorem states that *a simple closed Jordan curve divides the Argand plane into two open domains which have the curve as common boundary.*

Of these two domains one is bounded and it is called the **interior domain** ; the other is unbounded and is called the **exterior domain.** For example, the circle $|z| = r$ divides the Argand plane into two open domains given by $|z| < r$ and $|z| > r$. Out of these $|z| < r$ is bounded and is the interior of the circle ; the other $|z| > r$ is unbounded and is the exterior of the circle, $|z| = r$. The circle is the common boundary of the two domains.

2 Functions of a Complex Variable

If certain rules be given by means of which it is possible to find one or more complex numbers w for every value of z in a certain domain D, w is said to be a function of z defined on the domain D and we write

$$w = f\ (z).$$

Since $z = x + iy$, $f\ (z)$ will be of the form $u + iv$ where u and v are functions of two real variables x and y. Thus we can write $w = u\ (x, y) + i\, v\ (x, y)$, x, y are real.

Single valued and multiple valued functions: If w takes only one value for each value of z in the region D, w is said to be a *uniform* or *single valued function* of z. If there correspond two or more values of w for some or all values of z in the region D, w is called *multiple valued function* of z.

3 Neighbourhood of a Point

A neighbourhood of a point z_0 in the Argand plane is the set of all points z such that $|z - z_0| < \delta$, where δ is an arbitrary small positive number. The number δ is called the radius of this neighbourhood.

Deleted neighbourhood: If from a neighbourhood of a point z_0, the point z_0 itself is deleted or excluded, we get a *deleted neighbourhood* of z_0.

4 Limit and Continuity

Let $f\ (z)$ be any function of the complex variable z defined in a bounded and closed domain D. Then l is said to be the limit of $f\ (z)$ as z approaches a along any path in D if for any arbitrarily chosen *positive number ε, however small but not zero, there exists a corresponding number δ greater than zero such that*

$$| f(z) - l | < \varepsilon,$$

for all values of z for which $0 < | z - a | < \delta$.

In symbols, we write $\lim\limits_{z \to a} f(z) = l$.

Continuity: *A function $f(z)$ of a complex variable z defined in the closed and bounded domain D is said to be continuous at $a \in D$ if and only if for any arbitrarily chosen positive number ε, however small but not zero, there exists a corresponding number $\delta > 0$ such that*

$$| f(z) - f(a) | < \varepsilon \text{ whenever } | z - a | < \delta.$$

It follows from the definitions of limit and continuity that $f(z)$ is continuous at

$$z = a \text{ iff } \lim_{z \to a} f(z) = f(a).$$

We say that $f(z)$ is a continuous function in a domain D if it is continuous at every $z \in D$.

We can easily show that $f(z) = u(x, y) + i\,v(x, y)$ is a continuous function of z iff u and v are continuous functions of x and y.

Uniform continuity: *A function $f(z)$ defined in a domain D is said to be uniformly continuous in D if given $\varepsilon > 0$, there exists a $\delta > 0$ such that $| f(z_1) - f(z_2) | < \varepsilon$ whenever $| z_1 - z_2 | < \delta$, where z_1 and z_2 are points in D.*

It should be noted carefully that uniform continuity is a property associated with a domain and not with a single point of it.

If $f(z)$ is uniformly continuous in a domain D, it is continuous in D.

A function which is continuous in a closed and bounded domain D is uniformly continuous in D, whereas a function continuous in an open domain D' may fail to be uniformly continuous in the domain D'.

5 Differentiability

Since the mode of definitions of continuity is the same both in case of the functions of the real and complex variables therefore definition of differentiability of a complex function is identical with that of the real function.

Let $w = f(z)$ be a function of a complex variable z defined in a domain D. Then $f(z)$ is said to be differentiable at a point z_0 of D iff

$$\lim_{\Delta z \to 0} \frac{f(z_0 + \Delta z) - f(z_0)}{\Delta z} \quad \text{or} \quad \lim_{z \to z_0} \frac{f(z) - f(z_0)}{z - z_0} \text{ exists uniquely and finitely}$$

and this limit, if it exists finitely, *is called the* **differential coefficient** or **derivative** of f with respect to z at $z = z_0$.

It is denoted by $f'(z_0)$ or by $Df(z_0)$.

Diffraction of Atoms Using Standing Wave Light

6.1 Introduction

Diffraction of waves – like sound waves, water waves, and light waves – is characterized by the spreading or "flaring" of waves after passing through an aperture. For diffraction to occur, the size of the aperture must be comparable to the wavelength of the incident wave. A classic diffraction experiment was performed by Thomas Young in 1801, where a monochromatic beam of light is coherently split into two distinct beams after passing through two slits. In the region beyond the aperture, the split beams diffract and produce interference fringes on a screen placed a large distance away in comparison with the distance between the slits. As with other waves mentioned above, matter waves like electrons and neutrons also diffract after passing through an aperture. For instance, in electron beam diffraction, highly energetic electrons that are incident on a periodic crystalline structure diffract in a predictable manner prescribed by Bragg's law.

Beyond particles such as photons, electrons, and neutrons, Young's double slit experiment has been performed with atoms. In 1991, a highly excited helium atom was interfered after passing through two slits in gold foil. In contrast to the gold foil technique, most modern experiments use apertures made from light crystals to diffract atoms. This will be the focus of this chapter. We begin our discussion in Section 6.2 by reviewing the diffraction of light and matter waves. Next, we describe the interaction with detuned off-resonant light and solve the resulting dynamics under Bragg conditions and Raman transitions. The results of this chapter are used in the subsequent two chapters discussing metrology. For experiments that use the results we refer the reader to references found at the end of this chapter.

6.2 Theory of Diffraction

Diffraction gratings consist of many slits that are spaced at a constant interval of distance d between the slits. Gratings are often used to study different light sources. When light passes through a slit, it diffracts in accordance with Huygens's wave theory, where each slit acts as a source of light waves that produces a secondary wavefront. The wavefronts spread as they advance and give rise to diffraction. Thus, it is possible for a light wave from one slit to interfere with a light wave from another slit. The final interference pattern depends on the directional angle measured from the horizontal at which the rays are examined. To see this, consider a grating illuminated by a light wave of wavelength λ as shown in Fig. 6.1. Each slit on the grating is a

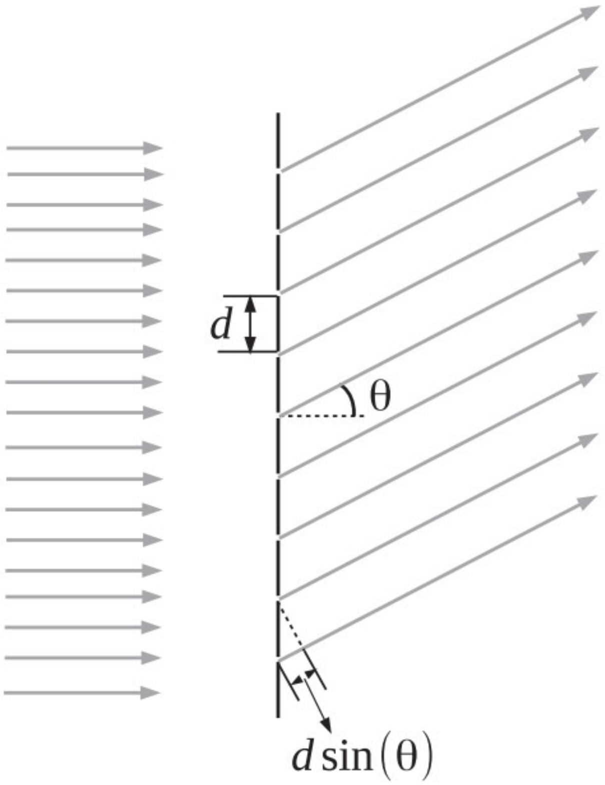

Fig. 6.1 The diffraction of light by a grating. Each slit on the grating is a source of light waves, and the slits are at equal distances *d* from one another. The wave from each slit is nearly parallel to the others, and the path difference of the light waves from any adjacent slits is $d \sin \theta$.

source of a light wave that emits rays of light that are mutually parallel to each other. They are also in phase as they leave the slit. As the rays propagate further toward a point on a screen, it is observed that the path difference between the rays depends on the angle a ray makes with the horizontal. For any two adjacent rays, the path difference between them is $d \sin \theta$. On the screen placed a large distance from the slit, bright bands are observed when all the waves arriving at the point on the screen are in phase. This is realized if the path difference is equal to a wavelength or integral multiples of a wavelength. Therefore, the maximum in a bright band is observed if the path difference is

$$d \sin \theta = m\lambda, \tag{6.1}$$

where $m = 0, \pm 1, \pm 2, \pm 3, \ldots$ is the diffraction order. To observe diffraction from the grating, the separation distance d between the slits should be large in comparison with the wavelength λ of light. Otherwise, the slits would appear to be the same source and no diffraction pattern would be observed. Because of this requirement, a diffraction grating made for one wave of a particular wavelength may not be suitable in the study of another wave of a very different wavelength.

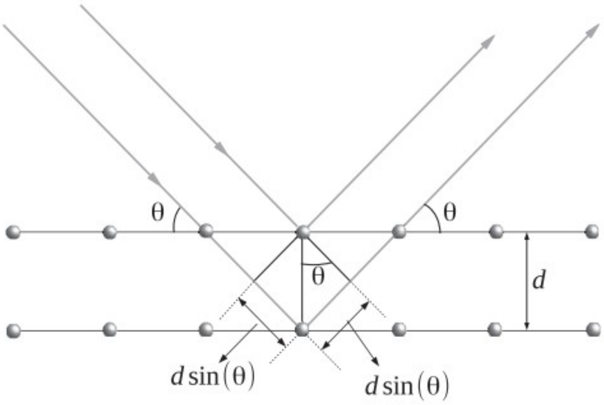

Fig. 6.2 The diffraction of a matter wave by a crystal. Each plane consists of atoms arranged in a regular fashion, and the planes are separated by a distance d. For waves incident on the crystal at angle θ to the plane, waves from the bottom plane travel an extra distance of $2d \sin\theta$ relative to those from the upper plane. Color version of this figure available at cambridge.org/quantumatomoptics.

Perhaps the simplest way to realize matter wave interference is to observe the diffraction of electrons in a crystal lattice. The slits in the crystal – NaCl, for instance – are made of atoms, which are arranged in a specific order. When matter waves are incident on a crystal, the atoms forming the crystal reflect the matter wave at regular intervals. The intensity of the emerging matter wave is very strong in a particular direction, which corresponds to constructive interference. For example, suppose that the incident matter wave makes an angle θ with the planes of the crystal, as shown in Fig. 6.2. Each plane is at a constant spacing d, and we consider two planes as shown in Fig. 6.2. Matter waves reflected from the upper plane travel a smaller distance compared with those reflected from the bottom plane. Waves from the two planes would reinforce at a point on the screen if the path difference $2d \sin\theta$ traveled by the waves is an integer multiple of the wavelength λ of the matter waves. Thus, a maximum exists within a constructive interference if

$$2d \sin\theta = m\lambda, \tag{6.2}$$

where $m = 1, 2, 3, \ldots$.

6.3 Ultra-cold Atom Interaction with Standing Light Wave

Material gratings, such as the crystals described in Section 6.2, work well to perform diffraction of particles such as electrons and neutrons but are less suited to diffraction of atoms. This is partly because atoms have a large mass compared to that of electrons and neutrons, which results in a much smaller de Broglie wavelength for a given velocity. Also, due to the charge neutrality of atoms, producing an energetic atom with high velocity was almost impossible until high-energy helium was produced via high-impact electron excitation. But even at that, the challenge still remained on how to diffract a stationary atom or an atom with negligible velocity, as found in ultra-cold

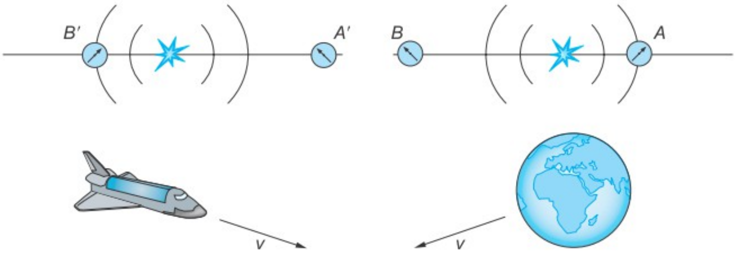
(*a*) Earth view of Earth clocks

(*b*) Spaceship view of spaceship clocks



(*c*) Earth view of spaceship clocks

(*d*) Spaceship view of Earth clocks

FIGURE 1-16 A light flash occurs on Earth midway between two Earth clocks. At the instant of the flash the midpoint of a passing spaceship coincides with the light source. (*a*) The Earth clocks record the lights' arrival simultaneously and are thus synchronized. (*b*) Clocks at both ends of the spaceship also record the lights' arrival simultaneously (Einstein's second postulate) and they, too, are synchronized. (*c*) However, the Earth observer sees the light reach the clock at B' *before* the light reaches the clock at A'. Since the spaceship clocks read the same time when the light arrives, the Earth observer concludes that the clocks at A' and B' are not synchronized. (*d*) Illustrates that the spaceship observer similarly concludes that the Earth clocks are not synchronized.

more detail in the next section. Figure 1-16 illustrates the relativity of simultaneity from a different perspective.

Questions

3. In addition to the method described above, what would be another possible method of synchronizing all of the clocks in an inertial reference system?
4. Using Figure 1-16*d*, explain how the spaceship observer concludes that the Earth clocks are not synchronized.

1-3 The Lorentz Transformation

We now consider a very important consequence of Einstein's postulates, the general relation between the spacetime coordinates x, y, z and t of an event as seen in reference frame S and the coordinates x', y', z' and t' of the same event as seen in reference frame S', which is moving with uniform velocity relative to S. For simplicity we will consider only the special case in which the origins of the two coordinate systems are coincident at time $t = t' = 0$ and S' is moving, relative to S, with speed v along the x (or x') axis and with the y' and z' axes parallel, respectively, to the y and z axes as shown in Figure 1-17. As we discussed earlier (Equation 1-2), the classical Galilean coordinate transformation is

$$x' = x - vt \qquad y' = y \qquad z' = z \qquad t' = t \tag{1-2}$$

which expresses coordinate measurements made by an observer in S' in terms of those measured by an observer in S. The inverse transformation is

$$x = x' + vt' \qquad y = y' \qquad z = z' \qquad t = t'$$

and simply reflects the fact that the sign of the relative velocity of the reference frames is different for the two observers. The corresponding classical velocity transformation was given in Equation 1-3, and the acceleration, as we saw earlier, is invariant under a Galilean transformation. (For the rest of the discussion we will ignore the equations for y and z, which do not change in this special case of motion along the x and x' axes.) These equations are consistent with experiment as long as v is much less than c.

It should be clear that the classical velocity transformation is not consistent with the Einstein postulates of special relativity. If light moves along the x axis with speed c in S, Equation 1-3 implies that the speed in S' is $u'_x = c - v$ rather than $u'_x = c$. The Galilean transformation equations must therefore be modified to be consistent with Einstein's postulates, but the result must reduce to the classical equations when v is much less than c. We will give a brief outline of one method of obtaining the relativistic transformation that is called the *Lorentz transformation*, so named because of its original discovery by H. A. Lorentz.[12] We assume the equation for x' to be of the form

$$x' = \gamma(x - vt) \tag{1-11}$$

where γ is a constant that can depend on v and c but not on the coordinates. If this equation is to reduce to the classical one, γ must approach 1 as v/c approaches 0. The inverse transformation must look the same except for the sign of the velocity:

$$x = \gamma(x' + vt') \tag{1-12}$$

With the arrangement of the axes in Figure 1-17, there is no relative motion of the frames in the y and z directions; hence $y' = y$ and $z' = z$. However, insertion of the as yet unknown multiplier γ modifies the classical transformation of time, $t' = t$. To see this, we substitute x' from Equation 1-11 into Equation 1-12 and solve for t'. The result is

$$t' = \gamma\left[t + \frac{(1 - \gamma^2)}{\gamma^2}\frac{x}{v}\right] \tag{1-13}$$

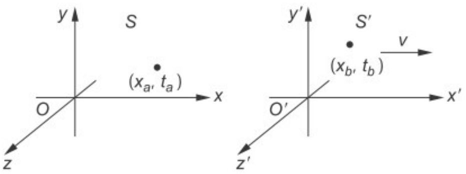


FIGURE 1-17 Two inertial frames S and S' with the latter moving at speed v in the $+x$ direction of system S. Each set of axes shown is simply the coordinate axes of a lattice like that in Figure 1-13. Remember, there is a clock at each intersection. A short time before the times represented by this diagram, O and O' were coincident and the lattices of S and S' were intermeshed.

Now let a flash of light start from the origin of S at $t = 0$. Since we have assumed that the origins coincide at $t = t' = 0$, the flash also starts at the origin of S' at $t' = 0$. The flash expands from *both* origins as a spherical wave. The equation for the wave front according to an observer in S is

$$x^2 + y^2 + z^2 = c^2t^2 \tag{1-14}$$

and according to an observer in S' it is

$$x'^2 + y'^2 + z'^2 = c^2t'^2 \tag{1-15}$$

where both equations are consistent with the second postulate. Consistency with the first postulate means that the relativistic transformation that we seek must transform Equation 1-14 into Equation 1-15, and vice versa. For example, substituting Equations 1-11 and 1-13 into 1-15 results in Equation 1-14 *if*

$$\gamma = \frac{1}{\sqrt{1 - \dfrac{v^2}{c^2}}} = \frac{1}{\sqrt{1 - \beta^2}} \tag{1-16}$$

where $\beta = v/c$. Notice that $\gamma = 1$ for $v = 0$ and $\gamma \to \infty$ for $v = c$. How this is done is illustrated in Example 1-2 below.

EXAMPLE 1-2 Relativistic Transformation Multiplier γ Show that γ must be given by Equation 1-16 if Equation 1-15 is to be transformed into Equation 1-14 consistent with Einstein's first postulate.

SOLUTION

Substituting Equations 1-11 and 1-13 into 1-15 and noting that $y' = y$ and $z' = z$ in this case yields

$$\gamma^2(x - vt)^2 + y^2 + z^2 = c^2\gamma^2\left[t + \frac{1 - \gamma^2}{\gamma^2}\frac{x}{v}\right]^2 \tag{1-17}$$

To be consistent with the first postulate, Equation 1-15 must be identical to Equation 1-14. This requires that the coefficient of the x^2 term in Equation 1-17 be equal to 1, that of the t^2 term be equal to c^2, and that of the xt term be equal to 0. Any of those conditions can be used to determine γ, and all yield the same result. Using, for example, the coefficient of x^2, we have from Equation 1-17 that

$$\gamma^2 - c^2\gamma^2\frac{(1 - \gamma^2)^2}{\gamma^4 v^2} = 1$$

which can be rearranged to

$$-c^2\frac{(1 - \gamma^2)^2}{\gamma^2 v^2} = (1 - \gamma^2)$$

Canceling $1 - \gamma^2$ on both sides and solving for γ yields

$$\gamma = \frac{1}{\sqrt{1 - \dfrac{v^2}{c^2}}}$$

With the value for γ found in Example 1-2, Equation 1-13 can be written in a somewhat simpler form and with it the complete Lorentz transformation becomes

$$x' = \gamma(x - vt) \qquad y' = y$$
$$t' = \gamma\left(t - \frac{vx}{c^2}\right) \qquad z' = z \tag{1-18}$$

and the inverse

$$x = \gamma(x' + vt') \qquad y = y'$$
$$t = \gamma\left(t' + \frac{vx'}{c^2}\right) \qquad z = z' \tag{1-19}$$

with

$$\gamma = \frac{1}{\sqrt{1 - \beta^2}}$$

EXAMPLE 1-3 Transformation of Time Intervals The arrivals of two cosmic-ray μ mesons (muons) are recorded by detectors in the laboratory, one at time t_a at location x_a and the second at time t_b at location x_b in the laboratory reference frame, S in Figure 1-17. What is the time interval between those two events in system S', which moves relative to S at speed v?

SOLUTION

Applying the time coordinate transformation from Equation 1-18,

$$t'_b - t'_a = \gamma\left(t_b - \frac{vx_b}{c^2}\right) - \gamma\left(t_a - \frac{vx_a}{c^2}\right)$$
$$t'_b - t'_a = \gamma(t_b - t_a) - \frac{\gamma v}{c^2}(x_b - x_a) \tag{1-20}$$

We see that the time interval measured in S' depends not just on the corresponding time interval in S, but also on the spatial separation of the clocks in S that measured the interval. This result should not come as a total surprise since we have already discovered that, although the clocks in S are synchronized with each other, they are not, in general, synchronized for observers in other inertial frames.

Special Case 1

If it should happen that the two events occur at the same location in S, that is, $x_a = x_b$, then $(t_b - t_a)$, the time interval measured on a clock located at the events, is called the *proper time interval.* Notice that, since $\gamma > 1$ for all frames moving relative to S, the proper time interval is the *minimum* time interval that can be measured between those events.

Special Case 2

Does there exist an inertial frame for which the events described above would be measured to be simultaneous? Since the question has been asked, you probably suspect that the answer is yes, and you are right. The two events will be simultaneous in a system S'' for which $t''_b - t''_a = 0$, that is, when

$$\gamma(t_b - t_a) = \frac{\gamma v}{c^2}(x_b - x_a)$$

or when

$$\beta = \frac{v}{c} = \left(\frac{t_b - t_a}{x_b - x_a}\right)c \qquad \textbf{1-21}$$

Notice that $(x_b - x_a)/c =$ time for a light beam to travel from x_a to x_b; thus we can characterize S'' as being that system whose speed relative to S is that fraction of c given by the time interval between the events divided by the travel time of light between them. (Note, too, that $c(t_b - t_a) > (x_b - x_a)$ implies that $\beta > 1$, a nonphysical situation that we will discuss in Section 1-4.)

While it is possible for us to get along in special relativity without the Lorentz transformation, it has an application that is quite valuable: it enables the spacetime coordinates of events measured by the measuring rods and clocks in the reference frame of one observer to be translated into the corresponding coordinates determined by the measuring rods and clocks of an observer in another inertial frame. As we will see in Section 1-4, such transformations lead to some startling results.

Relativistic Velocity Transformations

The transformation for velocities in special relativity can be obtained by differentiation of the Lorentz transformation, keeping in mind the definition of the velocity. Suppose a particle moves in S with velocity $\mathbf{u}$ whose components are $u_x = dx/dt$, $u_y = dy/dt$, and $u_z = dz/dt$. An observer in S' would measure the components $u'_x = dx'/dt'$, $u'_y = dy'/dt'$, and $u'_z = dz'/dt'$. Using the transformation equations, we obtain

$$dx' = \gamma(dx - vdt) \qquad dy' = dy$$

$$dt' = \gamma\left(dt - \frac{vdx}{c^2}\right) \qquad dz' = dz$$

from which we see that u'_x is given by

$$u'_x = \frac{dx'}{dt'} = \frac{\gamma(dx - vdt)}{\gamma\left(dt - \dfrac{vdx}{c^2}\right)} = \frac{(dx/dt - v)}{1 - \dfrac{v}{c^2}\dfrac{dx}{dt}}$$

or

$$u'_x = \frac{u_x - v}{1 - \dfrac{vu_x}{c^2}} \qquad \textbf{1-22}$$

and, if a particle has velocity components in the y and z directions, it is not difficult to find the components in S' in a similar manner.

$$u'_y = \frac{u_y}{\gamma\left(1 - \dfrac{vu_x}{c^2}\right)} \qquad u'_z = \frac{u_z}{\gamma\left(1 - \dfrac{vu_x}{c^2}\right)}$$

Remember that this form of the velocity transformation is specific to the arrangement of the coordinate axes in Figure 1-17. Note, too, that when $v \ll c$, that is, when $\beta = v/c \approx 0$ the relativistic velocity transforms reduce to the classical velocity addition of Equation 1-3. Likewise, the inverse velocity transformation is

$$u_x = \frac{u'_x + v}{\left(1 + \frac{vu'_x}{c^2}\right)} \qquad u_y = \frac{u'_y}{\gamma\left(1 + \frac{vu'_x}{c^2}\right)} \qquad u_z = \frac{u'_z}{\gamma\left(1 + \frac{vu'_x}{c^2}\right)} \qquad \textbf{1-23}$$

EXAMPLE 1-4 Relative Speeds of Cosmic Rays Suppose that two cosmic-ray protons approach Earth from opposite directions as shown in Figure 1-18*a*. The speeds relative to Earth are measured to be $v_1 = 0.6c$ and $v_2 = -0.8c$. What is Earth's velocity relative to each proton, and what is the velocity of each proton relative to the other?

SOLUTION

Consider each particle and Earth to be inertial reference frames S', S'', and S, with their respective x axes parallel as in Figure 1-18*b*. With this arrangement $v_1 = u_{1x} = 0.6c$ and $v_2 = u_{2x} = -0.8c$. Thus, the speed of Earth measured in S' is $v'_{Ex} = -0.6c$ and the speed of Earth measured in S'' is $v''_{Ex} = 0.8c$.

To find the speed of proton 2 with respect to proton 1, we apply Equation 1-22 to compute u'_{2x}, that is, the speed of particle 2 in S'. Its speed in S has been measured to be $u_{2x} = -0.8c$, where the S' system has relative speed $v_1 = 0.6c$ with respect to S. Thus, substituting into Equation 1-22, we obtain

$$u'_{2x} = \frac{-0.8c - (0.6c)}{1 - (0.6c)(-0.8c)/c^2} = \frac{-1.4c}{1.48} = -0.95c$$

and the first proton measures the second to be approaching (moving in the $-x'$ direction) at $0.95c$.

The observer in S'' must of course make a consistent measurement, that is, find the speed of proton 1 to be $0.95c$ in the $+x''$ direction. This can be readily shown by a second application of Equation 1-22 to compute u''_{1x}.

$$u''_{1x} = \frac{0.6c - (-0.8c)}{1 - (0.6c)(-0.8c)/c^2} = \frac{1.4c}{1.48} = 0.95c$$

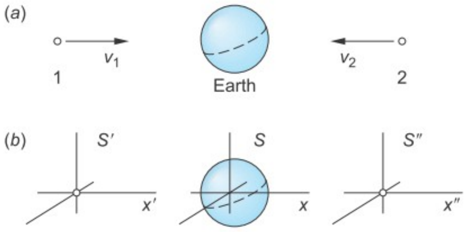

FIGURE 1-18 (*a*) Two cosmic-ray protons approach Earth from opposite directions at speeds v_1 and v_2 with respect to Earth. (*b*) Attaching an inertial frame to each particle and Earth enables one to visualize the several relative speeds involved and apply the velocity transformation correctly.

Questions

5. The Lorentz transformation for y and z is the same as the classical result: $y = y'$ and $z = z'$. Yet the relativistic velocity transformation does not give the classical result $u_y = u'_y$ and $u_z = u'_z$. Explain.
6. Since the velocity components of a moving particle are different in relatively moving frames, the *directions* of the velocity vectors are also different, in general. Explain why the fact that observers in S and S' measure different directions for a particle's motion is not an inconsistency in their observations.

Spacetime Diagrams

The relativistic discovery that time intervals between events are not the same for observers in different inertial reference frames underscores the four-dimensional character of spacetime. With the diagrams that we have used thus far, it is difficult to depict and visualize on the two-dimensional page events that occur at different times since each diagram is equivalent to a snapshot of spacetime at a particular instant. Showing events as a function of time typically requires a series of diagrams, such as Figures 1-14, 1-15, and 1-16, but even then our attention tends to be drawn to the space coordinate systems rather than the events, whereas it is the *events* that are fundamental. This difficulty is removed in special relativity with a simple, yet powerful graphing method called the *spacetime diagram*. (This is just a new name given to the t vs. x graphs that you first began to use when you discussed motion in introductory physics.) On the spacetime diagram we can graph both the space and time coordinates of many events in one or more inertial frames, albeit with one limitation. Since the page offers only two dimensions for graphing, we suppress, or ignore for now, two of the space dimensions, in particular y and z. With our choice of the relative motion of inertial frames along the x axis, $y' = y$ and $z' = z$ anyhow. (This is one of the reasons we made that convenient choice a few pages back, the other reason being mathematical simplicity.) This means that for the time being, we are limiting our attention to one space dimension and to time, that is, to events that occur, regardless of when, along one line in space. Should we need the other two dimensions, for example, in a consideration of velocity vector transformations, we can always use the Lorentz transformation equations.

In a spacetime diagram the space location of each event is plotted along the x axis horizontally and the time is plotted vertically. From the three-dimensional array of measuring rods and clocks in Figure 1-13, we will use only those located on the x axis as in Figure 1-19. (See, things are simpler already!) Since events that exhibit relativistic effects generally occur at high speeds, it will be convenient to multiply the time scale by the speed of light (a constant), which enables us to use the same units and scale on both the space and time axes, for example, meters of distance and meters of light travel time.[13] The time axis is, therefore, c times the time t in seconds, that is, ct. As we will see shortly, this choice prevents events from clustering about the axes and makes possible the straightforward addition of other inertial frames into the diagram.

As time advances, notice that in Figure 1-19 each clock in the array moves vertically upward along the dotted lines. Thus, as events A, B, C, and D occur in spacetime, one of the clocks of the array is at (or very near) each event when it happens. Remembering that the clocks in the reference frame are synchronized, you will see that the difference in the readings of clocks located at each event records the *proper time interval* between the events (see Example 1-3). In the figure, events A and D

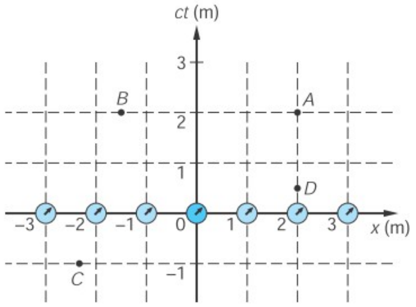

FIGURE 1-19 Spacetime diagram for an inertial reference frame S. Two of the space dimensions (y and z) are suppressed. The units on both the space and time axes are the same, meters. A meter of time means the time required for light to travel one meter, that is, 3.3×10^{-9} s.

occur at the same place ($x = 2$ m), but at different times. The time interval between them measured on clock 2 is the proper time interval since clock 2 is located at *both* events. Events A and B occur at different locations, but at the same time (i.e., simultaneously in this frame). Event C occurred before the present since $ct = -1$ m. For this discussion we will consider the time that the coordinate origins coincide, $ct = ct' = 0$, to be the present.

Worldlines in Spacetime Particles moving in space trace out a line in the spacetime diagram called the *worldline* of the particle. The worldline is the "trajectory" of the particle on a ct versus x graph. To illustrate, consider four particles moving in space (not spacetime) as shown in Figure 1-20*a*, which shows the array of synchronized clocks on the x axis and the space trajectories of four particles, each starting at $x = 0$ and moving at some constant speed, during 3 m of time. Figure 1-20*b* shows the worldline for each of the particles in spacetime. Notice that constant speed means that the worldline has constant slope; that is, it is a straight line (slope $= \Delta t/\Delta x = 1/(\Delta x/\Delta t) = 1/\text{speed}$). That was also the case when you first encountered elapsed time versus displacement graphs in introductory physics. Even then, you were plotting spacetime graphs and drawing worldlines! If the particle is accelerating—either speeding up like particle 5 in Figure 1-20*c* or slowing down like particle 6—the worldlines are curved. Thus, the worldline is the record of the particle's travel through spacetime, giving its speed (= 1/slope) and acceleration (= 1/rate at which the slope changes) at every instant.

EXAMPLE 1-5 Computing Speeds in Spacetime Find the speed u of particle 3 in Figure 1-20.

SOLUTION

The speed $u = \Delta x/\Delta t = 1/\text{slope}$ where we have $\Delta x = 1.5 - 0 = 1.5$ m and $c\Delta = c \cdot \Delta t = 3.0 - 0 = 3.0$ m (from Figure 1-20). Thus, $\Delta t = (3.0/c) = (3.0/3.0 \times 10^8) = 10^{-8}$ s and $u = 1.5 \text{ m}/10^{-8} \text{ s} = 1.5 \times 10^8 \text{ m/s} = 0.5c$.

The speed of particle 4, computed as shown in Example 1-5, turns out to be c, the speed of light. (Particle 4 is a light pulse.) The slope of its worldline $\Delta(ct)/\Delta x = 3 \text{ m}/3 \text{ m} = 1$. Similarly, the slope of the worldline of a light pulse moving in the

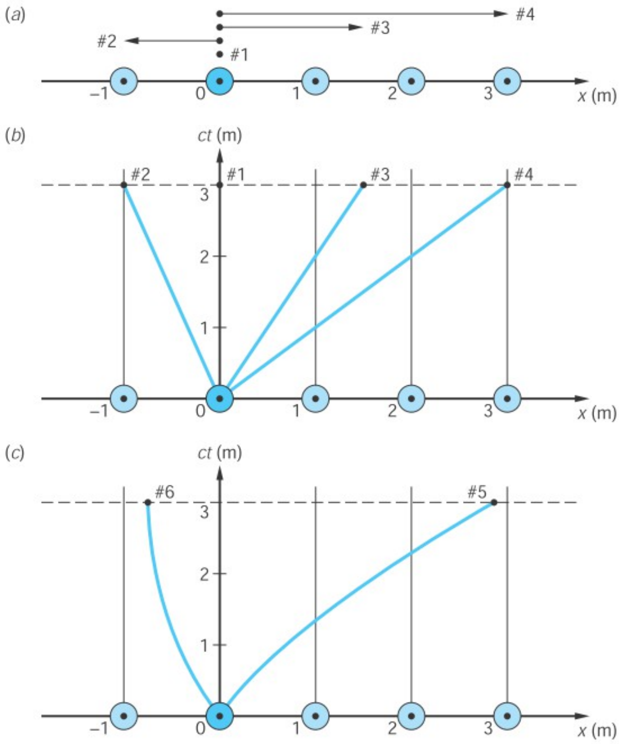

FIGURE 1-20 (*a*) The space trajectories of four particles with various constant speeds. Note that particle 1 has a speed of zero and particle 2 moves in the $-x$ direction. The worldlines of the particles are straight lines. (*b*) The worldline of particle 1 is also the ct axis since that particle remains at $x = 0$. The constant slopes are a consequence of the constant speeds. (*c*) For accelerating particles 5 and 6 [not shown in (*a*)], the worldlines are curved, the slope at any point yielding the instantaneous speed.

$-x$ direction is -1. Since relativity limits the speed of particles with mass to less than c, as we will see in Chapter 2, the slopes of worldlines for particles that move through $x = 0$ at $ct = 0$ are limited to the larger shaded triangle in Figure 1-21. The same limits to the slope apply at every point along a particle's worldline, such as point A on the curved spacetime trajectory in Figure 1-21. This means that the particle's possible worldlines for times greater than $ct = 2$ m must lie within the heavily shaded triangle.

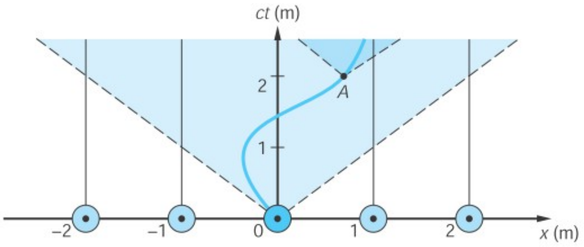

FIGURE 1-21 The speed-of-light limit to the speeds of particles limits the slopes of worldlines for particles that move through $x = 0$ at $ct = 0$ to the shaded area of spacetime, that is, to slopes < -1 and $> +1$. The dashed lines are worldlines of light flashes moving in the $-x$ and $+x$ directions. The curved worldline of the particle shown has the same limits at every instant. Notice that the particle's speed = 1/slope.

Event Analysis Using Worldlines Analyzing events and motion in inertial systems that are in relative motion can now be accomplished more easily than with diagrams such as Figures 1-14 through 1-18. Suppose we have two inertial frames S and S' with S' moving in the $+x$ direction of S at speed v as in those figures. The clocks in both systems are started at $t = t' = 0$ (the present) as the two origins $x = 0$ and $x' = 0$ coincide, and, as before, observers in each system have synchronized the clocks in their respective systems. The spacetime diagram for S is, of course, like that in Figure 1-19, but how does S' appear in that diagram, that is, with respect to an observer in S? Consider that, as the origin of S' (i.e., the point where $x' = 0$) moves in S, its worldline is the ct' axis since the ct' axis is the locus of all points with $x' = 0$ (just as the ct axis is the locus of points with $x = 0$). Thus, the slope of the ct' axis as seen by an observer in S can be found from Equation 1-18, the Lorentz transformation, as follows

$$x' = \gamma(x - vt) = 0 \quad \text{for} \qquad x' = 0$$

or

$$x = vt = (v/c)(ct) = \beta ct$$

and

$$ct = (1/\beta)x$$

which says that the slope (in S) of the worldline of the point $x' = 0$, the ct' axis, is $1/\beta$ (see Figure 1-22*a*).

In the same manner, the x' axis can be located using the fact that it is the locus of points for which $ct' = 0$. The Lorentz transformation once again provides the slope:

$$t' = \gamma\left(t - \frac{vx}{c^2}\right) = 0$$

or

$$t = \frac{vx}{c^2} \qquad \text{and} \qquad ct = \frac{v}{c}x = \beta x$$

Thus, the slope of the x' axis as measured by an observer in S is β, as shown in Figure 1-22*a*. Don't be confused by the fact that the x axes don't look parallel anymore. They are still parallel in *space*, but this is a *spacetime* diagram. It shows motion in both space and time. For example, the clock at $x' = 1$ m in Figure 1-22*b* passed the point $x = 0$ at about $ct = -1.5$ m as the x' axis of S' moved both upward and to the right in S. Remember, as time advances, the array of synchronized clocks and measuring rods that are the x axis also moves upward, so that, for example, when $ct = 1$, the origin of $S'(x' = 0, ct' = 0)$ has moved $vt = (v/c)ct = \beta ct$ to the right along the x axis.

Question

7. Explain how the spacetime diagram in Figure 1-22*b* would appear drawn by an observer in S'.

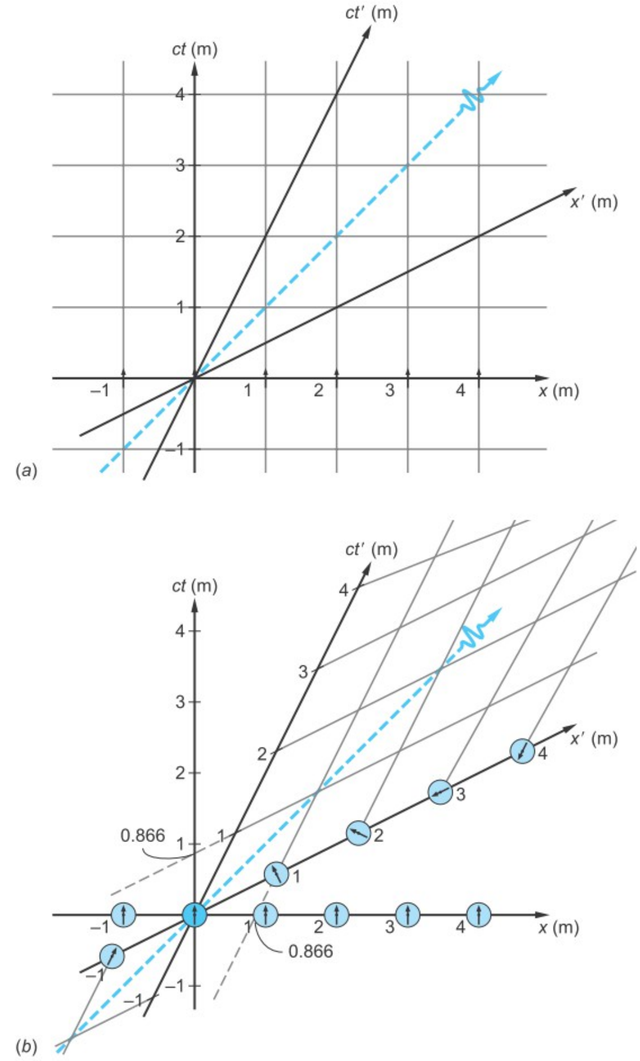

FIGURE 1-22 Spacetime diagram of S showing S' moving at speed $v = 0.5c$ in the $+x$ direction. The diagram is drawn with $t = t' = 0$ when the origins of S and S' coincided. The dashed line shows the worldline of a light flash that passed through the point $x = 0$ at $t = 0$ heading in the $+x$ direction. Its slope equals 1 in both S and S'. The ct' and x' axes of S' have slopes of $1/\beta = 2$ and $\beta = 0.5$, respectively. (*a*) Calibrating the axes of S' as described in Exploring (pages 26–27) allows the grid of coordinates to be drawn on S'. Interpretation is facilitated by remembering that (*b*) shows the system S' as it is observed in the spacetime diagram of S.

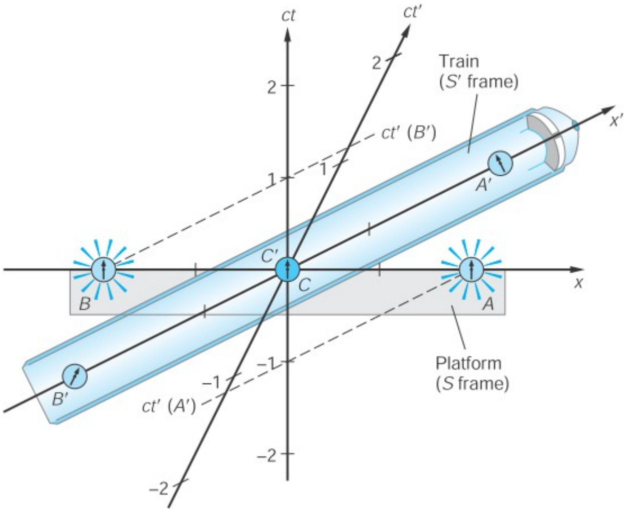

FIGURE 1-23 Spacetime equivalent of Figure 1-15, showing the spacetime diagram for the system *S* in which the platform is at rest. Measurements made by observers in *S*′ are read from the primed axes.

EXAMPLE 1-6 **Simultaneity in Spacetime** Use the train-platform example of Figure 1-15 and a suitable spacetime diagram to show that events simultaneous in one frame are not simultaneous in a frame moving relative to the first. (This is the corollary to the relativity of simultaneity that we first demonstrated in the previous section using Figure 1-15.)

SOLUTION

Suppose a train is passing a station platform at speed v and an observer C at the midpoint of the platform, system S, announces that light flashes will be emitted at clocks A and B located at opposite ends of the platform at $t = 0$. Let the train, system S', be a rocket train with $v = 0.5c$. As in the earlier discussion, clocks at C and C' both read 0 as C' passes C. Figure 1-23 shows this situation. It is the spacetime equivalent of Figure 1-15.

Two events occur; the light flashes. The flashes are simultaneous in S since both occur at $ct = 0$. In S', however, the event at A occurred at $ct'(A')$ (see Figure 1-23), about 1.2 ct' units *before* $ct' = 0$, and the event at B occurred at $ct'(B')$, about 1.2 ct' units *after* $ct' = 0$. Thus, the flashes are not simultaneous in S' and A occurs before B, as we also saw in Figure 1-15.

EXPLORING

Calibrating the Spacetime Axes

By calibrating the coordinate axes of S' consistent with the Lorentz transformation, we will be able to read the coordinates of events and calculate space and time intervals between events as measured in both S and S' directly from the diagram, in addition to calculating them from Equations 1-18 and 1-19. The calibration of the S' axes is straightforward and is accomplished as follows. The locus of points, for example, with

$x' = 1$ m, is a line parallel to the ct' axis through the point $x' = 1$ m, $ct' = 0$, just as we saw earlier that the ct' axis was the locus of those points with $x' = 0$ through the point $x' = 0$, $ct' = 0$. Substituting these values into the Lorentz transformation for x', we see that the line through $x' = 1$ m intercepts the x axis, that is, the line where $ct = 0$ at

$$x' = \gamma(x - vt) = \gamma(x - \beta ct) \qquad \textbf{1-24}$$
$$1 = \gamma x \qquad \text{or} \qquad x = 1/\gamma = \sqrt{1 - \beta^2}$$

or, in general,

$$x = x'\sqrt{1 - \beta^2}$$

In Figure 1-22*b*, where $\beta = 0.5$, the line $x' = 1$ m intercepts the x axis at $x = 0.866$ m. Similarly, if $x' = 2$ m, $x = 1.73$ m; if $x' = 3$ m, $x = 2.60$ m, and so on.

The ct' axis is calibrated in a precisely equivalent manner. The locus of points with $ct' = 1$ m is a line parallel to the x' axis through the point $ct' = 1$ m, $x' = 0$. Using the Lorentz transformation, the intercept of that line with the ct axis (where $x = 0$) is found as follows.

$$t' = \gamma(t - vx/c^2)$$

which can also be written as

$$ct' = \gamma(ct - \beta x) \qquad \textbf{1-25}$$

or $ct' = \gamma ct$ for $x = 0$. Thus, for $ct' = 1$ m, we have $1 = \gamma ct$ or $ct = (1 - \beta^2)^{1/2}$ and, again, in general, $ct = ct'(1 - \beta^2)^{1/2}$. The $x' \cdot ct'$ coordinate grid is shown in Figure 1-22*b*.

Notice in Figure 1-22*b* that the clocks located in S' are *not* found to be synchronized by observers in S, even though they are synchronized in S'. This is exactly the conclusion that we arrived at in the discussion of the lightning striking the train and platform. In addition, those with positive x' coordinates are behind the S' reference clock and those with negative x' coordinates are ahead, the differences being greatest for those clocks farthest away. This is a direct consequence of the Lorentz transformation of the time coordinate—that is, when $ct = 0$ in Equation 1-25, $ct' = -\gamma\beta x$. Note, too, that the slope of the worldline of the light beam equals 1 in S', as well as in S, as required by the second postulate.

1-4 Time Dilation and Length Contraction

The results of correct measurements of the time and space intervals between events do not depend on the kind of apparatus used for the measurements or on the events themselves. We are free therefore to choose any events and measuring apparatus that will help us understand the application of the Einstein postulates to the results of measurements. As you have already seen from previous examples, convenient events in relativity are those that produce light flashes. A convenient, simple such clock is a *light clock*, pictured schematically in Figure 1-24. A photocell detects the light pulse and sends a voltage pulse to an oscilloscope, which produces a vertical deflection of the oscilloscope's trace. The phosphorescent material on the face of the oscilloscope tube gives a persistent light that can be observed visually, photographed, or recorded electronically. The time between two light flashes is determined by measuring the distance between pulses on the scope and knowing the sweep speed. Such clocks can easily be calibrated and compared with other types of clocks. Although not drawn as in Figure 1-24, the clocks used in explanations in this section may be thought of as light clocks.

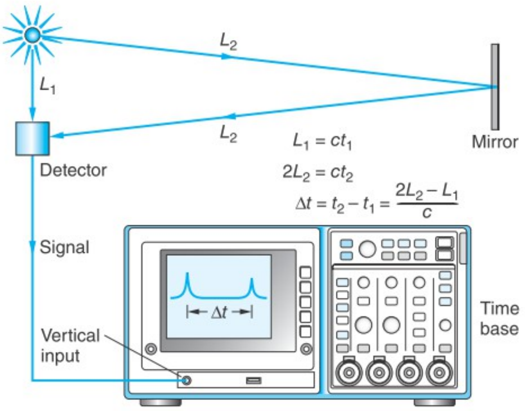

FIGURE 1-24 Light clock for measuring time intervals. The time is measured by reading the distance between pulses on the oscilloscope after calibrating the sweep speed.

Time Dilation (or Time Stretching)

We first consider an observer A' at rest in frame S' a distance D from a mirror, also in S', as shown in Figure 1-25*a*. He triggers a flash gun and measures the time interval $\Delta t'$ between the original flash and the return flash from the mirror. Since light travels with speed c, this time is $\Delta t' = (2D)/c$.

We now consider these same two events, the original flash of light and the returning flash, as observed in reference frame S, with respect to which S' is moving to the right with speed v. The events happen at two different places, x_1 and x_2, in frame S because between the original flash and the return flash observer A' has moved a horizontal distance $v\Delta t$, where Δt is the time interval between the events measured in S. In Figure 1-25*b*, a space diagram, we see that the path traveled by the light is longer in S than in S'. However, by Einstein's postulates, light travels with the same speed c in frame S as is does in frame S'. Since it travels farther in S at the same speed, it takes longer in S to reach the mirror and return. The time interval between flashes in S is thus longer than it is in S'. We can easily calculate Δt in terms of $\Delta t'$. From the triangle in Figure 1-25*c*, we see that

$$\left(\frac{c\Delta t}{2}\right)^2 = D^2 + \left(\frac{v\Delta t}{2}\right)^2$$

or

$$\Delta t = \frac{2D}{\sqrt{c^2 - v^2}} = \frac{2D}{c}\frac{1}{\sqrt{1 - v^2/c^2}}$$

Using $\Delta t' = 2D/c$, we have

$$\Delta t = \frac{\Delta t'}{\sqrt{1 - v^2/c^2}} = \gamma\Delta t' = \gamma\tau \qquad \mathbf{1\text{-}26}$$

where $\tau = \Delta t'$ is the *proper time interval* that we first encountered in Example 1-3. Equation 1-26 describes *time dilation*; that is, it tells us that the observer in frame S always measures the time interval between two events to be longer (since $\gamma > 1$) than the corresponding interval measured on the clock located at both events in the frame where they occur at the same location. Thus, observers in S conclude that the clock

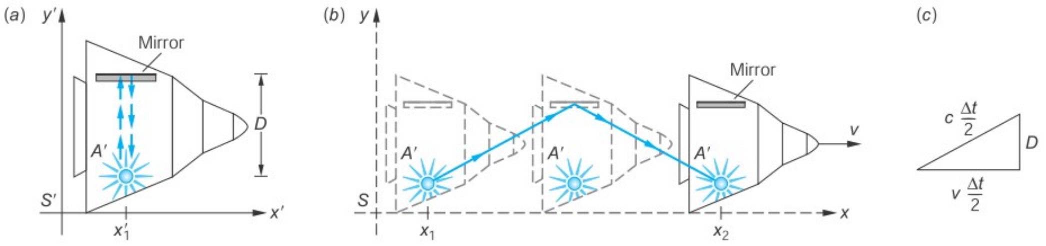

FIGURE 1-25 (*a*) Observer A' and the mirror are in a spaceship at rest in frame S'. The time it takes for the light pulse to reach the mirror and return is measured by A' to be $2D/c$. (*b*) In frame *S*, the spaceship is moving to the right with speed *v*. If the speed of light is the same in both frames, the time it takes for the light to reach the mirror and return is longer than $2D/c$ in *S* because the distance traveled is greater than $2D$. (*c*) A right triangle for computing the time Δt in frame *S*.

at A' in S' runs slow since that clock measures a smaller time interval between the two events. Notice that the faster S' moves with respect to *S*, the larger is γ, and the slower the S' clocks will tick. It appears to the *S* observer that time is being stretched out in S'.

Be careful! The *same* clock must be located at each event for $\Delta t'$ to be the proper time interval τ. We can see why this is true by noting that Equation 1-26 can be obtained directly from the inverse Lorentz transformation for *t*. Referring again to Figure 1-25 and calling the emission of the flash event 1 and its return event 2, we have that

$$\Delta t = t_2 - t_1 = \gamma\left(t_2' + \frac{vx_2'}{c^2}\right) - \gamma\left(t_1' + \frac{vx_1'}{c^2}\right)$$

$$\Delta t = \gamma(t_2' - t_1') + \frac{\gamma v}{c^2}(x_2' - x_1')$$

or

$$\Delta t = \gamma\Delta t' + \frac{\gamma v}{c^2}\Delta x' \qquad \textbf{1-27}$$

If the clock that records t_2' and t_1' is located at the events, then $\Delta x' = 0$. If that is not the case, however, $\Delta x' \neq 0$ and $\Delta t'$, though certainly a valid measurement, is not a proper time interval. Only a clock located *at* an event *when* it occurs can record a proper time interval.

EXAMPLE 1-7 **Spatial Separation of Events** Two events occur at the same point x_0' at times t_1' and t_2' in S', which moves with speed *v* relative to *S*. What is the spatial separation of these events measured in *S*?

SOLUTION

1. The location of the events in *S* is given by the Lorentz inverse transformation, Equation 1-19: $x = \gamma(x' + vt')$
2. The spatial separation of the two events $\Delta x = x_2 - x_1$ is then $\Delta x = \gamma(x_0' + vt_2') - \gamma(x_0' + vt_1')$

3. The $\gamma x'_0$ terms cancel: $\Delta x = \gamma v(t'_2 - t'_1) = \gamma v \Delta t'$
4. Since $\Delta t'$ is the proper time interval τ, Equation 1-26 yields $\Delta x = v\gamma\tau = v\Delta t$
5. Using the situation in Figure 1-26 as a numerical example, where $\beta = 0.5$ and $\gamma = 1.15$, we have
$$\Delta x = \gamma \frac{v}{c} \Delta(ct') = (1.15)(0.5)(2) = 1.15 \text{ m}$$

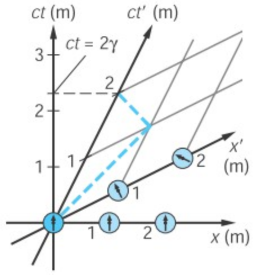

FIGURE 1-26 Spacetime diagram illustrating time dilation. The dashed line is the worldline of a light flash emitted at $x' = 0$ and reflected back to that point by a mirror at $x' = 1$ m. $\beta = 0.5$.

EXAMPLE 1-8 The Pregnant Elephant[14] Elephants have a gestation period of 21 months. Suppose that a freshly impregnated elephant is placed on a spaceship and sent toward a distant space jungle at $v = 0.75c$. If we monitor radio transmissions from the spaceship, how long after launch might we expect to hear the first squealing trumpet from the newborn calf?

SOLUTION

1. In S', the rest frame of the elephant, the time interval from launch to birth is $\tau = 21$ months. In the Earth frame S the time interval is Δt_1 given by Equation 1-26:
$$\Delta t_1 = \gamma\tau = \frac{1}{\sqrt{1-\beta^2}}\tau = \frac{1}{\sqrt{1-(0.75)^2}}(21 \text{ months}) = 31.7 \text{ months}$$
2. At that time the radio signal announcing the happy event starts toward Earth at speed c, but from where? Using the result of Example 1-7, since launch the spaceship has moved Δx in S given by
$$\Delta x = \gamma v\tau = \gamma\beta c\tau = (1.51)(0.75)(21\ c \cdot \text{months}) = 23.8c \cdot \text{months}$$
where $c \cdot$ month is the distance light travels in one month.
3. Notice that there is no need to convert Δx into meters since our interest is in how long it will take the radio signal to travel this distance in S. That time is Δt_2 given by
$$\Delta t_2 = \Delta x/c = 23.8c \cdot \text{months}/c = 23.8 \text{ months}$$
4. Thus, the good news will arrive at Earth at time Δt after launch where
$$\Delta t = \Delta t_1 + \Delta t_2 = 31.7 + 23.8 = 55.5 \text{ months}$$

Remarks: *This result, too, is readily obtained from a spacetime diagram. Figure 1-27 illustrates the general appearance of the spacetime diagram for this example, showing the elephant's worldline and the worldline of the radio signal.*

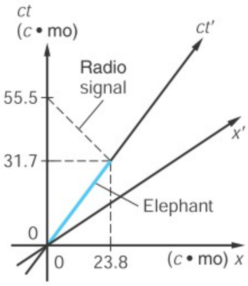

FIGURE 1-27 Sketch of the spacetime diagram for Example 1-8. $\beta = 0.75$. The colored line is the worldline of the pregnant elephant. The worldline of the radio signal is the dashed line at 45° toward the upper left.

Question

8. You are standing on a corner and a friend is driving past in an automobile. Both of you note the times when the car passes two different intersections and determine from your watch readings the time that elapses between the two events. Which of you has determined the proper time interval?

The time dilation of Equation 1-26 is easy to see in a spacetime diagram such as Figure 1-26, using the same round trip for a light pulse used above. Let the light flash leave $x' = 0$ at $ct' = 0$, when the S and S' origins coincided. The flash travels to $x' = 1$ m, reflects from a mirror located there, and returns to $x' = 0$. Let $\beta = 0.5$. The dotted line shows the worldline of the light beam, reflecting at ($x' = 1$, $ct' = 1$) and returning to $x' = 0$ at $ct' = 2$ m. Note that the S observer records the latter event at $ct > 2$ m; that is, the observer in S sees the S' clock running slow.

Experimental tests of the time dilation prediction have been performed using macroscopic clocks, in particular, accurate atomic clocks. In 1975, C. O. Alley conducted a test of both general and special relativity in which a set of atomic clocks were carried by a U.S. Navy antisubmarine patrol aircraft while it flew back and forth over the same path for 15 hours at altitudes between 8000 m and 10,000 m over Chesapeake Bay. The clocks in the plane were compared by laser pulses with an identical group of clocks on the ground. (See Figure 1-13 for one way such a comparison might be done.) Since the experiment was primarily intended to test the gravitational effect on clocks predicted by general relativity (see Section 2-5), the aircraft was deliberately flown at the rather sedate average speed of 270 knots (140 m/s) $= 4.7 \times 10^{-7}c$ so as to minimize the time dilation due to the relative speeds of the clocks. Even so, after deducting the effect of gravitation as predicted by general relativity, the airborne clocks lost an average of 5.6×10^{-9} s due to the relative speed during the 15-hour flight. This result agrees with the prediction of special relativity, 5.7×10^{-9} s to within 2 percent, even at this low relative speed. More recently, in 2010 J. C.-W. Chou and his coworkers at the National Institute of Science and Technology (NIST) used precision optical clocks to detect the minuscule time dilation at a speed of only 10 m/s, about the speed of a collegiate track sprinter. These and other experimental results leave little basis for further debate as to whether traveling clocks of all kinds lose time. They do.

Length Contraction

A phenomenon closely related to time dilation is *length contraction.* The length of an object measured in the reference frame in which the object is at rest is called its *proper length* L_p. In a reference frame in which the object is moving, the measured length parallel to the direction of motion is shorter than its proper length. Consider a rod at rest in the frame S' with one end at x'_2 and the other end at x'_1 as illustrated in Figure 1-28. The length of the rod in this frame is its proper length $L_p = x'_2 - x'_1$. Some care must be taken to find the length of the rod in frame S. In this frame, the rod is moving to the right with speed v, the speed of frame S'. The length of the rod in frame S is *defined* as $L = x_2 - x_1$, where x_2 is the position of one end at some time t_2 and x_1 is the position of the other end *at the same time* $t_1 = t_2$ as measured in frame S. Since the rod is at rest in S', t'_2 need not equal t'_1. Equation 1-18 is convenient to use to calculate $x_2 - x_1$ at some time t because it relates x, x', and t, whereas Equation 1-19 is not convenient because it relates x, x', and t':

$$x'_2 = \gamma(x_2 - vt_2) \quad \text{and} \quad x'_1 = \gamma(x_1 - vt_1)$$

Since $t_2 = t_1$, we obtain

$$x'_2 - x'_1 = \gamma(x_2 - x_1)$$

$$x_2 - x_1 = \frac{1}{\gamma}(x'_2 - x'_1) = \sqrt{1 - \frac{v^2}{c^2}}(x'_2 - x'_1)$$

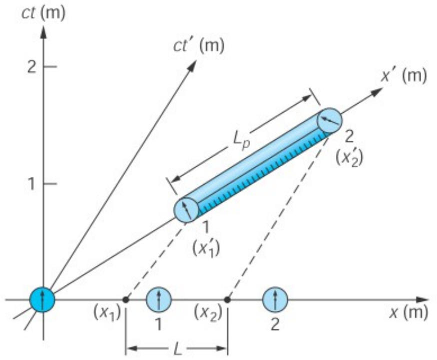

FIGURE 1-28 A measuring rod, a meter stick in this case, lies at rest in S' between $x'_2 = 2$ m and $x'_1 = 1$ m. System S' moves with $\beta = 0.79$ relative to S. Since the rod is in motion, S must measure the locations of the ends of the rod x_2 and x_1 simultaneously in order to have made a valid length measurement. L is obviously shorter than L_p. By direct measurement from the diagram (use a millimeter scale) $L/L_p = 0.62 = 1/\gamma$.

or

$$L = \frac{1}{\gamma}L_p = \sqrt{1 - \frac{v^2}{c^2}}L_p \qquad \textbf{1-28}$$

Thus, the length of a rod is smaller when it is measured in a frame with respect to which it is moving. Before Einstein's paper was published, Lorentz and FitzGerald had independently shown that the null result of the Michelson-Morley experiment could be explained by assuming that the lengths in the direction of the interferometer's motion contracted by the amount given in Equation 1-28. For that reason, the length contraction is often called the *Lorentz-FitzGerald contraction.*

EXAMPLE 1-9 Speed of S' A stick that has a proper length of 1 m moves in a direction parallel to its length with speed v relative to you. The length of the stick as measured by you is 0.914 meter. What is the speed v?

SOLUTION

1. The length of the stick measured in a frame relative to which it is moving with speed v is related to its proper length by Equation 1-28:

$$L = \frac{L_p}{\gamma}$$

2. Rearranging to solve for γ:

$$\gamma = \frac{L_p}{L}$$

3. Substituting the values of L_p and L:

$$\gamma = \frac{1\text{ m}}{0.914\text{ m}} = \frac{1}{\sqrt{1 - v^2/c^2}}$$

4. Solving for v:

$$\sqrt{1 - v^2/c^2} = 0.914$$

$$1 - v^2/c^2 = (0.914)^2 = 0.835$$

$$v^2/c^2 = 1 - 0.835 = 0.165$$

$$v^2 = 0.165c^2$$

$$v = 0.406c$$

It is important to remember that the relativistic contraction of moving lengths occurs only parallel to the relative motion of the reference frames. In particular, observers in relatively moving systems measure the same values for lengths in the y and y' and in the z and z' directions perpendicular to their relative motion. The result is that observers measure different shapes and angles for two- and three-dimensional objects (see Example 1-10 and Figures 1-29 and 1-30).

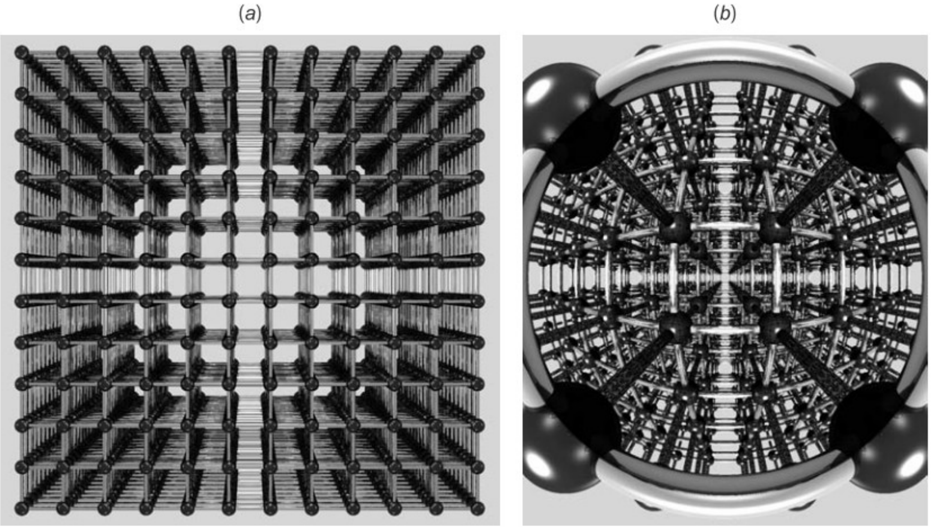

FIGURE 1-29 The appearance of rapidly moving objects depends on both length contraction in the direction of motion and the time when the observed light left the object. (*a*) The array of clocks and measuring rods that represents S' as viewed by an observer in S with $\beta = 0$. (*b*) When S' approaches the S observer with $\beta = 0.9$, the distortion of the lattice becomes apparent. This is what an observer on a cosmic-ray proton might see as it passes into the lattice of a face-centered-cubic crystal such as NaCl. [*P.-K. Hsiung, R. Dunn, and C. Cox. Courtesy of C. Cox, Adobe Systems, Inc., San Jose, CA.*]

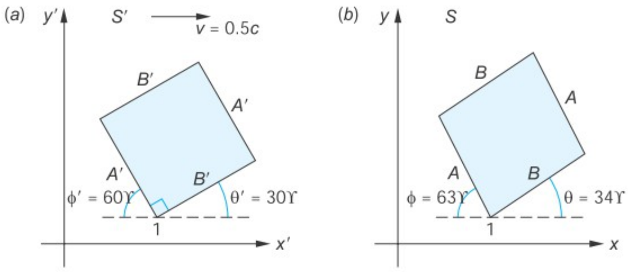

FIGURE 1-30 Length contraction distorts the shape and orientation of two- and three-dimensional objects. The observer in S measures the square shown in S' as a rotated parallelogram.

EXAMPLE 1-10 **The Shape of a Moving Square** Consider the square in the $x'y'$ plane of S' with one side making a 30° angle with the x' axis as in Figure 1-30*a*. If S' moves with $\beta = 0.5$ relative to S, what is the shape and orientation of the figure in S?

SOLUTION

The S observer measures the x components of each side to be shorter by a factor $1/\gamma$ than those measured in S'. Thus, S measures

$$A = [\cos^2 30 + \sin^2 30/\gamma^2]^{1/2} A' = 0.968A'$$

$$B = [\sin^2 30 + \cos^2 30/\gamma^2]^{1/2} B' = 0.901B'$$

Since the figure is a square in S', $A' = B'$. In addition, the angles between B and the x axis and between A and the x axis are given by, respectively,

$$\theta = \tan^{-1}\left[\frac{B'\sin 30}{B'\cos 30/\gamma}\right] = \tan^{-1}\left[\gamma\frac{\sin 30}{\cos 30}\right] = 33.7°$$

$$\varphi = \tan^{-1}\left[\frac{A'\cos 30}{A'\sin 30/\gamma}\right] = \tan^{-1}\left[\gamma\frac{\cos 30}{\sin 30}\right] = 63.4°$$

Thus, S concludes from geometry that the interior angle at vertex 1 is not 90°, but $180° - (63.4° + 33.7°) = 82.9°$—that is, the figure is not a square, but a parallelogram whose shorter sides make 33.7° angles with the x axis! Its shape and orientation in S are shown in Figure 1-30*b*.

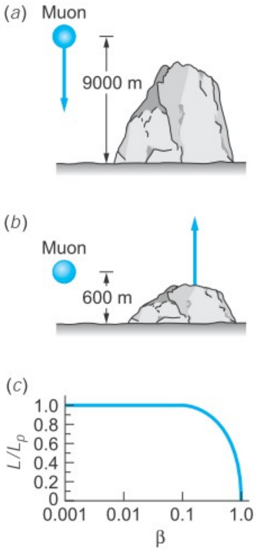

FIGURE 1-31 Although muons are created high above Earth and their mean lifetime is only about 2 μs when at rest, many appear at Earth's surface. (*a*) In Earth's reference frame, a typical muon moving at $0.998c$ has a mean lifetime of 30 μs and travels 9000 m in this time. (*b*) In the reference frame of the muon, the distance traveled by Earth is only 600 m in the muon's lifetime of 2 μs. (*c*) L varies only slightly from L_p until v is of the order of $0.1c$. $L \to 0$ as $v \to c$.

Muon Decay

An interesting example of both time dilation and length contraction is afforded by the appearance of muons as secondary radiation from cosmic rays. Muons decay according to the statistical law of radioactivity:

$$N(t) = N_0 e^{(-t/\tau)} \qquad \textbf{1-29}$$
